During the second day of the meeting, the COP president announced the Emirates Declaration on Sustainable Agriculture, Resilient Food Systems and Climate Action, which more than 160 countries have signed.[103] The nonbinding declaration acknowledges that food systems "must urgently adapt and transform" to respond to the climate crisis.[104] Signatory countries committed to "[m]aximize the climate and environmental benefits—while containing and reducing harmful impacts—associated with agriculture and food systems [including] by . . . shifting from higher greenhouse gas-emitting practices to more sustainable production and consumption approaches . . . ."[105] The Declaration tasks governments, for the first time, with including agriculture in their Nationally Determined Contributions[106] by COP30 in 2025,[107] and commits countries to improve their approaches to bolstering animal and ecosystem health within agriculture and food systems.[108]

In a short video message prepared for COP28, WHO Director-General Tedros Adhanom Ghebreyesus recognized that food systems are harming people and the planet, and noted their significant climate

impacts. Returning to the message of the WHO's 2019 report,[109] he called for transforming food systems by "shifting toward healthier, diversified, and more plant-based diets."[110]

During Food, Agriculture and Water Day—the first COP day ever dedicated to food systems[111]—the FAO announced its first "Roadmap" to achieve food security[112] without breaching the Paris Agreement goals.[113] The Roadmap addressed the differing climate impacts of food and the need for dietary change as follows: "High consumption of food products with high GHG footprints in some locations contribute unnecessarily to the emissions of agrifood systems. . . . The issue is to know not 'if' diets should change—for they absolutely must for human and planetary health—but how to obtain these results."[114] The Roadmap also recognized the need to consider environmental factors in national dietary guidelines and to utilize public food procurement programs to achieve climate goals.[115]

Also during COP28, references to food systems were included in the first-ever Global Stocktake of progress since the 2015 Paris Agreement,[116] although only after pressure from civil society and only in the adaptation (rather than mitigation[117]) section and in general terms.[118] In addition, UNEP released a report on the potential impacts

If not, the world will be unable to ensure a livable future for future generations." (internal quotation and citation omitted)).

118 Silvia Mantilla, *Hope amid Challenges: Key Outcomes & Missed Opportunities at COP28*, WORLD FED'N FOR ANIMALS (Dec. 17, 2023), https://wfa.org/hope-amid-challenges-key-outcomes-missed-opportunities-at-cop28; *Good COP, Bad COP: Brighter Green's Take on COP28*, BRIGHTER GREEN (Dec. 20, 2023) [hereinafter *Good COP, Bad COP*], https://mailchi.mp/brightergreen/end-of-year-2023 (both noting that, before advocacy by environmental and animal NGOs, food systems seemed likely to be left out of the Global Stocktake altogether). The Global Stocktake calls for "the implementation of integrated, multisectoral solutions, such as . . . sustainable agriculture [and] resilient food systems," and for "[a]ttaining climate-resilient food and agricultural production and supply and distribution of food, as well as increasing sustainable and regenerative production and equitable access to adequate food and nutrition for all." Conference of the Parties Serving as the Meeting of

of meat and dairy alternatives.[119] A "key finding" of the report was that "[n]ovel plant-based meat, cultivated meat, and fermentation-derived foods show potential for reduced environmental impacts compared to many conventional [animal-sourced foods]. They also show promise for reduced risk of zoonoses and antimicrobial resistance . . . ."[120]

Last but not least in terms of pragmatic impact, following advocacy by youth groups and NGOs, the COP president adopted a "Climate Conscious Catering" plan with the stated goal of having two-thirds of the food served be vegan or vegetarian.[121] COP28 also featured a "Food for Climate Pavilion" and more than 650 food-related events.[122]

2. COP28: Critiques

While all of these COP firsts are undoubtedly steps forward, many are skeptical of their impact and seriousness. Environmental writer and activist George Monbiot pointedly observed that COP28 "was meant to be the first climate summit at which the impacts of the food system were properly considered. But by the time 120 meat and dairy lobbyists had done their worst, nothing meaningful came out of it."[123] Indeed, the meat and dairy industries reportedly had at least 120 delegates present in Dubai, about three times as many as had attended the COP the year before in Egypt.[124]

Another damning assessment of the transformative value of COP28 for animal agriculture emissions was published in the U.S. industry publication *Meatingplace*, which noted the lack of concrete outcomes: "Discussing the transition to plant-based meat and dairy was on the agenda during COP28, but as the annual event wraps up, the

124 Rachel Sherrington et al., *Big Meat and Dairy Delegates Triple at COP28*, DESMOG (Dec. 8, 2023), https://www.desmog.com/2023/12/08/big-meat-dairy-delegates-triple-cop28.

conversation doesn't seem to have inspired any actual change."[125] The publication also observed that the FAO Roadmap "focused more on incremental improvements to the current food system without moves to change the animal agriculture sector or promote a move toward alt-meat and -dairy products."[126] Specifically as to the Declaration issued during the second day of COP28,[127] critics pointed out that its language "sidestepped" the "contentious issue" of meat consumption.[128]

Many observers were particularly critical of the shortcomings of the Roadmap issued by the FAO on Food Day,[129] noting that it did not adequately address the need for meat reduction, focused instead on technological fixes[130] and "intensified productivity,"[131] and "fail[ed] to express the urgency of reducing meat and dairy consumption and production to meet the targets set by the Paris climate agreement."[132] As observed by one expert in response to the Roadmap:

> This current draft puts a huge emphasis on incremental changes to the current industrial food system. But this is a flawed system that is wrecking nature, polluting the environment, and starving millions of

Comments by the FAO's Chief Economist Maximo Torero also garnered critical responses. Referring to the recommendation in the Roadmap that animal production be intensified "in relevant locations," Torero "said the way forward was for countries that are 'very efficient in producing livestock,' such as the Netherlands and New Zealand, to produce more meat and dairy and then ship those products across the world." Susannah Savage, *Ramp Up Meat Production to Address Health Challenge in Poorer Countries*, FIN. TIMES (Dec. 10, 2023), https://www.ft.com/content/2eb93884-0aa3-4590-98ec-5b15cc1d9f44. George Monbiot queried in response:

> Could he really be unaware that both these countries have been thrown into severe ecological and political crisis by the scale of their livestock industries? Yet now he wants them to produce even more—and for poorer nations to become dependent on these imports? Greetings to our visitor from Planet Meat.

Monbiot, *supra* note 123.

> people. . . . The next rounds of this process will need to go much further in proposing a real transformation of the status quo . . . .[133]

Immediately following the COP, the FAO released *Pathways Towards Lower Emissions*, a report analyzing options to mitigate the GHG impact of animal agriculture.[134] Experts and advocates criticized the report on a number of bases, including its focus on productivity and efficiency improvements, as well as for minimizing and questioning the positive climate impacts of dietary changes.[135] Two scientists whose studies were referenced in the report sent a letter to the FAO, requesting a retraction and stating that the report "seriously distort[ed]" their findings and underestimated the climate mitigation potential of dietary change.[136]

* * * * *

While progress has thus been limited and imperfect, after a long lag following the FAO's first analysis of the climate harms of animal agriculture in 2006, since 2018 a picture begins to emerge of growing calls on the international stage and in the EU for reduced consumption of animal products in response to the climate crisis.

IV. POLICY OPTIONS AND EXAMPLES

What options are available to leaders who would follow this international guidance and signaling? In fact, there are many policies that could reduce the climate harms of animal agriculture. Not only are these policies known and quite well understood,[137] as discussed in this Part, they are each currently being tried or considered somewhere in the world.

Notably, this Part does not include examples of mandatory limitations on animal agriculture's emissions via regulation. At present,

no country is limiting GHG emissions from animal agriculture through caps or other such mechanisms.[138] This is not surprising, as it is only relatively recently that such limits are being imposed by some countries on emissions from the largest source of GHG emissions: fossil fuels.[139] While there is an increasing focus around the world on limiting methane emissions—exemplified by the contrasting approaches in the Global Methane Pledge discussed above[140]—the early mandatory methane regulations apply to the energy sector and not to animal agriculture.[141] This is despite the fact that, as discussed above, animal agriculture is one of the most significant sources of anthropogenic methane.[142] Even *disclosure* of supply chain GHG emissions from animal agriculture is, for the most part, not required or provided at present.[143]

(May 6, 2024), https://www.wri.org/insights/tipping-point-for-corporate-climate-disclosure.

A. Public Relations and Information: Advertising Bans, Climate Labeling, and Confronting Industry Deception

One province and three cities in the Netherlands—first Haarlem in 2022, followed by the cities of Bloemendaal and Utrect and the province of Noord-Holland in 2023—are the first jurisdictions in the world to have banned meat and dairy advertising for climate reasons. The bans will apply to advertising spaces owned by the municiplaties, such as bus stops and billboards, and will take time to come into force (either because they have phase-in dates or will honor current contracts).[144] None of the bans are limited to meat and dairy; they also include other damaging industries and products such as fossil fuels, combustion engines, airline travel, alcohol, and gambling.[145]

A statement from the city of Bloemendaal explained that meat and dairy are included in the ban as part of necessary actions to reduce GHG emissions and deforestation.[146] When asked for the reasoning behind the ban, the leader of the Party for the Animals who had proposed it explained: "The main reason is that meat production leads to climate change. . . . Another reason is animal welfare."[147] A professor of sustainability from the University of Amsterdam observed that, while the bans may not be expected to directly change behavior, they have norm-setting power and can "stimulate the social debate."[148] As a case in point, he noted that the bans have been discussed well outside of the municipalities, indeed all over the world.[149]

In addition to such advertising limits, governments can set affirmative requirements for climate labeling on foods and also help police misleading claims. For example, in its Farm to Fork Strategy, the European Commission called for review of voluntary green claims and to creating a sustainability labelling framework to include climate impacts.[150] Similarly, in its Roadmap, the FAO recommends

150 FARM TO FORK STRATEGY, *supra* note 75, at 14.

improvements to food labeling to inform consumers of the environmental and social impacts of products.[151]

Governments are also starting to bring litigation to enforce consumer protection laws against animal agriculture companies that mislead the public about their climate impacts. In Sweden, the consumer protection agency successfully sued Arla Foods, a major dairy producer, obtaining an injunction preventing the company from continuing to pronounce that its dairy products have a "net-zero climate footprint."[152] Similarly, in a landmark U.S. lawsuit against the meat giant JBS, the New York State Attorney General alleges that JBS's "net zero by 2040" commitment is not only misleading to the public, but perhaps even impossible at JBS's current levels of production.[153]

B. Positive Supports: Shifting Subsidies, Food System Transition Plans, Dietary Guidelines, and Procurement

Most fundamentally, governments can shift subsidies and supports from animal agriculture to non-animal foods.[154] The industry is heavily subsidized around the world, with nearly a third of global agricultural support measures going to meat, milk, and other dairy production.[155] As discussed above, the World Bank has recently called for a shift of subsidies from high-emitting animal foods to alternatives,[156] and reformers decried the failure of the EU's Farm to Fork Strategy to end government subsidization of meat production and consumption.[157] At an EU meeting in late 2023, the Netherlands Minister of Agriculture, Nature, and Food Quality argued that, in line with its sustainability commitments, the European Union should stop providing subsidies for meat production.[158]

Breaking new ground, several countries have announced food system transition plans of varying ambition levels that seek to promote plant-based eating through a collection of policy approaches. For example, Taiwan has taken important steps in a 2023 climate law calling for government promotion of low-carbon diets, including plant-based and local foods and reduction of food waste.[159] Subsequent legislative resolutions in Taiwan also recognized the climate impact of dietary choices and that environmental impacts should be considered when developing dietary guidelines.[160] A private-public partnership in the Netherlands is developing a policy aimed at doubling consumption of legumes by 2030.[161] In late 2023, South Korea announced a national plant-based food promotion plan, describing development in this area as a "new growth engine," including for export.[162]

For the first time, Germany has budgeted significant funds (€38 million in 2024) for the promotion of alternative protein sources.[163] A Green Party elected representative described this investment as a "paradigm shift" and "a clear commitment to the protein transition."[164] Activities to be funded include: amendment of the national food and agriculture agency's protein crop strategy to focus primarily on proteins for human nutrition rather than for animal feed; a new center and stakeholder forum around the protein transition; €20 million for an

"opportunity program" to encourage exits from animal husbandry and into alternatives; and €10 million for projects to support promotion and production of alternatives.[165]

The most groundbreaking plan to date was enacted by Denmark in October 2023.[166] This is especially notable because Denmark has a powerful animal agriculture industry: it is the only European country with more pigs than people.[167] Denmark's Action Plan for Plant-Based Foods includes nearly $10 million for promotion of plant-based foods and $195 million to support the plant-based food transition,[168] and the Danish government investments will be supplemented by additional EU funding.[169] The Plan calls for significant reductions in consumption and production of meat and dairy. The Danish approach includes a broad variety of complimentary measures, including grants to support innovation and research, behavior change efforts, voluntary state-reviewed climate labels, training for chefs, changes to public procurement, promotion of export markets for alternatives, efforts to attract expertise and learn from other countries, improvement of the regulatory approval process for new products, and more.[170] In developing the Plan, advocacy groups like the Vegetarian Society worked with farmers' unions and the food lobby, focusing on consensus building and positive opportunities around new products and job creation.[171] A Danish MP and former environment minister described the collaboration this way: "Get the farmers on board, get the unions on board, but also be clear in your vision: say this is where we're going and do it incrementally."[172] Notably, an explicit goal of the Plan is to "serve as an example for the rest of the world."[173]

Early in 2023 in a separate effort, the Danish Parliament created a "Fund for Plant-Based Foods" with an investment of more than €90 million to support the production of more plant-based foods.[174] A

number of other countries have also announced funding for alternative proteins, including China, India, Japan, and the United Kingdom.[175]

In a sign of potential future developments in France, in mid-2023 the French Court of Accounts—which counsels the government on spending—advised the French government to develop "a strategy to reduce cattle herds" in order to achieve methane reduction targets, which the Court found "necessarily call for a significant reduction in livestock."[176] The Court recommended new policies to transition from existing subsidies to supports for sustainable farming and retraining for farmers.[177]

Dietary guidelines are another lever that policymakers can pull to reduce GHG emissions. To date, while most dietary guidelines do not incorporate environmental sustainability, a growing number do.[178] In its recent Roadmap, the FAO recommended that dietary guidelines should include environmental considerations.[179] Many of the supportive policies described above were preceded or accompanied by changes to dietary guidelines. For example, two years before Denmark adopted its comprehensive Action Plan for Plant-Based Foods, updates to its dietary guidelines called for reduction of the recommended adult meat consumption in line with EAT-*Lancet* guidelines.[180]

In other examples, Canada revised its dietary guidelines in 2019 to recommend that Canadians "consume plant-based more often,"[181] and in 2021 the U.K. National Food Strategy, an independent review commissioned by the government, called for a 30% decrease in meat production by 2032.[182] The Nordic Nutrition Recommendations, released in 2023 by the Nordic Council of Ministers,[183] integrates environmental

considerations for the first time. The Nordic Council described the Recommendations as "our bravest step yet" and "well aligned with our global commitments."[184] The Recommendations call for "a predominantly plant-based diet . . . , moderate intake of low fat dairy products, limited intake of red meat and poultry, and minimal intake of processed meat . . . ."[185] While the Recommendations are not binding and implementation is up to each individual country, they are usually widely followed and used for schools, hospitals, and elderly care.[186]

Another area of supportive policy is procurement, i.e., harnessing the government's purchasing power for dietary changes that are beneficial to the environment and to people's health. In a first step in its Farm to Fork Strategy, the European Commission committed to "determin[ing] the best way of setting minimum mandatory criteria for sustainable food procurement."[187] As a national-level example, a French climate law passed in 2021 requires school cafeterias to provide vegetarian meals once a week and public catering to offer vegetarian options.[188]

Many local governments around the world are using their authority and procurement power to move away from high-emitting animal-based foods.[189] For example, sixteen cities have signed onto the Good Food Cities Accelerator, committing to increase healthy plant-based food consumption and align food procurement with the EAT-*Lancet* "Planetary Health Diet" (about half the plate occupied by vegetables and fruit) by 2030.[190] The Good Food Purchasing Program in the United States, in which large municipalities like New York City participate, provides a set of tools and support to empower public institutions to

purchase food aligned with "five core values: local economies, health, valued workforce, animal welfare, and environmental sustainability."[191] New York City has also taken significant measures to decrease meat consumption, serving plant-based meals as the default option in public hospitals and twice weekly in public schools.[192] The City of Amsterdam adopted a motion put forward by the Party for the Animals aiming to make Amsterdam a "Plant-Based Capital," including plans to offer plant-based options and Vegan Fridays in public facilities and to move toward a set animal-plant protein ratio for public catering by 2030.[193] In a proposed comprehensive approach to food system change, thirty municipalities around the world, including Amsterdam, Edinburgh, and Los Angeles,[194] have called for the negotiation of a "Plant-Based Treaty" by which signatories would commit to: ending land use change for animal agriculture; promoting plant-based foods and transitioning away from animal-based foods; and restoring key ecosystems and reforesting.[195]

A final important type of supportive policy is regulatory approval for animal product alternatives in the context of cultivated meat. Cultivated or cultured meat is animal meat produced by cultivating cells.[196] Cultivated meat has already received regulatory approval for commercial sale in Singapore and the United States, and other countries may soon follow.[197]

C. Taxes[198]

Taxes on meat production or consumption have long been contemplated as a possible approach to reducing associated GHG emissions.[199] While a tax of this type could generally be expected to impact low-income households disproportionately because they spend a greater proportion of their income on food, pairing taxes with subsidies can reduce regressivity and encourage shifts to more sustainable diets.[200]

The most prominent current example is the Danish Parliament's approval in late 2024 of the world's first emissions tax on animal agriculture, to take effect in 2030.[201] The tax will apply to emissions from cattle, sheep, and pigs.[202] As with the consensus-building approach that led to the Danish Action Plan for Plant-Based Foods,[203] the proposal was discussed and agreed upon amongst a group including policymakers, labor unions, industry, and environmental groups.[204]

---

198 Another possible approach to limiting emissions from GHG-intensive products is rationing, or limiting each person's consumption below a specified cap. A recent survey of respondents from five countries on five continents found that, while rationing was about as accepted as taxation when applied to fossil fuels, taxation was consistently more acceptable than rationing when applied to meat. Oskar Lindgren et al., *Public Acceptability of Climate-Motivated Rationing*, HUMANS. & SOC. SCIS. COMMC'NS., Sept. 26, 2024, No. 1252, at 3. Of the countries surveyed, the United States had the lowest percentage (22%) who responded that meat rationing for climate protection purposes would be acceptable to them. *Id.* at 4. This research has not identified serious consideration of meat rationing anywhere in the world. *Id.* at 1.

203 The Danish Action Plan included a commitment to eventually institute an agricultural emissions tax. *See infra* note 327 and accompanying text.

204 Carlsson, *supra* note 201.

A tax on cow emissions proposed in New Zealand in 2022 by the center-left Labour Party was scrapped after the center-right National Party gained control in the October 2023 election.[205] The proposal had resulted in farmer protests and an outcry from the meat and dairy industries,[206] which have embraced the new government's plan.[207]

In 2022, the German government announced plans to spend €1 billion on investing in improving farmed animal housing and husbandry systems, for "animal welfare and climate protection."[208] One option being discussed to fund the proposal and other reforms to the animal agriculture sector is a tax on meat modeled on the existing coffee tax.[209]

D. Buyouts

Animal buyout programs, i.e., "schemes that compensate for the loss or decline in the value of production assets on livestock farms on the condition that production will be ceased permanently,"[210] are the most direct policy mechanism available to shrink the herd. While not common, animal buyouts have been used historically by governments for various reasons.[211] Past examples include the voluntary 1986 "Whole-Herd Buyout" program in the United States aimed at reducing the milk supply,[212] voluntary buyouts in the Netherlands and Flanders (the autonomous northern region of Belgium where Brussels in located)

starting around 2000 to reduce manure in order to comply with EU rules on nitrogen pollution,[213] and mandatory buyouts of mink in the Netherlands that were initially implemented in 2013 based on animal welfare concerns and then accelerated for public health reasons after coronavirus infections spread through mink farms.[214]

In order to achieve the intended population reductions and benefits, buyout programs must be carefully structured. For example, one expert advises that voluntary dairy cow buyout policies must ensure: additionality—in other words, that the animals who are removed are actually productive dairy cows (and not already at the end of milk production when they would be slaughtered anyway); that removed cows are not replaced, via some assurance of long-term stock diminishment; and that the program is attractive to farmers (a challenge when dairy production is profitable).[215]

In a leading example, the Dutch government appears to have been the first in the world to utilize an animal buyout program with an explicit purpose of reducing GHG emissions.[216] A 2019 pig buyout program that was initially requested by farmers to address odor problems was later granted additional government funding as a way of reaching climate and nitrogen pollution goals.[217] In addition, the 2019 Dutch Climate Agreement—the national policy to achieve emissions reductions in-line with the Paris Agreement—included plans for a voluntary buyout of dairy farmers in peat meadow areas, which are notable for their emissions reduction potential and biodiversity.[218] Provinces submitted initial buyout plans in late 2023.[219]

The Netherlands is perhaps a predictable place for the first buyouts related to climate goals, given that it has high farm animal densities, a serious nitrogen pollution problem with more than half of all nitrogen pollution coming from manure,[220] and a history of utilizing animal buyout programs for other purposes (e.g., odor control and reducing nitrogen pollution).[221] Nitrogen pollution can harm biodiversity and also contributes to climate change.[222] Measures that reduce nitrogen pollution also reduce emissions of the GHG nitrous oxide, the majority of which is formed when microbes process excess nitrogen from farmed animal manure and urine and from synthetic nitrogen fertilizer.[223]

Acute pressure on the Dutch government to reduce nitrogen pollution arose from a lawsuit filed in 2018 by a Dutch NGO against the national government.[224] The lawsuit alleged that high levels of nitrogen pollution in certain protected areas violated the EU Habitats Directive.[225] Eventually, the Court of Justice of the European Union agreed.[226] In response, the government announced plans to reduce the herd by as much as a third,[227] eventually identifying significant funds (€24.3 billion) for the transition, including to buy out 3,000 "peak emitter" farms at up to 120% of their value.[228] As of late 2024, 1,474 farmers had submitted applications for one or both of the buyout programs, with nearly a third committing to a buyout.[229] As described below in Part V.B, this Dutch "stikstofcrisis" (nitrogen crisis) resulted in widespread farmer protest and a significant political shakeup in the Netherlands. Indeed, buyout plans—while amongst the most direct

approaches to reducing GHG emissions from animal agriculture—can face significant opposition and political blowback if not structured and rolled out carefully.

Somewhat similar events played out in Flanders. In 2021, a climate policy committee advised the government that it should reduce animal numbers and encourage dietary shifts as part of meeting climate targets.[230] While the proposal was not taken up, after a ruling by the highest Flemish administrative court in 2021 ordering the government to reduce nitrogen pollution,[231] animal agriculture was again at the center of policy discussions. The responsive plan eventually approved by the government included both voluntary and mandatory animal buyouts, depending on their proximity to and impact on certain protected areas.[232] Uptake on the voluntary offers was low as of early 2024, reportedly with only seven pig farmers having accepted the buyout offer out of the 982 contacted by the government.[233] An industry publication explains: "The low interest in the scheme can be attributed to the economic trend of high pig prices, as well as criticism of the buyout conditions, such as limited benefits for older stables and restrictions on expanding other livestock activities on the farm."[234]

E. Tech Fixes and Climate Efficiency Approaches

> At this point it is naïve to expect that technological improvements alone will slow the impacts of growth and reduce the burden on the biosphere. And yet many still exhibit this naiveté.
>
> ~Kim Stanley Robinson,
> *The Ministry for the Future*[235]

The policy approaches discussed above have the potential to reduce the number of farmed animals or "shrink the herd," with animal food products replaced by more sustainable alternatives. There is another category of interventions that could be described as "climate efficiency" approaches—including feed additives, genetic engineering, and biogas digesters[236]—which aim to reduce emissions from animal agriculture by making each animal (or group of animals) more efficient in climate terms. An example of a climate efficiency policy is Canada's proposal

that would allow farmers to generate offset credits if they reduce enteric emissions from their cattle through strategies such as changing feed.[237]

Because such approaches do not challenge the fundamental structure or scale of the industry, they have been referred to as "industry-led" and "industry-friendly" and typically receive greater buy-in from industry actors.[238] For example, the authors of a recent survey of animal agriculture and climate policy in four countries in Western Europe note: "In general terms, in all countries, we observe the reproduction of a 'technology versus volume' discourse. Farmers' organisations and their supporting parties stress the importance of eco-efficiency and technical innovation to resolve environmental concerns. Environmental NGOs and green parties advocate reducing livestock production and changing human diets."[239]

This Article does not take the position that climate efficiency approaches are harmful or without merit.[240] The urgency of the climate crisis—which will affect all life on this planet, to varying degrees—demands that we act with urgency on all potentially helpful fronts.[241] But, for the reasons that follow, efficiency approaches by themselves will

[237] ENV'T & CLIMATE CHANGE CANADA, DRAFT FEDERAL OFFSET PROTOCOL: REDUCING ENTERIC METHANE EMISSIONS FROM BEEF CATTLE 1 (2023), https://www.canada.ca/content/dam/eccc/documents/pdf/climate-change/ghg-offset/REME%20protocol%20-%20EN.pdf.

[238] *E.g.*, Morris & Jacquet, *supra* note 62, at 1 (referring to "industry-led climate 'solutions' that maintain production"); Torrella, *supra* note 107 (describing "industry-friendly changes like tinkering with how livestock are fed and farmed"); Dutkiewicz, *Ireland Isn't Culling Cows*, *supra* note 215 ("Emissions restrictions policies quite simply interfere with a profitable and entrenched business model, which explains why farming groups, where they have participated in discussion about policy proposals, have favored soft interventions like developing methane-inhibiting feed additives over harder interventions like voluntary culls."). One expert draws this analogy: "Much as the coal industry starting hawking 'clean coal' in 2008 to avoid policies promoting a phaseout, the meat industry and its defenders are now arguing for clean cows." Dutkiewicz, *The Comforting Lie of Climate-Friendly Meat*, *supra* note 102.

[239] Boezeman et al., *supra* note 80, at 9; *see also Clash over Dutch Farming*, *supra* note 228 ("[T]echnologies [that reduce emissions] could potentially allow [Dutch] farmers to dodge the tougher approach that some policymakers have in mind: big cuts to the number of livestock in the Netherlands.").

[240] *E.g.*, 2018 IPCC REPORT, *supra* note 27, at 146 ("[E]ven within existing livestock production systems, a transition from extensive to more productive systems bears substantial GHG abatement potential, while improving food availability." (internal citations omitted)); EU ASSESSMENT REPORT 2024, *supra* note 50, at 157 ("[Methane] emissions can be reduced by measures to reduce emissions from enteric fermentation (the digestion process of ruminant livestock such as cattle) and by improved manure management.").

[241] *See* Torrella, *supra* note 107 ("Numerous environmental scientists . . . have called on wealthy countries to cut back on meat and eat more plant-based meals . . . . Down another path lies the more politically palatable, yet far less effective, approach of continuing to eat record amounts of meat in the West while deploying a host of technologies and farming practices, each of which can only marginally shave off livestock emissions. The world needs a mix of both approaches, but policy makers, out of political expediency and corporate capture, are barreling down the second path, a choice they'll likely come to regret as climate change intensifies.").

not be sufficient and should not be pursued at the exclusion of or to the detriment of other approaches.[242]

Indeed, some advocates refer to efficiency approaches to the climate problem of animal agriculture as "false solutions" for several reasons.[243] First, and perhaps most essentially, reducing the GHG emissions of animals in industrial systems does nothing to address the many other externalities of those systems,[244] which include harms to environmental justice communities,[245] zoonotic disease risks[246] and antimicrobial resistance,[247] other public health harms,[248] dangerous and exploitative

shift to reduce GHG emissions, such shifts (for example, from cows to pigs, or pigs to chickens[257]) do nothing to address these other externalities of industrialized animal agriculture systems.[258] The vast majority of animal products in the United States are raised in industrial settings.[259]

Second, reducing per animal emissions will not necessarily lead to reductions in total emissions if production and consumption of animal products continues to rise as predicted.[260] Also, increasing the productivity of individual animals often requires additional inputs with attendant GHG emissions.[261] Moreover, efficiency improvements can sometimes paradoxically result in increased demand and production (for

---

COMMUNITIES 35 (2008) ("[I]ndustrialization [of animal agriculture] draws wealth and life away from the very rural communities it purports to benefit and which once thrived as a result of diverse, and more sustainable, forms of livestock production.").

257 FAO ROADMAP, *supra* note 113, at 12 ("[S]hifting from large ruminant to small ruminant animals for meat products, and from ruminant to monogastric animals, in particular chicken, will reduce the GHG impacts of animal-food based [sic] products."); SUTTON ET AL., *supra* note 28, at 13 (proposing shifting subsidies from "red meat and dairy" to "low-emission foods, like *poultry* or fruits and vegetables" (emphasis added)).

258 Verkuijl et al., *supra* note 244, at 6–8. Looking specifically at animal welfare and the suffering of individual animals, it takes about 100 chickens to get the same amount of meat as one cow. Marina Bolotnikova & Kenny Torrella, *How Big Are Factory Farms? How Mega-Sized Factory Farms Took Over America's Food System, Explained in 9 Charts*, VOX (Feb. 26, 2024, 4:30 AM), https://www.vox.com/future-perfect/24079424/factory-farming-facts-meat-usda-agriculture-census.

259 Hannah Ritchie, *How Many Animals Are Factory Farmed?* OUR WORLD IN DATA (Sept. 25, 2023), https://ourworldindata.org/how-many-animals-are-factory-farmed (citing estimates based on USDA data that 99% of U.S. farm animals are raised on industrial-scale concentrated animal feeding operations, or "CAFOs," as defined by EPA, including 70% of cows, 98% of pigs and egg-laying hens, 99.9% of turkeys, and 99.97% of broiler (meat) chickens).

260 *See* IPCC, CLIMATE CHANGE AND LAND, *supra* note 67, at 440 ("Reductions in GHG emissions intensity (emissions per unit product) from livestock can support reductions in absolute emissions, *provided appropriate governance to limit total production is implemented at the same time* . . . ." (emphasis added)). Indeed, some animal agriculture companies have preferred to report on decreases in their per animal emissions while failing to be clear that overall emissions have increased because of growth in the size of the herd. *See* EMISSIONS IMPOSSIBLE, *supra* note 3, at 14–15. Similarly, campaigns like the "continuous improvement" campaign of the Meat Institute, a U.S.-based trade association, offer industry a comfortable baseline and will not necessarily result in emissions reductions. *See generally* N. AM. MEAT INST., IMPLEMENTING TOOLS: 2024 CONTINUOUS IMPROVEMENT REPORT (2024), https://meatinstitute.org/sites/default/files/documents /20241021%20Protein%20PACT%20continuous%20improvement%20report.pdf.

261 Gert-Jan Nabuurs et al., *Agriculture, Forestry and Other Land Uses*, *in* INTERGOV'TAL PANEL ON CLIMATE CHANGE, CLIMATE CHANGE 2022: MITIGATION OF CLIMATE CHANGE 750, 771 (Priyadarshi R. Shukla et al. eds., 2022) [hereinafter *IPCC Agriculture, Forestry and Other Land Uses*] ("[I]ncreased individual animal productivity generally requires increased inputs (e.g., feed) and this generates increased emissions . . . . In addition, the production of inputs to facilitate increased animal productivity, may indirectly drive further absolute GHG emissions along the feed supply chain.").

example as happened with more efficient cars and air conditioners),[262] or to shifts in production that undo emissions reductions.[263]

Third, many efficiency approaches are as yet unproven and potentially unscalable.[264] For example, an Irish government study found that, even if methane-inhibiting technologies and other mitigation measures were successfully implemented, agriculture would not be able to achieve Paris Agreement targets without also "limiting animal number increases and develop[ing] . . . new science."[265] Moreover, efficiency approaches usually come at a cost, and for that reason producers may be slow to implement them without regulatory pressure.[266] For example, the feed additive Bovaer has been shown to

---

[262] This phenomenon is known as the "Jevons Paradox" (named after 19th century economist William Stanley Jevons) or the "Rebound Effect." CHANGE BIOLOGY 681, 681 (2018) (undertaking life cycle assessment of potential indirect GHG effects of dairy intensification in the United Kingdom and describing replacement beef production in Brazil (because dairy cattle also become beef) resulting in a "small GHG savings for the UK GHG inventory, but . . . a net increase in international GHG emissions"). As observed in the recent EU Assessment Report, "reductions in the production and consumption of GHG-intensive agricultural products (especially livestock products) need to go hand in hand, otherwise emission reduction efforts risk being offset by increased imports (displacing emissions to other countries) or exports (maintaining EU emissions in spite of consumption changes)." EU ASSESSMENT REPORT 2024, *supra* note 50, at 155.

[264] *E.g.*, Dutkiewicz, *The Comforting Lie of Climate-Friendly Meat*, *supra* note 102 ("[T]he technologies proposed to reduce [methane from cows] might look good in small trials. But they haven't been implemented or shown to be effective or affordable at any meaningful scale."); *Novel Meat and Dairy Alternatives Could Help Curb Climate-Harming Emissions*, U.N. [265] TEAGASC CLIMATE CTR., MARGINAL ABATEMENT COST CURVE 2023: EXECUTIVE SUMMARY 11 (2023), https://www.teagasc.ie/publications/2023/marginal-abatement-cost-curve-2023---executive-summary.php; *see also id.* at 9 (finding that further research is needed to determine whether feed additives are effective and whether they have constraints or pose risks).

[266] Ben Elgin, *This Quick Fix Reduces Methane Emissions from Cow Burps*, BLOOMBERG L. (June 28, 2023), https://www.bloomberglaw.com/product/blaw/bloombergterminalnews/bloomberg-terminal-news/RWY8O5T0AFB4 ("[C]orporate giants that have promised huge and rapid cuts to their greenhouse gas emissions, like Danone, Nestle, Starbucks and JBS . . . have publicly declared an interest in using methane-curbing feed additives with the farmers or feedlots who supply their ingredients, but have yet to follow through at any sort of magnitude.").

reduce enteric methane from cows by thirty percent.[267] But it costs about $100 per cow per year and uptake has been slow, even by large companies.[268] In the words of one campaigner: "If you're going to talk about [feed additives], buy them and do this. Invest the money and make it a part of your emission-reduction plan. Some companies are presenting this as a silver bullet, but they're not at all serious about scaling it up, probably because of the cost."[269]

Fourth, even if efficiency approaches were affordable, feasible, and implemented at scale, farmed animals—and cattle in particular—would still be significant sources of GHG emissions. For example, even if the Bezos Earth Fund is correct that its methane-inhibiting research could reduce emissions by as much as thirty percent, "that would still make cows the highest-emission part of the food system."[270] Shifting diets would be more effective.[271]

Fifth, where efficiency approaches make industrial animal agriculture more profitable or even encourage its expansion and entrenchment, such efforts can act contrary to climate mitigation goals. Anaerobic digesters, which are systems that cap manure lagoons to seek to capture emitted methane, are perhaps the best example. As discussed elsewhere in this volume,[272] digesters have been the target of sustained criticism on a number of fronts,[273] including that they can make large-scale animal agriculture more profitable and even encourage expansion of facilities.[274] In California, where digesters have benefitted from

substantial government investment and support via the Low Carbon Fuel Standard and other programs,[275] some observers refer to a dangerous "manure gold rush."[276] In a recent piece on biogas digesters, a professor at UC Davis wrote:

> In colonial India, the British government wanted to reduce the number of cobras in Delhi, so it offered a bounty for dead cobras. Profit-seek[ers] responded by breeding cobras to receive the bounty. This phenomenon is known as the "cobra effect." There is a risk of the same thing happening when we pay people to capture methane from dairy cow manure.[277]

Moreover, digesters have benefitted from substantial government investment, an opportunity cost for other more beneficial mitigation approaches.[278]

Sixth, efficiency approaches can distract attention from other policy paths that prioritize the urgent need to reduce overall emissions from animal agriculture. In the parallel context of geoengineering (removing carbon from the atmosphere by technical means),[279] the U.N. Human Rights Council's Advisory Committee has warned that such approaches

may discourage immediate efforts to reduce emissions, "which makes disastrous future scenarios more probable."[280] Denmark's Minister for Global Climate Policy remarked about geoengineering: "It very easily becomes an excuse for not doing all the things that we already can do and that we know will work."[281]

Finally, efficiency approaches may delay large animal agriculture companies from seriously considering transformative change and investing in alternative production models. Looking past posturing about farmers and meat culture, these are profit-focused companies that (at least in theory and setting aside transition costs) should not have a vested interest in continuing to raise and slaughter animals.[282] Large meat and dairy companies have invested in non-animal alternatives[283] (although often not at the scale that they suggest),[284] and may to some extent identify as "protein" producers.[285]

V. POLITICAL REALITIES: THE EXAMPLE OF FARMER PROTESTS AND RETRENCHMENT IN EUROPE

As with all policy change, each of the approaches described above would benefit some stakeholders and not be aligned with the current interests of others. It is not surprising then that significant political pushback has arisen in response to the acceleration of policy around climate and animal agriculture.

As background, the last several years have seen widespread farmer protests in Europe, and abandonment of core agricultural reforms that would be necessary to achieve the promise of the Green New Deal and the Farm to Fork Strategy.[286] The protests share certain themes and motivations in common, but also differ significantly in their causes and contexts. For example, an interactive map of European farmer protests during 2023 prepared by Politico shows they were motivated by a variety of concerns including: cheap imports, electricity and fuel costs (including the removal of diesel fuel subsidies), low prices for farm products, delays in promised subsidy payments, and the EU requirement to leave four percent of land fallow.[287]

While not all of the farmers' grievances are closely connected to efforts to reduce animal agriculture's GHG emissions,[288] some of them are. Relevant themes include anger about the EU's Green Deal as well as frustration about responses to nitrogen pollution from manure.[289]

Following protests, in early 2024 references to cutting non-carbon dioxide agricultural emissions—including methane and nitrous oxide from animal agriculture—were removed in the final version of the European Commission's communication launching the process for setting 2040 climate goals.[290] Advocacy groups described this "last-minute watering down" as a capitulation.[291]

The Netherlands, Ireland, and Flanders have had active farmer protests relating to climate and animal agriculture. Notably, in each of those countries, while many sectors are facing emissions limitations in order to meet binding climate targets, the outcry has been especially loud from farmers. In the Netherlands, a court order prevented the government from issuing permits for all sorts of projects (not just animal agriculture facilities) that emitted nitrogen.[292] Even though "[o]vernight, 18,000 construction projects, including critical infrastructure and housing development, were mothballed," the loudest response came from the farmers.[293] Downtown Brussels was inundated with hundreds of tractors in 2023, as farmers there protested plans to reduce nitrogen pollution in the Flanders region.[294] And in Ireland, where government plans seek a 50% reduction of emissions from the transport sector, 40% from commercial and public buildings, and only

25% from agriculture—agricultural cuts have generated the most vocal opposition.[295]

The Dutch farmer protests are a particularly instructive example of political peril around environmental animal agriculture policy. As described above,[296] after court judgments found that the Dutch government was not compliant with EU directives requiring the protection of natural areas from nitrogen pollution, the government announced its intention to shrink the national herd by as much as a third.[297] The Dutch Minister for Nitrogen and Nature Policy recognized at the time that the plan did not allow for a "future for all [Dutch] farmers," and the plan itself noted that "this approach will be so radical that it will take a great deal from many to shape it."[298]

In response, tens of thousands of farmers blocked roads with tractors, staged mass protests, and set hay and manure on fire.[299] The farmer protests have, in some instances, become linked to or instrumentalized by far-right parties.[300] Right-wing Dutch leader Geert Wilders and Marine le Pen in France expressed support for the farmers, and former U.S. President Donald Trump warned that "climate fanatics" would come next for U.S. farmers.[301] A Dutch academic expert in social movements observed: "Political scientists call it issue expansion. It's a small issue, but it expands because of vicious circles and before you

know it, it's all about the great reset,"[302] referring to a white nationalist conspiracy theory.[303]

In March 2023, the new Farmer-Citizen Movement (BBB), which had run explicitly against the nitrogen reduction policies, stunningly won a larger share of the vote than any other Dutch party.[304] Far-right leader Geert Wilders and his Freedom Party now have the largest bloc of seats in parliament and ministers from his party were appointed to the cabinet for the first time in summer 2024.[305] Wilders ran an anti-EU campaign including a focus on immigration and climate policy, calling for a withdrawal from international climate obligations.[306]

All of this political turmoil has delayed and endangered the prospects for addressing the pressing environmental issue of nitrogen pollution from animal agriculture.[307] If the country cannot reduce nitrogen pollution in high-value conservation areas in line with EU rules and as directed by the Court of Justice of the European Union, it will face substantial fines.[308] Dutch naturalists fear that the fate of fragile habitats hangs in the balance.[309]

As another example, Ireland may eventually face similar challenges. The European Commission successfully sued Ireland for its failures to limit nitrogen pollution, and later issued a ruling condemning Ireland's continuing noncompliance, noting among other things the challenges of "overgrazing" and "agricultural activities causing nitrogen deposition."[310] Like the Netherlands, Ireland has a large animal agriculture industry, with seven million commercially farmed cows for its five million people.[311] Cows are responsible for about one-fifth of all of Ireland's anthropogenic GHG emissions.[312] As part of meeting its Paris Agreement commitment to reach carbon neutrality by 2050, the Irish government has undertaken to reduce GHG emissions from agriculture by 25% by 2030.[313]

An online kerfuffle originating from Ireland illustrates the potential for dramatic reactions to factual policy discussions of the environmental

impacts of animal agriculture. A 2022 report from a working group of the Irish Department of Agriculture suggested the possibility of a "voluntary exit/reduction scheme" under which farmers would be paid for removing cows and agree not to replace them for at least five years.[314] A similar idea was described in a government document obtained by a journalist, which stated that removing about ten percent of Ireland's dairy cows would be needed to keep binding emissions targets within reach.[315] Even though no such plan was enacted or even formally proposed or debated, an international media firestorm ensued, surrealistically leading to Elon Musk tweeting: "This really needs to stop. Killing some cows doesn't matter for climate change."[316]

Thus, even the suggestion of an Irish government policy to shrink the herd caused international controversy. But Ireland may not be able to achieve its agricultural emission goals without reducing the number of cattle. A 2023 report by Ireland's Agriculture and Food Development Authority found that "limiting animal number increases" will be necessary to reach emissions targets.[317] In the words of one Irish climate scientist: "Various tried and untried methods have been advanced to suggest compliance with the 25% emissions ceiling," but without success; "[o]nly a reduction in numbers can achieve the targets in the short term."[318]

VI. PATHS FORWARD

> [T]he last four years in the Netherlands have been a warning sign for the global environmental movement. When plans to address biodiversity and climate change—whether through decarbonization, expansion of conservation areas, or agriculture reform—collide with people's livelihoods and sense of place in the world, chaos can and will follow. . . . Already, the Netherlands' political miasma has begun to seep across its borders, a cloud descending onto other parts of Europe like ammonia from a megafarm.
>
> ~In the Clash over Dutch Farming,
> Europe's Future Arrives,
> Ashoka Mukpo[319]

> If there is some kind of main message of the Netherlands towards the world, it would be to act now. The environmental and societal costs will be much higher and more painful if we wait too long, for farmers and citizens alike.

~Kirsten Haanraads,
World Wildlife Fund
Netherlands[320]

Building from the preceding discussion and examples, this Part discusses considerations that could be important in advancing policy to mitigate animal agriculture's climate harms. One clear lesson from the political difficulties in the Netherlands is that earlier action, before the threat of a court judgment and potential fines, may have offered policymakers better options and more opportunity to ease into change. With the benefit of hindsight, the Dutch government seems to have missed an earlier opportunity to "draw[] up long-term plans to reform agricultural production before the situation worsened."[321]

The time-sensitivity and lack of maneuverability in the Dutch situation arose in part from the fact that the policy change was driven by a court decision.[322] Should the conclusion be that litigation is an overly rigid tool for such complicated matters as climate and animal agriculture policy? On the other hand, if environmental advocates had not resorted to litigation, pollution could have continued unchecked, ultimately resulting in an even more difficult situation and more harms to nature and society. Indeed, the Dutch advocates reportedly "begged" for attention from policymakers before resorting to litigation.[323] Even without the catalyst of litigation, the current lack of adequate climate mitigation, if continued, will force urgent changes to food systems.[324] Rather than imperiling our food systems, early mitigation action to curtail emissions from agriculture can be expected to lower long-term food prices, reduce hunger risk, and use less water.[325]

Starting policy change sooner also creates time to build consensus and sequence interventions. The Danish Plant-Based Action Plan provides examples of both. The Plan reportedly grew out of a yearslong process of stakeholder discussions including farmers, industry,

ENV'T L. 145, 247 (2024) ("Well-founded litigation might be uniquely positioned to facilitate action—which likely must include reduced production and consumption of animal products—where gridlocked political processes have failed.").

324 BLINDSPOT, *supra* note 83, at 43 ("If we fail to act now, runaway climate change will force us to adapt our eating habits because of collapsing food-production systems, increasing poverty and inequality. If we act quickly, we can manage the transition to healthier and more nature- and climate-friendly diets that are more just and equitable. This is where our choices and opportunities lie."); *see also* SUTTON ET AL., *supra* note 28, at 1 ("[C]onditions are set to deteriorate even further as the world attempts to feed a global population that will grow by 2 billion by 2050. More food means accelerating food production, land use changes, and related emissions, which exacerbate global heating. In turn, global heating will affect future agricultural yields and food security.").

325 SUTTON ET AL., *supra* note 28, at 8–10, 13.

government, and environmental and animal groups.[326] Another key characteristic of the Danish approach is that the initial measures focus on building demand and opportunity (the carrot); it is not until those efforts are well underway that measures like an agriculture carbon tax (the stick) would be implemented.[327] While carrots will not be sufficient by themselves,[328] the sequencing being tried in Denmark seems promising.

Indeed, the role of building in time for sustained discussion amongst stakeholders, allowing them an opportunity to appreciate each other's positions and challenges, emerges as an important strategy for avoiding the most adversarial of outcomes. In 2020, after farmer protests prompted by environmental regulation, Germany created a "Commission on the Future of Agriculture" bringing together consumers, farmers, environmentalists, and researchers.[329] The German coalition was modeled on a similar coalition that had been created around moving away from coal.[330] The Commission succeeded in arriving at a consensus position, with all participants recognizing that the current food system requires reform to achieve both economic and environmental sustainability.[331] Policy makers can look to prior transitions for lessons on both the adversarial battles that can result without creating space for consensus-building, and the new opportunities that can be created by such discussions.

If we might expect the grim realities of our changing climate and the patent harms of industrial animal agriculture to push stakeholders to a consensus around the need for some level of change, what principles should guide our consideration of policy options? Ensuring international equity and a just transition will be critical. As to the first, not all policy approaches and goals are appropriate in all places.[332] As recognized by the EAT-*Lancet* Commission, some populations depend on animal agriculture, and others face nutrition challenges in contexts where available plant-sourced foods may not be sufficient.[333] Moreover,

responsibility for historical emissions, scale of consumption of animal products, and stage of development are highly relevant to discussions of which countries should lead the way on dietary change.[334]

In looking at the various approaches around the world—as well as the political repercussions experienced in the Netherlands and elsewhere—a key grounding principle for a discussion of climate policy for animal agriculture is the need for a just transition for farmers, ranchers, and workers.[335] The International Labour Organization defines a just transition as "greening the economy in a way that is as fair and inclusive as possible to everyone concerned, creating decent work opportunities and leaving no one behind."[336] Most discussions of just transitions in climate policy to date have focused on the shift from fossil fuels to renewable energy, but the applicability and utility of this concept to agricultural climate transitions is now also being discussed.[337] Both the European Green Deal and the Farm-to-Fork strategy recognize the importance of a just transition.[338] In the context of climate reform of the food system, a just transition "means reducing emissions while ensuring jobs, good health, livelihoods, and food security to vulnerable groups and smallholder farmers."[339] A Green Party Member of EU Parliament observed earlier this year that one of the flaws in the Farm to Fork Strategy that may have diminished its chances of success was a lack of economic support, particularly for farmers.[340]

It is an understatement to say that achieving a just transition in animal agriculture will be complex.[341] Dietary choices implicate familial

and cultural traditions, nutrition, livelihoods, significant industry profits and power, and more.[342] Electoral timeframes are in many ways poorly suited for this challenge. While food system reform may benefit farmers in the medium and long run—by improving resilience in the face of climate change, reducing environmental damage, and creating new income streams—substantial investment will be required to assist those most affected.[343] Delaying the necessary changes can result in a "Pyrrhic victory" for farmers, who may then face more drastic changes and a loss of social support down the road.[344] And given that farmers directly experience the realities of a changing climate, many of them are in favor of adaptation. One Italian farmer criticized the EU Commission's decision to lessen environmental regulation in the Common Agriculture Policy, explaining: "Climate change is there. This is not a political opinion. We are not environmentalists. We are peasants. But we see that it's costly to work against nature."[345]

Engaging with farmers and others who work within the industrial animal agriculture system to ensure a just transition will be essential. One Dutch farmer put it this way: "The farmers are the victims of this whole system. And the agri-industry is earning the money."[346] Tim Benton, director of research on food production and the environment at the Chatham House think tank in London, also encourages a focus on the farmers' perspective:

> The EU's reversal on agriculture-specific climate goals highlights the need for a meticulously-planned 'just transition'—a shift toward climate-friendly farming that doesn't ignore farmers' economic needs. Farmers are increasingly fed up with being seen as the whipping boy of food-systems emissions, in terms of them being told they are bad people and bad

But they say the burden should be more evenly spread."); Andreoni, *supra* note 289 ("What the farmers I have spoken to have told me is that the burden and the cost of fighting climate change should be shared more evenly.").

> managers of the land. If we are going to do transitions, then we have to bring people along with us.[347]

Another fundamental question in terms of supporting those most affected by the transition is who should bear the cost. While there is of course a role for government support—which could be achieved in part by reducing or eliminating subsidies for meat[348]—others assert that the agribusinesses that have long benefited from externalizing the costs of their environmental harms should be held accountable,[349] either by policy-driven resource shifts or, where necessary, by litigation.

Whether and how these approaches could be effectively translated to the U.S. context is an urgent question, particularly in light of the scale of the U.S. industry and its emissions. To date, U.S. climate policies have focused on voluntary and incentive-based approaches to animal agriculture.[350] In her insightful article, *Is Meat the New Tobacco?*, Professor Lingxi Chenyang posits that reducing meat demand may actually be easier in some respects than it was to reduce tobacco demand.[351] She recommends two categories of U.S. federal policy reforms as a starting point: (i) removing barriers to information about how industrial meat is produced[352] (such as by repealing ag-gag laws),[353] reforming the federal checkoff programs that collect funds from producers for generic promotion of animal products,[354] reforming federal certification programs to incorporate climate sustainability goals, and (ii) implementing place-based substitutions starting with schools and the National School Lunch Program.[355] While acknowledging that these

355 *Id.* at 10357–61.

reforms will not by themselves significantly reduce meat consumption, she presents them as "steps in the right direction" to "create a friendlier environment for more drastic regulatory measures."[356] Her approach is thus sensitive to the sequencing of interventions, and similar to the Danish effort in that respect. While the United States doubtless has further to go than even high-producing countries in Europe, starting with more modest legal reforms to help change the atmosphere could be a way in.

VII. CONCLUSION

> We cannot continue doing animal agriculture as we now practice it and is accepted. Let me change that just a bit: if we want to have a healthier population, reduce the incidence of respiratory illnesses and cancer-causing agents, and if we wish to have a healthier environment, with cleaner water, renewable resources, replenishable soil, wildlife habitat, and overall cleaner air to breathe, then we cannot continue doing animal agriculture as we now practice it and is widely accepted.
>
> ~Former U.S. Senator from Iowa Tom Harkin, remarks at *Industrial Farm Animal Production, the Environment, and Public Health* conference at Drake University (2024)[357]

Politicians and policy makers are beginning to acknowledge that the industrial animal agriculture system is not sustainable on its current trajectory.[358] Having surveyed this developing policy landscape, one is left with the impression that progress is not inevitable—far from it, in light of significant political pushback—but that there is an emerging scaffold of both international signaling and national and provincial policy onto which future efforts can be built. Such efforts must be informed by prior clashes between environmental protection and livelihoods, seeking to redirect government support away from large-scale agribusiness and toward ensuring a just transition for communities.

If politicians fall short, private actors will increasingly look for other avenues, through litigation or otherwise.[359] In the first prominent move of its kind, in March 2024 the Dutch supermarket chain Jumbo stopped offering price promotions (i.e., discounts) on fresh beef, pork,

and chicken.[360] The company has also lowered prices of its own-brand meat substitutes to reach price parity, explaining these changes as part of the company's work toward "the protein transition."[361] Perhaps it is not surprising that this innovation would come in the Netherlands, amidst the striking mix of innovation and obstacles that have arisen there. Perhaps the supermarket was inspired by the municipal meat advertising bans in Dutch cities. Or perhaps, in response to the furor of the farmer protests and political turmoil, the company thought it could help support the transition using its own toolbox.

Reining in industrial animal agriculture's emissions, and remedying its many other harms, will require a multitude of actors and solutions. If we are unable to muster the political will to address the harms of animal agriculture before the changing climate further imperils our food systems, we will have missed a critical opportunity to protect our collective future.

ABSTRACT

The environmental impacts of livestock production are attracting increasing attention, especially the emission of greenhouse gases (GHGs). Currently, pork is the most widely consumed meat product in the world, and its production is expected to grow in the next few decades. This paper deals with the production of carbon dioxide (CO_2), methane (CH_4) and nitrous oxide (N_2O) by animals and by manure from pig buildings, with a focus on the influence of rearing techniques and nutrition. GHG emissions in piggeries originate from animals through CO_2 exhalation and CH_4 enteric fermentation, and from manure through the release of CO_2, CH_4 and N_2O. The level of the CO_2 exhalation (E-$CO_{2,\ pig}$) depends on the physiological stage, the body weight (BW), the production level and the feed intake of the animals concerned. Enteric CH_4 (E-$CH_{4,\ pig}$) is principally related to dietary fibre intake and the fermentative capacity of the pig's hindgut. Based on a review of the literature, the following equations are proposed in order to estimate E-$CO_{2,\ pig}$ (in kg day^{-1}) and E-$CH_{4,pig}$ (in g day^{-1}) for fattening pigs: E-$CO_{2,\ pig} = 0.136 \times BW^{0.573}$; E-$CH_{4,pig} = 0.012 \times$ dRes; with BW (in kg) and dRes for digestible residues (in g day^{-1}). Numerous pathways are responsible for GHG production in manure. In addition, the microbial, physical and chemical properties of manure interact and modulate the level of emissions. Influencing factors for removal systems for both liquid and solid fractions of manure have been investigated. A large range of parameters showing an impact on the level of GHG production from pig houses has been reported. However, few of these can be considered unquestionably as GHG mitigation techniques because some strategies have shown contradictory effects depending on the gas, the circumstances and the study. Nevertheless, frequent manure removal seems to be an efficient means to reduce concurrently CO_2-, CH_4- and N_2O-emissions from pig buildings for both slatted and bedded floor systems. Manure removal operations may be associated with specific storage conditions and efficient treatment in order to further reduce emissions. Several feeding strategies have been tested to decrease GHG emissions but they seem to be ineffective in reducing emissions both significantly and durably. In general, good management practices that enhance zootechnical performance will have beneficial consequences on GHG emission intensity. Taking into account the results described in the literature regarding CO_2-, CH_4- and N_2O-production from animals and manure in pig houses, we estimate total GHG emissions to 448.3 kg CO_2equiv. per slaughter pig produced or 4.87 kg CO_2equiv. per kg carcass. The fattening period accounts for more than 70% of total emissions, while the gestation, lactation and weaning periods each contribute to about 10% of total emissions. Emissions of CO_2, CH_4 and N_2O contribute to 81, 17 and 2% of total emissions from pig buildings, representing 3.87, 0.83 and 0.11 kg CO_2equiv. per kg carcass, respectively.

1. Introduction

Globally, livestock production accounts for 18% of anthropogenic emissions of greenhouse gases (GHGs) (Steinfeld et al., 2006). Pork is the most widely consumed meat product in the world, and pig production is the second contributor of GHG emissions from livestock sector, with about 13% of total emissions being related to livestock (Tables 1 and 2; FAO, 2011). By 2050, worldwide pork consumption is expected to increase by almost 40% (FAO, 2011). Most of that increase in consumption will occur in developing countries, owing to demographic growth, changes in food preferences and better access to food due to the intensification of livestock systems close to growing urban populations (FAO, 2011). Presently, industrial farm animal production systems account for over half of pork production, and developing countries contribute to about half of this industrial production (Steinfield et al., 2006). In the future, these shares are expected to grow dramatically. Therefore, the environmental impact of industrial pig production represents a crucial issue for consideration in ensuring sustainability in meat production. Moreover, reducing GHG emissions would mitigate the adverse effects of GHGs on global climate change (increased temperature, higher sea level, drought, soil erosion and loss of global crop productivity) (IPCC, 2007).

Within this context, this paper aims to study the factors that influence the production levels of carbon dioxide (CO_2), methane (CH_4) and nitrous oxide (N_2O) by animals and manure at pig house level. Emissions associated with feed production, land use and land use change, energy consumption, manure spreading, transportation and food processing are not included in this discussion. Emissions associated with outside manure storage and manure treatments are also outside the scope of this review. These issues will, nevertheless, be briefly touched upon due to the link with emissions released from pig buildings. Direct CO_2 emissions from animals and from manure are usually excluded from GHG assessment because it is assumed that they are compensated by CO_2 consumption through the photosynthesis of plants used as feed. Consequently, CO_2 production by animals and by manure is rarely addressed in the literature. However, these CO_2 emissions at house level are not negligible and may differ from one rearing system to another (Philippe et al., 2007a,b). Moreover, since the synthesis pathways of carbon compounds are interlinked, it seems relevant to consider CO_2 and CH_4 emissions comprehensively. Indeed, a significant reduction in one gas could be compensated by an increase in another. Thus, the choice has been made to include CO_2 emissions in this paper in order to avoid any errors of judgement in assessing the environmental effect of a particular type of GHG mitigation technique.

The paper is organized as follows. Firstly, it describes the processes that are responsible for the production of CO_2, CH_4 and N_2O by animals and by manure at pig house level. Secondly, emission factors reported in the literature are reviewed according to the physiological stages of pig development, and an overall emission factor is proposed for the complete pig production process. Finally, the effects of pig rearing conditions (including dietary factors) on emissions are studied and some mitigation techniques are described.

2. Sources of emissions

2.1. Carbon dioxide

The emissions of CO_2 from pig houses come from two sources: exhalation by pigs and release from manure.

2.1.1. Exhalation by pigs

CO_2 production during respiration is related to the respiratory quotient, defined as the ratio between the volume of CO_2 production and the volume of oxygen consumption. In practice,

Table 1
Projected human population (in billion people) and global meat consumption (in million tons) from 2010 to 2050.

Species	Greenhouse gas emissions (million tons CO_2equiv. $year^{-1}$)			
	CO_2 emissions	CH_4 emissions	N_2O emissions	Total emissions
Cattle	1166.2 (61%)	2072.8 (81%)	661.6 (60%)	3900.6 (70%)
Small ruminants	69.9 (4%)	244.5 (10%)	202.6 (18%)	517.0 (9%)
Pigs	338.9 (18%)	237.3 (9%)	131.1 (12%)	707.3 (13%)
Poultry	332.2 (17%)	–	107.3 (10%)	439.5 (8%)
Total	1907.2 (100%)	2554.5 (100%)	1102.6 (100%)	5564.3 (100%)

CO_2equiv.: emissions of CO_2-equivalents, including CO_2, CH_4 and N_2O, taking into account the global warming potential of 25 and 298 for CH_4 and N_2O, respectively.

the respiratory quotients reported in the literature are around 1.10 for growing pigs, around 1.00 for piglets and around 0.90 for reproductive sows (Moehn et al., 2004; Pedersen et al., 2008; Atakora et al., 2011b). CO_2 exhalation can also be derived from animal heat production (HP), which corresponds to the energy used for maintenance, production (growth or milk production) and thermoregulation (Noblet et al., 1989). The International Commission of Agricultural Engineering (CIGR, 2002) stated that HP should be estimated by taking into account the pig's body weight (BW), the production level and the feed energy intake. The production of respiratory CO_2- can be derived from these models, and corresponds to 2.23, 3.68, 0.88 and 1.70 kg CO_2 $head^{-1}$ day^{-1} for gestating sows, lactating sows, weaned piglets and fattening pigs, respectively (CIGR, 2002). Other experiments have been carried out to measure or estimate CO_2 exhalation from practical parameters. Models developed for fattening pigs are presented in Table 3 and illustrated in Fig. 1. In cases of a lack of data, models were simplified to express the CO_2 exhalation function of BW, according to data obtained by Aubry et al. (2004). An aggregation of the models reported in Table 3 gives the following equation proposed to predict CO_2 exhalation (E-$CO_{2,\,pig}$, in kg CO_2 day^{-1}) for pigs of 20–120 kg BW (Fig. 1; $R^2 = 0.91$):

$$E - CO_{2,\,pig} = 0.136\,BW^{0.573} \quad (1)$$

Thus, respiratory CO_2 production can be estimated to about 1.55 kg day^{-1} for a pig of 70 kg BW.

2.1.2. Release from manure

For many years, levels of CO_2 emissions from manure were believed to be negligible (Anderson et al., 1987; van 't Klooster and Heitlager, 1994). According to some recent research, the levels of CO_2 released from manure have been estimated to be 4–5% of the CO_2 exhaled by animals (CIGR, 2002; de Sousa and Pedersen, 2004; Dong et al., 2007). However, some authors have reported CO_2 release accounting for 10–30% of respiratory production (Jeppsson, 2000, 2002; Philippe et al., 2007a,b; Pedersen et al., 2008; Philippe et al., 2012a). During an experiment carried out in a commercial fattening unit, emissions from manure were evaluated to be at around 40% of the tranquil CO_2 exhalation rate (Ni et al., 1999b). The production of CO_2 from manure certainly needs to be taken into account, even though it is not the main source of CO_2 in pig houses.

In manure, CO_2 originates from three sources: (1) the rapid hydrolysis of urea into NH_3 and CO_2 catalysed by the enzyme urease; (2) the anaerobic fermentation of organic matter into intermediate volatile fatty acids (VFAs), CH_4 and CO_2; (3) the aerobic degradation of organic matter (Jeppsson, 2000; Moller et al., 2004; Wolter et al., 2004). For liquid manure, anaerobic processes have been frequently considered as the main source of CO_2 (Ni et al., 1999b). However, this conclusion is contradictory to the results of Moller et al. (2004), who observed under laboratory conditions that aerobic and anaerobic processes are of almost equal importance at a temperature of 20 °C, while a lower temperature (15 °C) favoured the aerobic processes. Moreover, crust formation at the surface of the slurry can also lead to CH_4 oxidation into CO_2 during the passage through the porous areas of the crust.

For solid manure, the principal origin of CO_2 is aerobic production, the so-called composting process, performed by a mesophilic/thermophilic microbial community that converts degradable organic matter (Hellmann et al., 1997; Wolter et al., 2004). The composting process is influenced by several factors, such as temperature, moisture content, carbon/nitrogen ratio, degradability of carbon compounds, pH level and the physical structure of the organic material (Andersson, 1996; Jeppsson, 2000; Paillat et al., 2005).

2.2. Methane

Methane originates from the anaerobic degradation of organic matter performed by bacteria in the digestive tract of the pigs and in the manure.

2.2.1. Enteric fermentation

The level of enteric CH_4 production is mainly determined by the fibre content of the diet and the fermentative capacity of the pig's hindgut. Thus, increased levels of dietary fibre are associated with increased CH_4 production, while fermentative capacity depends on the physiological stage of the pigs, with typically higher CH_4 production for adult pigs (Le Goff et al., 2002a).

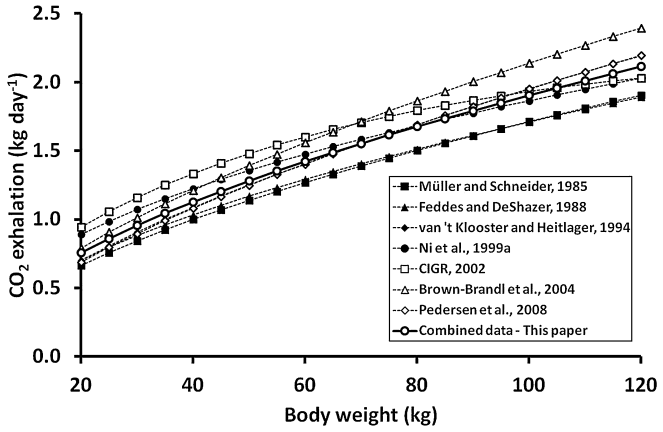

Fig. 1. Carbon dioxide (CO_2) exhalation by pigs estimated according to body weight.

Greater enteric production by sows can be explained by several factors, including increased feeding capacity, better intrinsic ability of bacterial flora to digest fibre, a greater number of bacteria, a reduction in the relative feeding level, and increased transit time (Le Goff et al., 2002a). Fig. 2 illustrates the production of enteric CH_4 for fattening pigs and adult sows reported in the literature according to the level of fibre intake, the so-called digestible residues (dRes), as proposed in INRA-AFZ (2004) and defined as the difference between digested organic matter and digested protein, fat, starch and sugar. By compiling these data, the following equations have been developed to predict the CH_4 enteric production (E-$CH_{4,pig/sow}$, in g CH_4 day^{-1}) from dRes intakes (g day^{-1}) for fattening pigs (Eq. (2)) and for adult sows (Eq. (3)):

$$E - CH_{4,pig} = 0.012 \times dRes (R^2 = 0.77) \quad (2)$$

$$E - CH_{4,sow} = 0.021 \times dRes (R^2 = 0.90) \quad (3)$$

For example, the ingestion of 300 g of dRes is associated with the enteric production of 3.6 g CH_4 by fattening pigs and 6.3 g CH_4 by adult sows. Enteric emissions represent energy losses of 56.65 kJ per g of CH_4 produced, which represents about 0.4–0.5% of digestible energy (DE) for fattening pigs and 1.0–1.5% DE for adult sows. According to the tier 1 methodology from the IPCC guidelines for national inventories (IPCC, 2006), enteric CH_4 is estimated at 1.5 kg per head per year, corresponding to 4.1 g CH_4 day^{-1}, whatever the diet composition and physiological stage. Taking into account conventional diet composition, level of ingestion and/or growth performance Vermorel et al. (2008) estimated for French production daily enteric CH_4 emissions to 0.8, 2.4 and 8.2 g CH_4 $head^{-1}$ for weaned piglets (up to 20 kg), fattening pigs (from 20 kg) and reproductive sows, respectively. Corresponding values for German production were proposed by Dämmgen et al. (2012a) at 0.9, 2.5 and 6.1 g CH_4, respectively.

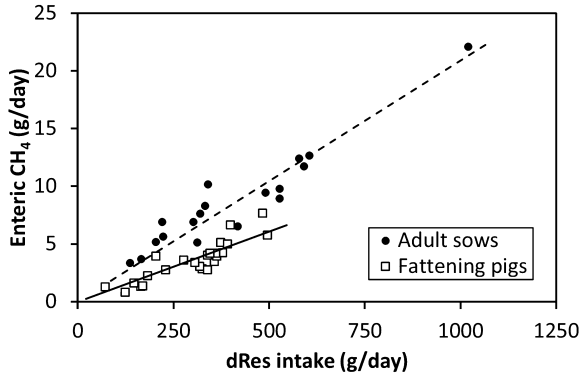

Fig. 2. Estimations of enteric methane (CH_4) production by adult sows and fattening pigs according to the intake of digestive residues (dRes defined as the difference between digested organic matter and digested protein, fat, starch and sugar).Source: adapted from Noblet et al., 1994; Jorgensen et al., 1996; Olesen and Jorgensen, 2001; Le Goff et al., 2002a,b; Ramonet et al., 2000; Galassi et al., 2004, 2005; Jorgensen, 2007; Jorgensen et al., 2007; Serena et al., 2008.

2.2.2. Release from manure

The release of CH_4 from manure originates from the temporal succession of microbial processes (Hellmann et al., 1997; Monteny et al., 2006). Initially, unspecified bacteria convert easily degradable substrates into VFAs, CO_2 and H_2. This extensive microbial activity increases the temperature of the manure and provides suitable conditions for methanogenic bacteria to convert acetate, CO_2 and H_2 into methane under a thermophilic environment. Factors that favour CH_4 production are lack of oxygen, high temperature, a high level of degradable organic matter, high moisture content, a low redox potential, a neutral pH, and a C/N ratio of between 15 and 30 (Moller et al., 2004; Amon et al., 2006; Kebreab et al., 2006).

According to the guidelines for National Greenhouse Gas Inventories (IPCC, 2006), CH_4 emissions from manure (E-$CH_{4,manure}$, in m^3) can be estimated based on the amount of excreted volatile solid (VS) or organic matter (OM), in kg; the ultimate CH_4 potential (B_0), in m^3 CH_4 per kg VS or OM; and the methane conversion factor (MCF), in percentage:

$$E - CH_{4,manure} = VS \times B_0 \times MCF$$

The IPCC (2006) recommends values for VS, B_0 and MCF, depending on the region of the world, the climate, the livestock categories and the type of manure. In Western Europe, the recommended value for VS is 0.30 kg pig^{-1} day^{-1} (IPCC, 2006). In the literature, B_0 values vary from 0.29 to 0.53 m^3 per kg VS or OM (Moller et al., 2004; Chae et al., 2008; Vedrenne et al., 2008; Jarret et al., 2011; Dämmgen et al., 2012b). The B_0 value proposed by the IPCC (2006) is 0.45 m^3 per kg VS. In the literature, extreme MCF values range from 2% to 80% according to manure type, manure management, storage duration, diet composition and temperature (Moller et al., 2004; Jarret et al., 2011; Dämmgen et al., 2012b; Rodhe et al., 2012). In their study, Moller et al. (2004) showed that during long-term storage (90 days), the slurry MCF value increased from 5.3 to 31.3% at temperatures ranging from 15 to 20 °C, respectively. On the other hand, at high temperatures, reducing the storage duration from 90 to 30 days decreased the MCF to 10.9%. Taking into account the proportion of manure management system usage, the emission factor for gas releases from swine manure in temperate Western Europe is estimated to 12 kg CH_4 $head^{-1}$ $year^{-1}$, or 32.9 g CH_4 day^{-1}, including inside and outside storage (IPCC, 2006).

2.3. Nitrous oxide

In pig houses, N_2O originates only from manure. Its formation mainly occurs during incomplete nitrification/denitrification processes performed by micro-organisms that normally convert NH_3 into non-polluting molecular nitrogen (N_2). The main microbial pathways involved in N_2O synthesis are presented in Fig. 3. An abiotic conversion of ammonium under acidic conditions, so-called chemo-denitrification, can also be at the origin of N_2O (Oenema et al., 2005; Petersen and Miller, 2006).

Nitrification, the process that converts ammonia into nitrate (NO_3^-), is usually carried out by autotrophic bacteria that require aerobic conditions with a pH value of above 5 (Kebreab et al., 2006). During nitrification, N_2O is synthesized as a by-product when there is a lack of oxygen and/or a nitrite accumulation. Denitrification is the reduction of NO_3^- into N_2, with many

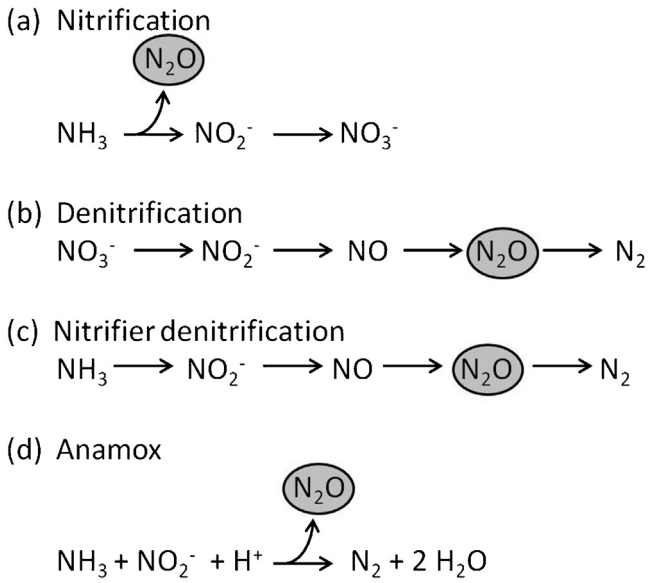

Fig. 3. Microbial pathways involved in N_2O synthesis in manure.

intermediate compounds being produced during the process (NO_2^-, nitric oxide (NO), and N_2O). In manure, denitrification is principally performed by heterotrophic facultative aerobic bacteria. The accumulation of N_2O in manure is favoured in the presence of oxygen and/or low availability of degradable carbohydrates (Poth and Focht, 1985; Driemer and Van den Weghe, 1997). The production of N_2O can also occur during other microbial pathways: the oxidation of ammonium under aerobic or anaerobic conditions, the so-called nitrifier denitrification and anamox processes, respectively. Most nitrifying and denitrifying microorganisms are mesophilic, and thus, the formation of N_2O is generally inhibited by temperatures above 40–50 °C (Hellmann et al., 1997; Kebreab et al., 2006). However, some authors have detected N_2O synthesis under thermophilic conditions (Wolter et al., 2004; Szanto et al., 2007). The relative contribution of these numerous pathways has still to be determined. Nevertheless, N_2O synthesis is known to require a close combination of aerobic and anaerobic areas. These heterogeneous conditions are largely encountered within litter but are rarer in slurry. However, N_2O emissions can occur from slurry when a dry crust is formed on the surface containing a combination of anaerobic and aerobic micro-sites. In any case, N_2O production from manure has a highly stochastic nature, especially due to its numerous sources of emission and environmental controls.

The guidelines for National Greenhouse Gas Inventories (IPCC, 2006) recommend estimating direct N_2O emissions by multiplying N excreted by animals (N_{ex}) by a specific conversion factor for each type of manure management system. For example, this conversion factor is 0.2% N_{ex} for pit storage under animals and 1% N_{ex} for deep bedding. Assuming 40 g N_{ex} pig^{-1} day^{-1}, this represents 0.13 and 0.63 g N_2O pig^{-1} day^{-1}, respectively.

3. Contribution by physiological stage

Several authors have measured GHG emissions from pig houses under practical conditions. Table 4 summarizes results from

Table 4
Emission factors at house level for carbon dioxide (CO_2), methane (CH_4) and nitrous oxide (N_2O) related to the physiological stage of the pigs (kept on a slatted floor).

CO_2equiv.: emissions of CO_2-equivalents, including CO_2, CH_4 and N_2O, taking into account the global warming potential of 25 and 298 for CH_4 and N_2O, respectively.
LU: livestock unit, equal to 500 kg BW. In cases of a lack of data, default values for body weight (BW) were estimated to 200, 220, 18 and 70 kg for gestating sows, farrowing sows (including piglets), weaned piglets and fattening pigs, respectively.

research involving the study of CO_2, CH_4 and N_2O together for pigs kept on slatted floors at their different physiological stages. In order to facilitate a comparison between physiological stages and between gases, emissions are expressed in the table as CO_2-equivalents per livestock unit. The CO_2-equivalents (CO_2equiv.) take into account the global warming potential of each gas, which is evaluated to 25 and 298 times that of CO_2 over a 100-year period for CH_4 and N_2O, respectively (IPCC, 2007). The livestock unit (LU) is equal to 500 kg body weight.

The CO_2 emissions related to fattening pigs are quite similar between the studies, while the corresponding values for the other physiological stages shows greater variation, especially for weaned piglets. Similar findings have also been observed by Philippe et al. (2011b) regarding NH_3 emissions. The discrepancy between the results of the studies, as shown in Table 4, may be attributed to differences in housing conditions, ventilation systems, management practices, diet formulation and gas measurement method. Nevertheless, the average emission factors proposed by physiological stage seem consistent between the studies. Indeed, gestating sows present the lowest value (8.26 kg CO_2 LU^{-1} day^{-1}, or 3.3 kg CO_2 sow^{-1} day^{-1}), as influenced by their low feed intake (restricted feeding, low energy density of the diet) and metabolism. Farrowing sows (including piglets) and weaned piglets are associated with the highest emissions (17.73 kg CO_2 LU^{-1} day^{-1}, or 8.87 kg CO_2 sow^{-1} day^{-1}, and 19.05 kg CO_2 LU^{-1} day^{-1}, or 0.69 kg CO_2 pig^{-1} day^{-1}, respectively), as a consequence of ad libitum feeding and intensive productive status (milk production and growth). Emissions related to fattening pigs (15.3 kg CO_2 LU^{-1} day^{-1}, or 2.1 kg CO_2 pig^{-1} day^{-1}) are slightly lower than the latter.

The CH_4 emissions reported in the literature present a large range of variation within each physiological stage. In addition to the variation factors described above for CO_2, the manure removal strategy and the storage duration inside the building seem to play an important role regarding the level of emissions (see below). For the other physiological stages, higher emissions were also observed with a longer duration of indoor manure storage. Table 4 shows that, on average, the mean emission factors expressed per LU do not differ significantly between physiological stages, ranging from 2.62 kg CO_2equiv. LU^{-1} day^{-1} for gestating sows, to 4.37 kg CO_2equiv. LU^{-1} day^{-1} for weaned piglets, with intermediate values for fattening pigs (2.98 kg CO_2equiv. LU^{-1} day^{-1}) and farrowing sows (3.77 kg CO_2equiv. LU^{-1} day^{-1}). Corresponding values expressed per animal are 41.9, 6.3, 16.7 and 78.5 g CH_4 day^{-1}, respectively. The CH_4 emissions associated with gestating sows could be deemed quite low, considering the high fibre content of their diet and their large fermentative capacity. In fact, these effects are counterbalanced by the restricted feeding usually applied at this stage.

As can be seen in Table 4, the N_2O emissions measured from pig houses fitted with a slatted floor were relatively low whatever the pigs' physiological stage. In some experiments (Lägue et al., 2004; Zhang et al., 2007), the production of N_2O emissions was even lower than the detection limit of the measurement equipment, giving small mean values as a result. In this context, important relative differences between studies or physiological stages do not have significant meaning. Thus, it seems more appropriate to consider a generic emission factor for all the stages. Based on the values reported in Table 4, an average emission of 0.40 kg CO_2equiv. LU^{-1} day^{-1} could be proposed.

Also based on these values, total GHG emissions from pig buildings are estimated to 11.11 kg CO_2equiv. $LU^{-1}day^{-1}$ for gestating sows and around 20 kg CO_2equiv. $LU^{-1}day^{-1}$ for lactating sows, weaned piglets and fattening pigs, reflecting the relative metabolism rate of each physiological stage.

The contribution of each physiological stage to GHG emission intensity expressed per unit of product is estimated using the data from Table 4 and is presented in Table 5. Overall, GHG emissions from pig houses are estimated to 448.4 kg CO_2equiv. per slaughter pig produced or 4.87 kg CO_2equiv. per kg carcass. The fattening period accounts for more than 70% of total emissions, while the gestation, lactation and weaning periods each contribute to about 10% of total emissions. Thus, it can be concluded that efforts to reduce emissions should primarily target fattening pigs. Emissions of CO_2, CH_4 and N_2O contribute to 81, 17 and 2% of total emissions from buildings, representing 3.87, 0.83 and 0.17 kg CO_2equiv. per kg carcass, respectively. These figures show the important share of CO_2 in global emissions contributed by pigs and their manure. However, these sources of emission are usually neglected in GHG evaluation. Indeed, several authors have developed life cycle assessment (LCA) studies to estimate the intensity of emissions given off in pig production. These models exclude CO_2 emissions from respiration and manure but include GHG emissions for feed production, manure storage and spreading, and energy consumption. Reported values range from 3.07 to 5.79 kg CO_2equiv. per kg carcass (Vergé et al., 2009; Pelletier et al., 2010; Lesschen et al., 2011; Weiss and Leip, 2012). The discrepancy between these studies comes from the differences in methodology, type of pig production, boundaries of the system, emission categories and allocation.

4. Influencing factors

The GHG emissions from pig houses are principally influenced by floor type, manure management and nutrition of the pigs. The climatic conditions inside the building also impact emission levels.

Table 5
Contribution of the physiological stage of pigs on greenhouse gas emissions per unit of product (assuming no allocation to slaughter by-products).

Physiological stage	Days	Greenhouse gas emissions (kg CO_2equiv.[a])		
		Day^{-1} $animal^{-1}$[b]	Slaughter pig^{-1}[c]	kg $carcass^{-1}$[d]
Dry and gestating sows	125	4.44	55.6	0.60 (12%)
Lactating sows[e]	28	10.78	30.2	0.33 (7%)
Weaned piglets[f]	50	0.86	42.8	0.47 (10%)
Fattening pigs[g]	120	2.67	319.9	3.48 (71%)
Total	323	–	448.4	4.87 (100%)

4.1. Climatic conditions

Gaseous emissions are positively related to temperature and ventilation rate. An experiment carried out in a commercial pig house emptied of pigs showed that CO_2 emissions from slurry doubled when the manure temperature increased from 15 to 20 °C, and increased from 0.8 to 25.8 g CO_2 h^{-1} per m^2 of slurry when the ventilation rate ranged from 160 to 3350 m^3 h^{-1} (Ni et al., 1999b). Ngwabie et al. (2011) reported that CH_4 emissions doubled when the indoor temperature in a fattening pig unit increased from 16.8 to 22.8 °C. Blanes-Vidal et al. (2008) estimated the correlation between averaged ventilation flow and CH_4 emission to be 0.79 on an hourly basis.

Typically, gaseous emissions from pig houses present a diurnal pattern as a consequence of the comprehensive effects of temperature, ventilation rate and animal activity. The highest emission rates are usually observed during feeding time (Van Milgen et al., 1997; Moehn et al., 2004). For fattening pigs fed ad libitum, a first peak of emission occurs in the morning and a second peak in the afternoon, as illustrated for CO_2 emissions in Fig. 4 (adapted from Philippe et al., 2013). Modification of the feeding schedule can have an impact on the level of daily emissions, as demonstrated by Groenestein et al. (2003) with gestating sows.

The location of the fans in the building also contributes to a modulation of the emission levels. Air inlets or outlets located near the manure surface increase the level of emissions due to greater air flow at the interface (Hayes et al., 2006). In any case, using climate conditions to modulate the release of GHGs seems rather impractical since the ambient parameters must primarily respect the physiological needs of the animals. Nevertheless, optimization of the heating and ventilation in the housing system can have a beneficial effect on emission levels. Good practice includes insulation of the building, adaptation to internal (e.g. density of the pigs and their physiological stage) and external factors (e.g. season and weather), management of air circulation and regular monitoring of the ventilation devices. Regulation of climatic parameters also has an influence on the health, performance, welfare and behaviour of the pigs, thereby causing indirect effects on the level of emissions. In addition, energy saving related to optimal management of climatic factors can be considered environmentally and economically beneficial.

4.2. Floor type and manure management

In pig production, the most frequent housing conditions are based on a slatted floor with a deep pit underneath for the storage of slurry. Alongside this traditional system, bedded systems have met with renewed interest during recent decades, as these systems are related to improved welfare, reduced odour nuisance and a better brand image for livestock production. For both housing systems, a large range of parameters may influence the levels of GHG emissions.

4.2.1. Slatted floor systems

4.2.1.1. Proportion of the slatted area. It is usually assumed that the emission of pollutant gases can be reduced by lowering the slurry emitting surface. With the implementation of a partly slatted floor, some authors have observed a reduction in CO_2 production by 7–13% compared with a fully slatted floor, confirming that slurry is not the main source of emission (Table 6; Sun et al., 2008; Guingand et al., 2010). For CH_4 production, contradictory results have been reported in the literature, with decreased emissions (Lägue et al., 2004; Philippe et al., 2014a) or increased emissions being associated with partly slatted floors (Guingand et al., 2010). The effect of a slatted floor area on N_2O emissions has also shown conflicting results (Fitamant et al., 1999; Lägue et al., 2004; Guingand et al., 2010; Philippe et al., 2014a). In any case, absolute N_2O emissions from slurry have been shown to remain quite low, whatever the type of slatted floor. Cumulative emissions of GHGs (expressed in CO_2-equiv.) have been shown to be reduced by 4–13% by the application of a partly slatted floor compared with a fully slatted floor (Table 6).

Costs associated with partly slatted floors are quite similar to those of fully slatted floors despite a slightly higher labour cost due to pen fouling and the need for additional cleaning (Krieter, 2002). Application of partly slatted floors in existing fully slatted buildings is rather limited. Solid plates can be easily placed on the floor to create a partly slatted floor, but the total surface of the pit will remain unchanged, with no potential effects on emissions.

4.2.1.2. Slurry removal strategy. The increase in the slurry level could favour emissions, since it has been suggested that a smaller space between the slats and the surface of manure increases air turbulence and the release of gases (Ye et al., 2009). However, several authors have reported that a higher slurry depth does not

Table 6
Effect of the proportion of slatted floor (fully or partly slatted floor) on emissions (pig^{-1} day^{-1}) of carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O) and CO_2-equivalent (CO_2equiv., including CO_2, CH_4 and N_2O and taking into account the global warming potential of 25 and 298 for CH_4 and N_2O, respectively) associated with fattening pigs.

promote the release of gases (Lägue et al., 2004; Haeussermann et al., 2006).

Nevertheless, frequent removal of manure has been proposed as a means to diminish the release of emissions from pig buildings. Total emissions within outside storage will also be reduced provided the temperature is lower outside than inside or where specific manure treatments are applied. In their study of CH_4 and N_2O emissions from pig units, Osada et al. (1998) showed that weekly removal of manure reduced the level of these emissions by about 10% compared with the traditional deep-pit system. With the same removal strategy, Guarino et al. (2003) observed a reduction of 19% in CH_4 emissions, but a doubling of N_2O emissions. Yet cumulative emissions (expressed in CO_2-equiv.) were shown to be lowered by 16%. Lavoie et al. (2006) found that when manure was removed three times a week instead of only once, CH_4 emissions were reduced by 16% and N_2O emissions remained insignificant. Results from these three studies regarding CO_2 emissions would suggest that the level of these emissions is not impacted by the removal frequency of manure (Osada et al., 1998; Guarino et al., 2003; Lavoie et al., 2006).

Pit flushing is also an efficient means to mitigate emissions. Sommer et al. (2004) estimated to 35% the reduction potential of cumulative GHGs (CH_4 and N_2O) with daily flushing compared with having a static pit. By combining frequent flushing (six times a day) with a reduced slurry surface, Lagadec et al. (2012) measured a 35% reduction in cumulative emissions (CH_4 and N_2O) with the use of manure gutters and by 55% with the use of a flushing tube, compared with having a static pit. Kroodsma et al. (1993) showed that the frequency, duration and pressure of the flushing water also impacted the efficiency of mitigation. Their results demonstrated that frequent flushing (every 1–2 h) for short periods (2 s) was more effective than prolonged (3–6 s) but less frequent flushing (every 3.5 h). The use of fresh water, as opposed to recycled water, has also been found to further reduce emissions (Kroodsma et al., 1993). This is especially the case for CH_4 because methanogenesis is rapidly initiated in the channel if a small proportion of the slurry remains in the pit after emptying. Without inoculums in the pit, CH_4 formation is low and is initiated after a few days (Sommer et al., 2007).

Accumulated manure can also be removed by scraping. The standard flat scraper system consists of a shallow slurry pit with a horizontal steel scraper under the slatted floor, allowing the manure to be removed from the building every day or several times a week (Groenestein, 1994). With this system, reductions of 15% for CO_2 emissions and of around 50% for CH_4 and N_2O emissions have been obtained under experimental conditions (Godbout et al., 2006; Lagadec et al., 2012). However under practical conditions, this technique has failed to significantly reduce CH_4 emissions (Lagadec et al., 2012).

Other systems have been developed to associate manure removal with under-slat separation of liquid/solid fractions. The V-shaped scraper system involves a channel with two inclined surfaces on each side of a central gutter. The liquid fraction runs off continuously under the force of gravity towards the gutter, and the solid fraction remaining on the inclined surfaces is frequently scraped (Godbout et al., 2006). These authors observed that, when manure was scraped every 2–3 days, although CO_2 emissions remained unchanged, CH_4 emissions reduced by 20%, in comparison with a deep-pit emptied once a week. Furthermore, Lagadec et al. (2012) demonstrated a 50% reduction in N_2O emissions in the case of a scraping frequency of between 3 and 12 times a day, compared with having a static pit. With the V-shaped conveyor belt system, urine constantly flows down in the middle of the belt under the force of gravity, and faeces are removed by the rotation of the belt (de Vries et al., 2013). Results obtained by de Vries et al. (2013) showed that this technique reduced CO_2 emissions by 47% and CH_4 emissions by 90%, but increased N_2O emissions by 250%. Overall, cumulative emissions (CO_2, CH_4 and N_2O) were lowered by 80% (de Vries et al., 2013).

Implementation of elementary frequent manure removal techniques does not seem to be associated with extra cost and could be easily applied in existing buildings. By contrast, flushing strategies (using manure gutters or flushing tubes) require major modifications to be made to existing houses. For new buildings, these systems are economically advantageous due to the reduced requirement to dig a shallow pit and the low operational costs (Guarino et al., 2003). For scraping systems, buildings costs are estimated to be higher than for traditional deep pit systems, i.e. +25 to +35% per animal place (Hamel et al., 2004; Lagadec et al., 2012). Aarnink et al. (2007) estimate the cost for new buildings to be fitted with V-shaped conveyor belts to be 10–15% lower than for traditional systems. However, applicability of these latest techniques in existing houses would appear difficult owing to the required modification of the existing manure outlets.

4.2.1.3. Other techniques. Some other original techniques have been developed to reduce GHG emissions from pig houses. Incorporation of humic acids into slurry has been shown to reduce CH_4 emissions by 34% by improving methanotrophic bacteria, but not to modify CO_2 or N_2O emissions (Shah and Kolar, 2012). The addition of quebracho tannins into slurry has also been shown to reduce CH_4 emissions by up to 95% due to the noxious effects of these compounds on methanogens. Soybean oil sprinkling and misting with essential oils have been shown to decrease CO_2 and CH_4 emissions by about 20% (Ni et al., 2008). By contrast, the addition of clay or zeolite to slurry has been shown to result in increased CH_4 emissions, as a consequence of the neutralization of the toxic effect of ammonia on methanogenic bacteria (Hansen et al., 1999; Kotsopoulos et al., 2008). The use of TiO_2-based paints and coatings has been shown to reduce CH_4 emissions by up to 27% due to the oxidative photocatalytic properties of the chemical (Costa et al., 2012). These findings would need to be confirmed in further studies and, in some cases, the underlying mechanisms require clarification.

4.2.1.4. Outside storage and slurry treatment. The release of gases during the outside storage of slurries is influenced by numerous factors. Seasonal and weather conditions, such as air temperature, relative humidity, wind speed and rainfall, modulate the production of GHGs from slurry (Lägue et al., 2004). Natural or synthetic coverings have been proposed as a means of mitigating emissions by reducing the emitting area, heating and turbulence at the slurry surface. However, some authors have reported increased emissions despite slurry cover (Loyon et al., 2006; Guarino et al., 2006; Van der Zaag et al., 2008). Several slurry treatments have been developed to facilitate the management of emissions and to mitigate their environmental impact. These slurry treatments include, among others, solid–liquid separation, biofiltration, vermifiltration and aerobic or anaerobic treatments (Godbout et al., 2003; Lägue et al., 2004; Loyon et al., 2007; Dinuccio et al., 2008; Lessard et al., 2009; Luth et al., 2011). Generally, strategies that reduce GHG emissions from slurry, preserve its energetic and agronomic values, and favour nutrient uptake for next steps are environmentally efficient. Among the numerous techniques available, anaerobic digestion of slurry with the production of a biogas rich in CO_2 and CH_4 offers an interesting opportunity to significantly reduce GHG emissions due to a lowered release of gases from manure, the production of renewable energy (electricity and heat) and the replacement of fossil fuel consumption. Adoption of an anaerobic digester in a pig farm for 100 fattening places has been estimated to offset a total of 125 t CO_2equiv. per year (Kaparaju and Rintala, 2011). The different

techniques used to treat manure can be combined, and numerous modifications/adaptations have been developed. The level of GHG emissions related to these techniques depends on various parameters such as the type and the duration of treatment, the stage of the process, and the volume and the composition of the manure fraction. Thus, knowledge of the specific conditions for the treatment is essential for precise environmental assessment.

4.2.2. Bedded floor systems

Compared with slatted floor systems, bedded floor systems are usually associated with reduced CH_4 emissions, increased CO_2 emissions, hugely elevated N_2O emissions, and an overall increase in CO_2equiv. emissions (Table 7). The specific environment encountered within the litter, especially the combination of aerobic and anaerobic areas, as opposed to strictly anaerobic slurry, explains these emission factors. Nevertheless, bedded systems combine a wide range of rearing techniques that impact the level of emissions. Indeed, the litter may differ by the bedding material, the amount and frequency of application, the space allowance, the litter management and the removal strategy. These parameters influence the physico-chemical characteristics of the manure, such as density, humidity, temperature, pH and C/N ratio, all of which interact to modulate gas emission levels (Dewes, 1996; Groenestein and Van Faassen, 1996; Misselbrook and Powell, 2005).

Implementation of a bedded system is associated with low building costs due to reduced digging requirements. This technique may also be easily applicable in existing buildings with a concrete solid floor. However, the price of bedding material and the labour involved in litter management induce an increased cost, estimated to be between +5 and 10% compared with slatted floor systems (Krieter, 2002; Philippe et al., 2006b). The availability of substrates may constitute important opportunities or limitations of application, resulting in a different economic balance from area to area.

4.2.2.1. Type of substrate. Several bedding materials have been tested regarding their GHG emissions. The most frequent substrate used is straw, but sawdust, wood shavings or peat may also be used (Jeppsson, 1998; Robin et al., 1999; Nicks, 2004). Results of studies comparing straw litters and sawdust litters show that sawdust litters produce fewer CH_4 emissions but hugely greater N_2O emissions (Table 8). Table 8 shows that, overall, the CO_2equiv. emissions from these studies are higher with the use of sawdust; this is mainly due to the greater contribution of N_2O emissions. Interactions within the litter may explain these results. Indeed, the higher manure density observed with sawdust impairs the composting process, which normally increases the temperature of the manure and amount of air exchange through it (Jeppsson, 2000). Comparing different bedding types under barn conditions, Jeppsson (2000) found manure temperatures of 23.9 and 35.5 °C, respectively, with wood shavings and chopped straw. Lower temperatures favour the activity of nitrifying and denitrifying bacteria, with a higher level of N_2O production as a by-product (Sommer, 2001; Hansen et al., 2006). By contrast, CH_4 production is very heat-dependent, and lower temperatures will significantly diminish these emissions (Hansen et al., 2006). Husted (1994) found that emissions of CH_4 from dung heaps could be divided by a factor ranging from 2.7 to 10.3 when heap temperatures were decreased by 10 °C. Moreover, CH_4 production is also controlled by the rate of its transport throughout the manure and by oxidation (Conrad, 1989). If CH_4 production is reduced and the path of its spread is slow in the presence of oxygen, oxidation is likely to occur and consequently lower CH_4 emissions will be released (Hao and Larney, 2011). Thus, the oxidation of CH_4 into CO_2 could counterbalance the reduction in CO_2 production via the composting process.

4.2.2.2. Amount of substrate and frequency of application. Studies of the effect of the amount of substrate on GHG emissions have shown conflicting results, except for N_2O, for which reductions have been systematically observed with increased amounts of bedding material (Yamulki, 2006; Sommer and Moller, 2000; Guingand and Rugani, 2013; Philippe et al., 2014b). Indeed, Guingand and Rugani (2013) reported that N_2O emissions were lowered by 57% when straw supplies increased from 60 to 90 kg per fattening period. Higher aeration of the litter and/or increased temperatures may explain this finding. For CO_2 and CH_4 production, the underlying mechanisms seem unclear, since contradictions appear in the literature between authors (Jeppsson, 2000; Sommer and Moller, 2000; Yamulki, 2006; Rigolot et al., 2010; Guingand and Rugani, 2013; Philippe et al., 2014b). For instance, Jeppsson (2000) showed that an increase of 25% in straw supply was associated with increased (+72%) CO_2 emissions, while Philippe et al. (2014b) observed unchanged emissions with a straw rate ranging from 50 kg to 100 kg per fattening pig. In practice, interactions between the microbial pathways and the physico-chemical properties of the litter modulate the level of emissions with variable effects according to specific conditions. The main characteristics of manure involved in these processes are dry matter content, C/N ratio, availability of carbohydrates, aeration and temperature. Regarding CH_4, on the one hand, extra substrate may inhibit gas production because of greater aeration (Rigolot et al., 2010; Yamulki, 2006; Sommer and

Moller, 2000). On the other hand, extra substrate may promote emissions by providing degradable carbohydrates for methanogenic bacteria (Guingand and Rugani, 2013; Philippe et al., 2014b).

The effect of the frequency of straw application has been addressed by Guingand and Rugani (2013). The authors observed increased emissions of CH_4 (+40%) and N_2O (+167%) when straw was supplied every week compared with every 2 weeks, although the total amount of straw was similar for both frequencies.

4.2.2.3. Surface area of the bedded area. Some studies have examined the impact on emissions of the surface area of the bedded area. Based on experimental data, Hassouna et al. (2005) proposed two emission factors for N_2O emissions related to animal density: 4–12% N_{ex} with less than 2 m^2 fattening pig^{-1} and 2–8% N_{ex} with more than 2 m^2 fattening pig^{-1}. With gestating sows, Philippe et al. (2010) measured a reduction in CO_2-, CH_4- and N_2O-emissions by 12, 33 and 28%, respectively, when the available bedded area was increased from 2.5 to 3.0 m^2 per animal.

4.2.2.4. Litter removal strategy. As in the case of slurry systems, manure removal strategies have been proposed to reduce pollutant emissions from bedded systems.

The height of a manure pile influences the level of GHG emissions. Under laboratory conditions, Dong et al. (2011) increased manure height from 10 to 40 cm by increasing the amount of manure from 6.6 to 22.8 kg. The authors obtained a lowering of CO_2- and N_2O-emissions by 53 and 11%, respectively, but a doubling of CH_4 emissions, resulting from an increase in anaerobic conditions. With straw-based deep litters, GHG emissions increase regularly over the course of time throughout the same fattening period, principally due to the accumulation of dejection (Philippe et al., 2007a; Philippe et al., 2010; Philippe et al., 2012a). In their study, Nicks et al. (2004) found that the rearing of three successive batches of pigs on the same litter did not increase the CO_2 and N_2O emissions from one fattening period to another, but that it did significantly increase CH_4 emissions from 3.3 to 12.7 g CH_4 pig^{-1} day^{-1} between the first and the third batch. Thus, frequent manure removal has been suggested as a means to mitigate emissions, and straw flow systems have been developed in response (Bruce, 1990). In this system, straw is supplied at the top of a sloped lying area. It travels down the slope with the aid of pig motion, is mixed with dung and then goes out of the pen into a passage from which manure is regularly scraped and removed. This kind of manure management is efficient in diminishing GHG emissions, as observed by Philippe et al. (2012a), who measured a reduction by 10, 46 and 55% for CO_2-, CH_4- and N_2O-emissions, respectively, compared with deep-litter. Overall, these authors found that CO_2equiv. emissions (including CO_2, CH_4 and N_2O) were reduced by 50%.

During the outside storage of solid manure, air temperature seems not to significantly influence the level of emissions, in contrast with wind speed or rainfall episodes (Wolter et al., 2004). Manure operations such as turning, stacking or covering impact on GHG emissions, but there have been some contradictory findings between studies (Hellmann et al., 1997; Paillat et al., 2005; Szanto et al., 2007; Jiang et al., 2013). Interlinked relationships between biological, physical and chemical factors inside the manure heap may explain these discrepancies. Whatever the storage conditions and treatment of manure, it is imperative that these conserve the energetic and agronomic value of the manure.

4.3. Nutrition

The main dietary strategy proposed for the abatement of pollutant gas emissions is the manipulation of the levels of crude protein and fibre content in the diet. Some dietary additives have also been studied for their impact on GHG emissions.

Evaluation of the cost-effectiveness of dietary manipulation is made difficult principally due to the large fluctuation in raw material prices depending on market conditions. For instance, the economic impact of the level of crude protein in the diet is greatly affected by the cost of soybean meal, on the one hand, and synthetic amino acids on the other hand. For the 2004–2008 period, Pineiro et al. (2009) found that the cost difference between reduced crude protein diet supplemented with amino acids and the standard diet fluctuated from +5 to 6€ per pig produced. Feedstuffs rich in dietary fibre are quite inexpensive since they are usually by-products of the feed, food or biofuel industries (e.g.: sugar beet pulp, wheat bran and distiller's grain). However, the price of high fibre diets greatly depends on local opportunities and the availability of such ingredients. Dietary manipulations are mitigation methods that are easy for farmers to apply and that can be adapted according to the circumstances.

4.3.1. Crude protein content

Diets reduced in crude protein content (CPC) but supplemented with amino acids have been given to pigs to match the protein supply with their growth potential and so to improve the efficiency of protein utilization, with similar zootechnical performance but with resulting reduced N excretion and NH_3 production (Philippe et al., 2011b). Thus, it has been suggested that a lower CPC could also reduce N_2O emissions, since NH_3 is the precursor of the formation of N_2O (Misselbrook et al., 1998). However, experiments have failed to corroborate this hypothesis (Table 9). Indeed, laboratory-scale experiments based on slurry samples have resulted in similar levels of N_2O emissions despite CPC being reduced by 15–20% (Clark et al., 2005; Le et al., 2009; Osada et al., 2011). Under barn conditions with fattening pigs on litter, Philippe et al. (2006a) reported a doubling of N_2O emissions (1.02 vs. 0.52 g N_2O pig^{-1} day^{-1}) with CPC reduced by 18%. It has also been assumed that a lower CPC would reduce CO_2- and CH_4-emissions due to improved nutrient utilization, but contradictory findings have also been observed for these gases (Table 9). In studies

involving respiratory chambers, most results have shown a non-significant difference in CO_2-exhalation despite a CPC reduction of up to 45% (Atakora et al., 2003, 2005, 2011a,b). Quiniou et al. (1995) measured an increase of 7% in respiratory CO_2 production with fattening pigs, while Atakora et al. (2002) noted a decreased production of 5–7% with reproductive sows. Regarding CH_4 emissions, some authors have reported reductions ranging from 13% under field conditions (Philippe et al., 2006a) to 60% in respiratory chambers (Atakora et al., 2002). Reduced VFA production with a low CPC diet could explain these results, since VFAs are precursors of CH_4 (Velthof et al., 2005). However, non-significant differences or increases in CH_4 production have also been obtained by some authors in cases of reduced CPC (Atakora et al., 2005; Clark et al., 2005; Le et al., 2009; Osada et al., 2011). Philippe et al. (2006a) reported a 7% increase in cumulative GHG emissions (including CO_2, CH_4 and N_2O) with pigs on litter consuming a reduced CPC diet. This was due to a higher contribution of N_2O despite lower CH_4 emissions.

4.3.2. Dietary fibre

Several studies have dealt with the impact of dietary fibre on GHG emissions (Table 10). It has been established that diets rich in fibre increase CH_4 production from both sources – animal and manure. Linear relationships were given in Section 2.2.1 for predicting enteric CH_4 production from ingested dietary fibre. But digestive production can also be modulated by parameters such as the botanical origin, the solubility and the fermentability of the fibre (Philippe et al., 2008). An experiment on sows fed different diets with a similar dietary fibre content but different sources of fibre showed a higher CH_4 production in cases where maize bran was incorporated compared with wheat bran (7.6 vs. 5.1 g CH_4 sow^{-1} day^{-1}; Le Goff et al., 2002b). Indeed, soluble fibres, as found in maize bran, sugar beet pulp or potato pulp, have a higher digestibility and fermentability than insoluble fibres, as found in wheat bran, pea hulls or seed residues (Jorgensen et al., 2007).

Higher CH_4 releases from slurry in cases of a fibrous diet have been reported under laboratory conditions by some authors (Clark et al., 2005; Velthof et al., 2005; Jarret et al., 2012). Jarret et al. (2012) compared CH_4 production from the slurries of fattening pigs fed a conventional diet (11% NDF) or a fibrous diet with 20% dried distiller's grain with solubles (DDGS; 14% NDF) and they obtained higher emissions (+76%) with the fibrous diet. The authors explained this result in terms of the lower digestibility of high fibre diets and thus the higher quantity of excreted OM (0.32 vs. 0.19 kg pig^{-1} day^{-1}). The B_0 of excreta, on the other hand, did not differ significantly between treatments (around 0.38 m^3 per kg OM). By contrast to these results, Clark et al. (2005) did not observe a significant difference in CH_4 emissions under in vitro conditions, whatever the fibre content. At house level, CH_4 emissions have been shown to increase by 13–52% with fibrous diets as much with a slatted floor as with a bedded floor (Philippe et al., 2009, 2012a,b, 2013; Pepple et al., 2011).

Regarding CO_2 production, conflicting results have been reported depending on the study and the source of emissions (Table 10). Schrama et al. (1998) measured a 25% lowering of CO_2 exhalation as a consequence of a reduction in pig activity. At house level, Philippe et al. (2009) observed an increase of 24% in emissions with a diet based on sugar beet pulp (48% NSP) compared with a conventional diet based on cereals (26% NSP). The reduced feed efficiency observed with a fibrous diet could explain this result.

N_2O emissions from slurry-based systems are unaffected by dietary fibre content (Clark et al., 2005; Pepple et al., 2011; Philippe et al., 2012b), in contrast to bedded systems, for which emissions have been shown to reduce with a high-fibre diet (Philippe et al., 2009, 2012b). In fact, with a fibrous diet, the pig's motivation to

manipulate and to chew the straw is reduced, as a sign of greater satiety (Philippe et al., 2008). Thus, the litter is more aerated with longer wisps of straw, which limits N_2O production.

Overall, cumulative GHG emissions (combining CO_2, CH_4 and N_2O) seem to be little influenced by the presence of dietary fibre. This can be seen in reports by authors regarding emissions within a context of pigs receiving increased dietary fibre. Emission levels at house level ranged from −6 to +9% compared with emissions produced by pigs consuming a conventional diet (Philippe et al., 2009, 2012a,b). An exception to this finding can be seen in the study of Pepple et al. (2011), who observed that CO_2equiv. emissions increased by 28% where pigs received a high fibre diet. The authors explained this result in terms of the large contribution of CH_4 in their experimental conditions due to a long storage duration of slurries inside the building.

4.3.3. Feed additives

Several feed additives have been studied for their influence on environmental factors, especially on ammonia emissions, but few experiments have dealt with greenhouse gas emissions resulting from these additives.

Most studies have argued that feed supplementations that improve nutrient digestibility and growth performance in pigs potentially reduce pollutant gas emissions on an absolute scale and per product unit (Moehn et al., 2007). However, this statement has rarely been experimentally tested and validated.

Cellulases and hemicellulases have been added to animal diets in order to counterbalance the anti-nutritional effects of fermentable fibres and to improve animal performance (O'Shea et al., 2010). A further beneficial effect of these enzymes may be a reduction in CH_4 production by enteric bacteria, which are linearly related to fibre ingestion. However, Moehn et al. (2007) observed a tendency for increased CH_4 emissions despite xylanase supplementation.

Dietary inclusion of acidifying salts has also been suggested as a means to modify GHG production. Yet Aarnink et al. (2008) did not observe a significant difference in CH_4 and N_2O emissions despite the addition of 1% benzoic acid in the diet of fattening pigs. Eriksen et al. (2010) showed that a diet supplemented with 2% benzoic acid resulted in a transient reduction in CH_4-emissions from slurries stored under laboratory conditions (from day 20 to 34 of storage). The authors explained this result in terms of the inhibition of methanogenic bacteria, possibly due to a reduction in manure pH, the toxic effect of sulphides or the direct impact of benzoic acid. The temporality of the reduction could reflect the adaptation of the bacteria to slurry acidification.

Yucca extract inclusion has been proposed as a means to inhibit urease activity and to chemically convert or bind NH_3 (Duffy and Brooks, 1998), leading to an improvement in the performance and health status of pigs (Colina et al., 2001). However, Amon et al. (1995) measured an increase in CO_2 production with the dietary addition of *Yucca shidigera* extract. The effects on CH_4 and N_2O emissions of the inclusion of *Yucca* extract in the diet of pigs are still unknown.

The addition of phytase, primarily used to reduce phosphorus excretion, has been shown to increase feed efficiency and protein deposition, and this could possibly lead to a decrease in emissions (Ball and Möhn, 2003). However, to the best of our knowledge, the addition of phytase has not been studied for its effect on GHG emissions.

Probiotic agents are believed to improve the microbial environment in the gut, leading to better digestibility, performance and health status as a result (Fuller, 1989; Tsukahara et al., 2001). Under laboratory conditions, Tsukahara et al. (2001) measured emissions from the intestinal content of piglets fed a diet supplemented with a mixture of live lactic acid bacteria (*Lactobacillus acidophilus*,*Bifidobacterium bifidum* and *Enterococcus faecalis*). The authors obtained reductions of approximately 50 and 35% for CO_2- and CH_4-emissions, respectively, explained by the fact that lactic acid bacteria are stoichiometrically less favourable to gas production (Stanier et al., 1986). Barn experiments would need to be carried out to confirm these findings on a larger scale.

5. Conclusion

This review has reported and analysed the results of studies in the literature regarding GHG emissions produced by animals and manure in pig houses. Taking into account the results regarding CO_2-, CH_4- and N_2O-production, cumulative emissions of GHGs produced by pigs and manure at pig house level are estimated to approximately 4.87 kg CO_2equiv. per kg of carcass. Although CO_2 is the main contributor of these emissions (accounting for about 81%), this gas is usually not included in the calculation of overall GHG production because it is assumed that CO_2 emitted by livestock is compensated during photosynthesis by plants used as feed. In addition in the past, CO_2 emissions from manure were often erroneously considered negligible, while they can represent up to 40% of respiratory production.

The production levels of CO_2, as for CH_4 and N_2O, can be altered by several factors, such as housing conditions, manure management and diet composition. For instance, comparisons between slatted and bedded floor systems show higher CO_2equiv. emissions from bedded floor systems due to greater CO_2 emissions but mainly due to high N_2O emissions that are not counterbalanced by the eventual reduction in CH_4 emissions. While litter systems are usually associated with a better brand image and are commonly required for environmental labelling, the data reported in this review show that the environmental benefits are not always so obvious for all aspects of the production process. Moreover, GHG emissions from bedded systems greatly depend on the type, the amount and the frequency of substrate supply. These parameters may interact, with variable impacts, on emission levels. Further studies need to be carried out in order to understand more precisely the underlying phenomena and interactions that modulate GHG production from litter.

Whatever the floor type, frequent manure removal is an efficient means used to diminish GHG emissions from pig buildings on the condition that emissions from outside storage operations are prevented. This is particularly true for CH_4 production, which increases greatly over the course of time and in ambient temperatures. Frequent manure removal seems particularly advantageous since manure treatments can be associated with the removal. In this sense, separation of the solid and liquid fractions of the slurry provides interesting opportunities. Indeed, this separation reduces storage requirements and transportation costs, and offers more homogenous materials for land spreading, recycling or other specific treatments in order to enhance the agronomic, energetic and environmental profitability of the processes.

Regarding dietary strategies, inclusion of fibre impacts on GHG production by increasing CH_4 emissions from the digestive tract and from the manure. For gestating sows fed with a high fibre diet and kept on a straw based deep litter, concurrent reductions in N_2O emissions have been observed, resulting in a limited effect on CO_2equiv. emissions. A reduction in dietary CPC, which is well-known to reduce N excretion, has been shown to fail to limit the release of N_2O from manure. Other feeding strategies have also been used to investigate the assumption that improved nutrient utilization can lower GHG emissions. However, this statement has not been systematically proven in experiments, since diets supplemented with feed additives such as acidifying salts, *Yucca*

extracts or probiotics seem ineffective in significantly reducing the intensity of GHG emissions. Nevertheless, innovative nutritional options could be examined in the future, as they appear to be efficient in reducing emissions. Recycling of the co-products from the feed-, food- or biofuel-processing industry into animal feed requires further investigation, as this could provide economical and ecological advantages due to the allocation of the cost and the impacts. Overall, feeding strategies offer the advantage of being easy to implement and quick to adapt according to the availability and cost of raw materials, which fluctuate temporally.

Good management practices that respect the physiological requirements of the animals and that promote their zootechnical potential will have beneficial consequences on performance and indirectly on the intensity of GHG emissions. In light of this, factors such as the design of the building, the regulation of bioclimatic parameters, the sanitary status of the herd and genetic selection may modulate the level of GHG production.

The choice of rearing technique is also guided by other elements, such as animal welfare, the agronomical value of manure, investment and operating costs. Specific field conditions lead to decisions in favour of mitigation techniques. Options presented in this review may contribute to a reduction in the intensity of emissions generated by pig production. However, in order to be universally efficient, these strategies would need to be integrated on a larger scale taking into account supplementary emissions associated with pre-, on- and post-farm processing, such as feed production, energy consumption, manure spreading and the transportation of animal and products.

Climate Change and Livestock Production: A Literature Review

Muxi Cheng *, Bruce McCarl and Chengcheng Fei

Department of Agricultural Economics, Texas A&M University, College Station, TX 77840, USA; mccarl@tamu.edu (B.M.); chengcheng.fei@agnet.tamu.edu (C.F.)
* Correspondence: muxicheng@tamu.edu

Abstract: Globally, the climate is changing, and this has implications for livestock. Climate affects livestock growth rates, milk and egg production, reproductive performance, morbidity, and mortality, along with feed supply. Simultaneously, livestock is a climate change driver, generating 14.5% of total anthropogenic Greenhouse Gas (GHG) emissions. Herein, we review the literature addressing climate change and livestock, covering impacts, emissions, adaptation possibilities, and mitigation strategies. While the existing literature principally focuses on ruminants, we extended the scope to include non-ruminants. We found that livestock are affected by climate change and do enhance climate change through emissions but that there are adaptation and mitigation actions that can limit the effects of climate change. We also suggest some research directions and especially find the need for work in developing country settings. In the context of climate change, adaptation measures are pivotal to sustaining the growing demand for livestock products, but often their relevance depends on local conditions. Furthermore, mitigation is key to limiting the future extent of climate change and there are a number of possible strategies.

Keywords: livestock production; adaptation; mitigation

1. Introduction

Livestock products and services play an important role for humans. Globally, livestock occupy about 26% of the ice-free land with one-third of the cropland being used for feed production [1]. Livestock production generates nearly 40% of global agricultural gross domestic product (GDP). Livestock provide 33% of the global protein and 17% of the global calories consumed. Production creates substantial employment opportunities for rural households [2,3]. Additionally, livestock are a major provider of food, nutritional security, livelihood, and income in developing countries [4].

Driven by population and income growth plus urbanization, the demand for livestock products is growing rapidly. Simultaneously, livestock production is facing increasing pressure from climate change effects, such as increasing temperatures, more variable precipitation patterns, more frequent extreme events, and increasing carbon dioxide concentrations [5]. Such changes have been found to impact livestock performance across many regions and are projected to have growing impacts. Predictive models broadly indicate the impact will be negative [6]. Meanwhile, livestock are a direct source of both methane and nitrous oxide and an indirect source of those gases and carbon through land use and feed production. Globally, the livestock emissions share is an estimated 14.5% of total anthropogenic emissions [7].

The interaction between ongoing climate change and demands for increasing livestock production makes it challenging to increase production while lowering climate impacts and Greenhouse Gas (GHG) emissions. Addressing such challenges requires an understanding of climate change effects on livestock production, as well as the effect of both adaptation and mitigation actions. This paper overviews climate change impacts on livestock production, livestock emissions, and possible adaptation and mitigation actions. In constructing this

review, we relied on material from 157 references, with the papers classified as shown in Table 1.

Table 1. Counts of papers used in the review by category.

Category	Sub-Category	Number of Papers Cited
By topic	Climate change impacts and adaptation	95
	Livestock emissions and mitigation	27
	Comprehensive treatment	31
By year	Before 2000	12
	2000 to 2010	39
	2011 to 2021	102
By region	North America	42
	Europe	14
	Asia	8
	Africa and Australia	8
	Region not specified	40
	Multi-region/global	41
By livestock species	Ruminants	41
	Hogs	15
	Poultry	18
	Not livestock	32
	Multiple livestock	47

2. Impact of Climate Change on Livestock Production

The climate is changing, exhibiting higher temperatures, increasing precipitation variation, and more frequent extremes. This is driven by increasing carbon dioxide (CO_2) concentrations. Such changes have been found to alter livestock and associated feed production. We will follow Collier [8] and broadly divide the impacts into direct and indirect effects: Direct effects refer to climate and CO_2 impacts on livestock thermoregulation, metabolism, immune system function, and production. Indirect effects derive from the influence of climate on feed production, water availability, and pest/pathogen populations. A brief summary of the impacts appears in Table 2. In addition, the impacts are elaborated below.

Table 2. Climate change impacts on livestock production.

Impact Type	Observed Impacts	Major Influential Factors
Direct Impact	Reduced feed intake	Increased temperature (heat stress)
	Decline in animal milk and meat production	
	Decreased reproductive performance	
	Negatively affected immune functions	
	Increased mortality	
Indirect Impact	Changes in feedstuff crop yields	Elevated CO_2 level
	Changes in pasture composition and forage production	
	Changes in forage quality	Increased temperature and elevated CO_2 level
	Shrinking water availability and increasing water use	Increased temperature
	Larger seasonal variation in resource availability	More frequent extreme climate events
	Increased disease, pest, and parasite stress	Increased temperature and changes in the precipitation pattern

2.1. Direct Effects

The thermal environment is the major climatic factor that affects animal production. This involves a combination of air temperature, humidity, and air movement [9]. The relationship describing the best conditions of these is often referred to as the thermal comfort zone. In this zone, animals exhibit optimum performance and minimal energy expenditure [10]. When conditions rise above this zone, extra energy is required to maintain thermoregulation and production processes become less effective [11]. Animals suffer from thermal stress when the environmental temperature deviates outside the thermal comfort zone. The phenotypic response of animals to an individual source of stress can be called acclimation [12,13]. Heat stress is more problematic and has a greater effect than cold stress [14,15]. Climate change is also almost certainly increasing temperatures and, in association, increasing heat stress and lowering cold stress. Therefore, heat stress has been the dominant topic within the discussion of thermal stress.

Heat stress has been found to have negative effects on livestock. The estimated annual U.S. livestock industry loss caused by heat stress falls between $1.7 and $2.4 billion [16]. Heat stress occurs when animals are not able to dissipate sufficient heat to keep homeothermy [17]. This has been found to lead to increased respiration, pulse, and heart rate, along with increased body temperatures [18]. In turn, this can result in reduced feed intake, milk production, and reproduction efficiency, as well as changes in mortality and immune system function. Below, we discuss these impacts in more detail, with emphasis on animal performance rather than underlying biological mechanisms.

2.1.1. Feed Intake

Reduced feed intake is one response to high environmental temperatures. Ruminants experience reduced appetite, gut motility, and rumination under increased heat stress [19,20]. Lactating dairy cows exhibit a reduction in feed intake as ambient temperatures rise above 25–26 °C and show more rapid declines above 30 °C [21]. Goats are less susceptible to heat stress than other ruminants. However, their voluntary feed intake declines when the ambient temperature is more than 10 °C above their thermal comfort zone [22].

Hogs exposed to heat stress exhibit increased body temperature, and their feed intake decreases by 10.9% when temperatures increase from 20 to 35 °C [23]. Such impacts persist beyond the period when the hogs are exposed to heat stress. Hence it is suggested that feeding in early morning hours could help avoid reduced feed intake [24].

Poultry animals also exhibit reduced feed intake when exposed to high temperatures. An increase in ambient temperature from 21.1 to 32.2 °C has been found to lead to a 9.5% drop in feed intake for birds from the post-hatch period to 6 weeks of age [25]. The reduction in feed intake causes decreased feed conversion efficiency and daily weight gain [26–29].

More generally, across all the livestock types, heat-stress-related decreased feed intake leads to decreased milk, meat, and egg production, which in turn leads to further sectoral losses.

2.1.2. Animal Production: Milk and Others

Studies indicate that the dairy industry suffers greater heat-stress-related economic loss than does the other U.S. livestock sectors [16]. Under heat stress, dairy cows reduce feed dry matter intake and this explains approximately 35% of the decrease in milk production [30]. Meanwhile, as high-producing dairy cows are larger and emit more metabolic heat than lower-producing breeds, the most productive breeds exhibit more sensitivity to heat stress [3]. As a consequence, milk production declines as heat-stress-caused metabolic heat production increases [21]. In addition to milk production, hot and humid environments also affect milk composition. Ravagnolo et al. [31] and Gorniak [32] have indicated that lactating cows start to suffer from heat stress at a temperature–humidity index of 72 and above this level, milk protein and milk fat content declines as the index increases.

Similar changes in milk composition have been found for dairy goats [33] and buffaloes [34] but have only been narrowly studied.

Meat production has been found to be affected by heat stress for all major commercial livestock types [35]. Heat-stressed ruminants exhibit reduced body size, carcass weight, and fat thickness and lower meat quality [10,36,37]. Small ruminants, such as goats and sheep, have been found to be more adapted to a hot and humid environment [38]. However, feedlot cattle have been found to be more vulnerable due to their being raised with greater exposure to rough radiant surfaces and fed high-energy diets [35,39].

Similar to ruminants, hogs exhibit reduced carcass weight and meat quality when exposed to a high temperature [40]. Under high ambient temperature, they have also been found to exhibit reduced average daily gain of 9.8% when compared to thermoneutral animals [41].

Chickens exposed to heat stress increase energy expenditure to maintain thermoneutral conditions at the expense of growth [42]. Heat-stressed broilers exhibit reduced weight gain, feed conversion rates, protein concentration, and breast muscle weight [43–45]. For laying hens, egg shell strength, daily feed intake, egg mass, and egg production are more sensitive to heat stress compared to other traits [46]. In addition, significant declines in egg shell quality and egg production are observed in breeders [47]. The reduction in egg quality and production caused by heat stress can be mediated by alterations in dietary calcium [48].

2.1.3. Reproduction

Heat stress affects reproduction for both sexes. For females, heat stress reduces estrous period and fertility while increasing the incidence of anestrous and embryonic death. For males, there are declines in semen quality, testicular volume, and quantity of fertile sperm. Significant seasonal differences in reproductive performance in both sexes have been reported [49].

Although poultry reproduction is also affected by heat stress, birds may exhibit a difference in performance compared to mammals. Male broilers are reported to be more sensitive to heat-related infertility than female broilers [50]. For layers, environmental stress could delay the process of ovulation, reduce yolk quality, and affect hatchability [51].

2.1.4. Disease and Parasite Stress

Many factors, including species, breed, geographical location, disease characteristics, and animal susceptibility, contribute to the effects of climate change on livestock health [52]. In terms of animals themselves, the immune system is their major body defense that protects them from environmental stressors and other noxious insults [53]. Heat stress can negatively affect immune functions via cell-mediated and humoral immune responses [54]. As a result, periods of hot weather can cause livestock to be more vulnerable to diseases and raise the incidence of certain diseases (such as mastitis), leading to an increased potential of morbidity and death [55–57].

In addition, heat stress could affect the health condition of livestock through other functional pathways. For example, growing hogs may suffer from intestinal injuries if exposed to acute heat for several hours [28]. Broilers and laying hens are also reported to experience intestinal microbiota alterations under heat stress [58,59].

Simultaneously, increased temperature and altered precipitation may accelerate the incidence of pathogens and parasites. Although the effect of pathogens and parasites on livestock is generally regarded as an indirect effect, it is covered in this section since it is usually discussed in conjunction with animal health. This would affect the distribution and abundance of vector-borne pests and introduce new diseases [52,60]. These may increase the potential for morbidity/mortality and associated economic loss [61]. Compared to other impacts, climate change effect on livestock disease is more difficult to estimate and predict due to the nature of disease and climate-change-driven alterations to livestock. Such impact assessment is even more challenging in developing countries [52,61].

2.1.5. Mortality

Mortality is an important heat stress impact that has significant associated economic loss. Studies on dairy cows and hogs show that added heat stress increases mortality rates [62–64]. Hot and humid weather has been found to be more life threatening to cows and hogs compared to hot but dry conditions, and a temperature higher than 37.7 °C with over 50% humidity was shown to be detrimental [65].

For poultry, the body temperature of birds is usually higher and more variable than that of mammals and they are more sensitive to rising temperature. Chickens can function normally up to ambient temperature of 27 °C or a body temperature of 41 °C, but an increase of 4 °C in body temperature would be lethal to them [66].

2.2. Indirect Effects

Livestock feed is mostly composed of forages and grain/oilseed crop product. Production of those items is affected by climate, as are water supplies, both through irrigation and soil moisture. Thus climate change indirectly imposes effects, mainly through its impacts on feed supply and water. There exists a huge body of literature focusing on climate change impacts on crop production, and herein we are not trying to cover the details of this research area (for a review, see Reilly et al. [67], Shukla et al. [68], and IPCC [69]). In terms of solely livestock production, crops and forages provide feedstocks consumed by livestock. In this regard, climate change affects the supply of livestock feed but the magnitude of this impact on livestock production while commonly discussed has not been separately evaluated. We discuss the general aspects of this discussion in the remainder of this section.

First, let us introduce some terminology. The International Forage and Grazing Terminology Committee [70] defines forage as "edible parts of plants that can provide feed for grazing animals or that can be harvested for feeding." Forage plants can be roughly divided into two large groups: grasses and legumes. Besides these two groups, forage plants include others, such as woody species. As they are usually not considered as major feed for domestic animals and the impacts of climate change on woody species feed have not been well investigated, we will not cover them in this review. Two relevant studies to refer to are Papanastasis et al. [71] and Hejcman et al. [72]. Legumes can be grouped into cool season (C3) and warm season categories (C4) based on leaf anatomy [73]. Increases in atmospheric CO_2 and temperature are alter forage quantity and quality, with the magnitude dependent on the livestock system [74], location, and species. Precipitation patterns and extreme climate events are also influential, with the main impacts being production variation. Other influential factors include water supplies, which will be discussed in more detail below.

CO_2 contributes to crop growth [75]. C3 crop (soybeans, cotton, and wheat) yields increase under increased CO_2 concentrations, while yields of C4 crops (corn and sorghum) do not directly respond to the elevated CO_2 but may indirectly benefit under drought. Other climatic factors that affect livestock feed supply quantity are precipitation; temperature; and extreme events, such as drought. Increased precipitation is beneficial to corn, sorghum, rice, and soybean [76,77]. As for temperature, C4 species enjoy greater effects from temperature rise, but such effects depend on location, plant species, and production system [52,78]. Drought causes significant crop yield reductions, especially in hot regions [79,80]. A recent study in Europe found that drought stress is the main driver of losses for corn and winter wheat, especially in low-yielding years [81]. These climatic factors are often confounded, and their effects on vegetation growth are not easy to isolate. For example, higher temperatures at lower latitudes may be associated with higher water stress, while higher temperatures at higher latitudes may increase suitability for cropping and expand the length of the growing season.

Grass forage supplies are also affected by climate change. In terms of grassland and pasture, increases in average temperature bring significant changes in pasture composition, patterns, and biome distribution. Changes in precipitation patterns and more frequent droughts may lead to shorter pasture growing periods. Some research has indicated

that changes in temperature, CO_2 levels, and nitrogen deposition decrease the primary production in pasture [82], while some argue that higher temperatures favor grasses over forbs and legumes.

2.2.1. Forage Quality

Adequate nutrition is critical to weight gain, production, and reproduction, and forage is an important nutrition component for ruminants. As forage quality varies greatly within and between forage crops and nutritional needs vary among animal species, providing suitable feed to animals requires a balance. Most forage-quality studies have focused on digestibility, nutritive value, voluntary intake, and effects of anti-quality factors [83]. Forages of higher digestibility supply more energy per unit dry matter (DM) consumed. Nutritive values reported by forage analysis usually include neutral detergent fiber (NDF); acid detergent fiber (ADF); crude protein (CP); and minerals, such as calcium (Ca), phosphorus (P), magnesium (Mg), and potassium (K) [84]. Quality can be affected by climate through increased temperatures and dry conditions, which cause variations in concentrations of water-soluble carbohydrates and nitrogen [82]. Forage quality may also increase due to an increase in nonstructural carbohydrates resulting from elevated CO_2 level [85]. However, quality may also decrease since rising temperatures can increase lignin within plant tissues and therefore reduce digestibility [86]. Lee et al. [87] suggest that increasing temperature reduces forage nutritive values and correspondingly may lead to higher methane production.

2.2.2. Water

Water is scarce worldwide, and the magnitude of water scarcity depends on the supply relative to the demand. Agriculture is the single largest global water user, accounting for 69% of fresh water withdrawals [88]. As human populations, incomes, and livestock product demand increase, water scarcity will likely grow in importance as a constraint on production agriculture. The livestock sector uses water for consumption by animals, growing feed crops, and product processing [52]. It accounts for about 22% of the total evapotranspiration (ET) from global agricultural land and 41% of total consumptive water use [89].

Climate change is projected to change water availability [69,90] and water usage in animal production [3]. Rising temperatures are likely to increase per animal and per land area animal water consumption and irrigation water use [91,92]. Water salination caused by sea-level rise is another concern [93,94]. Competition for water between livestock, crops, and nonagricultural uses will increase in the coming decades, and it requires more efficient production systems to address water scarcity issue [95].

2.2.3. Seasonal Variation and Extreme Climate Events

Climate change may alter the seasonal pattern and variability of resource availability and crop yield [96,97], imposing further impacts on livestock production. As the frequency and duration of heat waves increase, animals will suffer from additional heat stress [62]. Knee et al. [98] found significant seasonal differences in cattle muscle glycogen and also that conditions with nutritious and abundant pastures coincide with better beef quality in spring and that worse pastures coincide with worse beef quality in summer. Moreover, changes in seasonal patterns of forage availability could bring additional challenges for grazing management and livestock management [99]. Increasing risk of extreme drought threatens forage quantity, and adaptation strategies are required to cope with such extreme events [100]. In addition, changes in snow melt timing alter water availability patterns during the year, which affects feed supplies [96,101].

3. Impact of Livestock Production on GHG Emissions

Livestock is a substantial contributor to global GHGs, with emissions estimated at 8.1 gigatons of CO_2-eq per annum or 14.5% of total anthropogenic emissions [7]. The three

main GHGs emitted by livestock are methane (CH_4), nitrous oxide (N_2O), and carbon dioxide (CO_2). Their relative incidence has been explored using the FAO Global Livestock Environmental Assessment Model (GLEAM) [102] and are converted to CO_2 equivalents using 100-year global warming potentials from IPCC (2014) (298 for N_2O and 34 for CH_4).

The GLEAM results indicate that emissions from livestock supply chains consist of 50% methane (CH_4), 24% nitrous oxide (N_2O), and 26% carbon dioxide (CO_2), with emissions by category shown in Figure 1. In terms of species, cattle are the major contributor, with about 62% of total livestock emissions. Other species (hogs, poultry, buffaloes, and small ruminants) each represent between 7 and 11% of the sector's emissions. Within cattle, beef and dairy animals generate similar amounts of total emissions. Figure 2 shows the global estimates of livestock emissions by species.

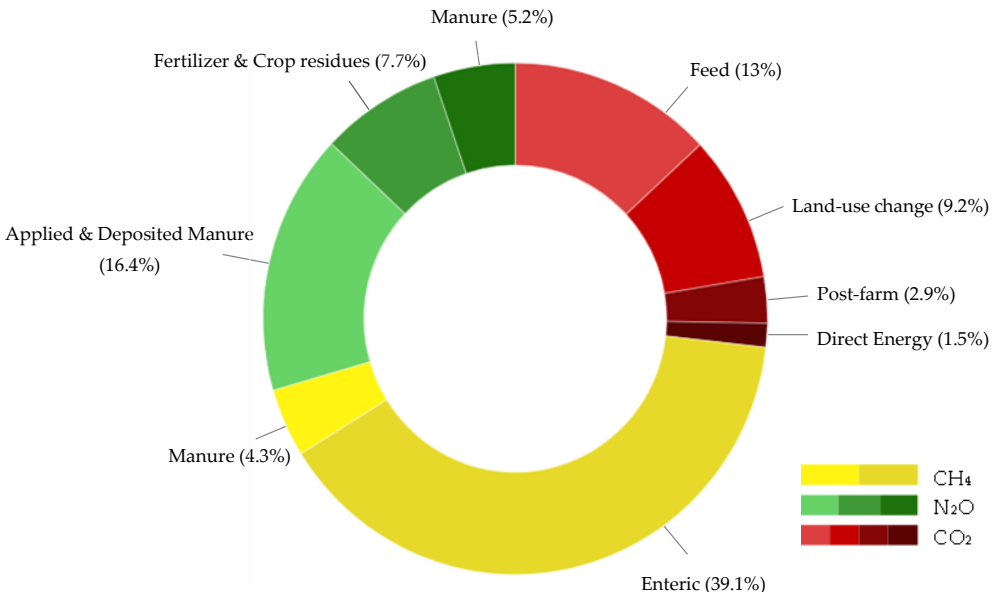

Figure 1. Emissions from livestock (by category), where methane (CH_4) emissions are portrayed in yellow, nitrous oxide (N_2O) in green, and carbon dioxide (CO_2) in red. Figure drawn by authors with data source from [7].

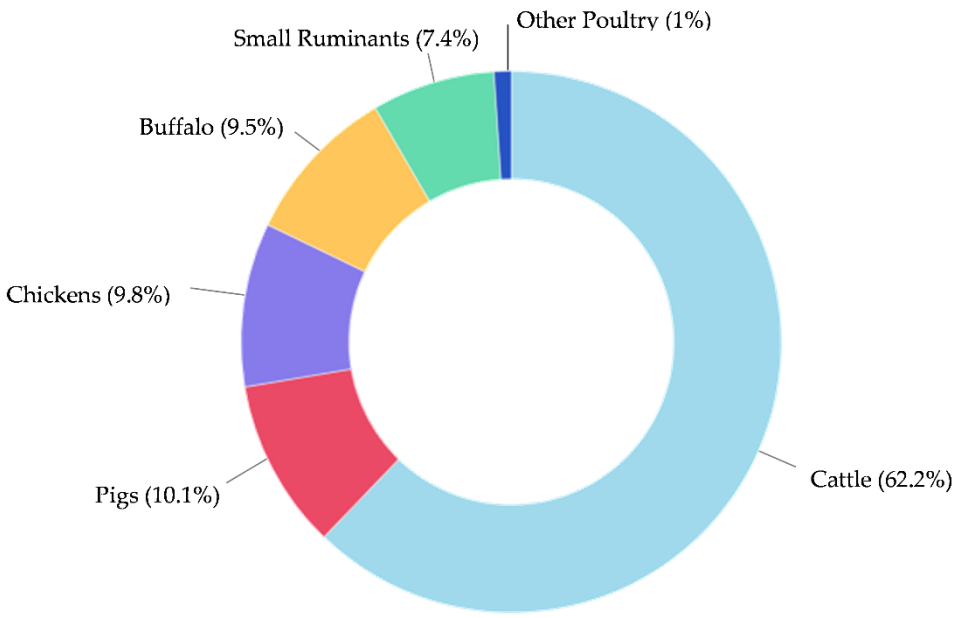

Figure 2. Emissions from livestock (by species). Figure drawn by authors with data source from [102].

Livestock GHG emissions arise directly through raising animals, including enteric fermentation, manure, and associated energy consumption. Indirect emissions mainly come from feed production and related land use change. Some studies indicate that indirect emissions exceed direct emissions, while others show the opposite [103,104].

3.1. Direct Effects: Enteric Fermentation and Manure Management

Enteric fermentation occurs mainly within ruminant animals' digestive systems, where microbes break down coarse plant materials and, in the process, produce methane, which is emitted by exhaling, belching, and other means. This is the largest ruminant emission source [105]. Non-ruminants also produce methane during digestion but in much smaller amounts. A variety of factors affect ruminant emission quantity, such as feed characteristics, use of feed additives, and animal health condition. The most influential ones are feed quality and feed intake. Higher feed digestibility leads to lower enteric methane emission and higher animal production. Increased feed intake leads to more methane being produced. The rate of conversion from feed energy intake to methane depends on species, production systems, and regional characteristics [7].

Manure also contributes to emissions in the form of methane and nitrous oxide (N_2O) emissions. The anaerobic decomposition of organic material releases methane, and nitrous oxide is released mainly from ammonia decomposition. Organic matter and nitrogen content in manure are the two chemical components that can lead to N_2O emissions during storage and processing [104]. Hogs and dairy cows are the largest source of manure-related methane emissions [106]. The largest manure-related N_2O emissions come from soil emissions associated with manure application [103]. The manure storage and handling process greatly affects resultant emissions, particularly when manure is handled in ponds or lagoons [106]. Other factors that affect manure emissions include air temperature, moisture, duration of waste management, and animal diet. If manure is handled through solid systems (e.g., deposited on pastures), N_2O emissions will be higher than methane since the generation of N_2O requires both aerobic and anaerobic conditions. Methane emissions are higher when manure is treated in liquid systems using lagoons or ponds.

3.2. Indirect Effects: Feed Production and Land Use Change

3.2.1. Feed Production

Emissions related to feed production, processing, and transport constitute about 45% of livestock-related emissions. Of all these feed-related emissions, N_2O from fertilization of feed crops and CH_4 from manure application to pasture generate about 50%, while related land use change generates about 25% [7]. Emissions from feed production consists of CO_2, N_2O, and CH_4. CO_2 emission arises from the production of fertilizers and pesticides for feed crops, feed transportation and processing, fuel used in production, and associated land use change. N_2O emissions are mainly from fertilizer use and manure application, with a small portion coming from the cultivation of leguminous feed crops (e.g., rice, soybeans, peas, alfalfa, and clover). The amount of feed-related CH_4 emissions is much smaller than that of feed-related CO_2 and N_2O emissions.

3.2.2. Land Use Change

Land use change is another indirect source of livestock-related GHG emissions. Gerber et al. [7] calculated that land use change contributes 9.2% of total livestock GHG emissions. This occurs through land use change to produce pasture (6%) and feed crops (3.2%). Agricultural land occupies 38% of the global land surface, with about two-thirds of this for livestock [107]. Driven by population growth, urbanization, and growing incomes, the demand for livestock and livestock products is expected to increase, inducing more livestock production. By 2050 compared to 2005/2007, world meat production is projected to increase by 76% and milk by 63% [108]. Associated with this, grazing intensities are projected to increase by about 70%, with feed demand almost doubled [109].

Historically, increased production of livestock and livestock feed has significantly impacted land use, which affects the natural carbon cycle [3]. Plants take CO_2 from the atmosphere and nitrogen (N) from the soil and store them in above- and below-ground biomass. Forest lands sequester more carbon in soil and vegetation than croplands and pastures, and thus when forest land is converted to cropland and pasture, much of the sequestered carbon is released into the atmosphere.

There is debate on appropriate procedures for accounting for emissions from land-use change, and there is no current shared consensus. Different scale and land-use change factors result in significantly different results. [110]. Steinfeld et al. [103] estimated that deforestation due to the expansion of pasture and feed crops is responsible for 8% of total anthropogenic CO_2 emissions. Hong et al. [111] estimated that land-use emissions accounted for 27% of global total anthropogenic GHG emissions during the 1970—2017 period.

3.2.3. Energy Consumption

Energy consumption is another source of CO_2 emissions, mainly related to fossil fuel use. For livestock, energy-related emissions occur across the supply chain spanning from production of fertilizers, use of machinery, and transport of feed and livestock. On-the farm animal-related energy includes that used for heating/cooling, ventilation, illumination, and milking. Upstream feed production uses energy in production, drying, and commodity transport. Downstream energy is used in processing livestock commodities and packing and transporting final products to retailers. The total energy consumption along the livestock supply chain contributes about 25% of total emissions in the livestock sector [7].

4. Adaptation

Climate change adaptation refers to adjustment in ecological, social, or economic systems to reduce the negative or enhance the positive impacts of climate change. In an agricultural setting, adaptation can occur through ecological change or human action. For livestock, natural adaptation results from different mechanisms through which animals adapt to climatic conditions. Human adaptation involves actions and practices that could help animals adapt to climate change and enhance the livestock performance. In a livestock context, adaptation actions can be divided into three broad classifications: animal responses, management actions, and resource [112].

4.1. Animal Responses

Animals can adapt through physiological, biochemical, immunological, anatomical, and behavioral responses [113]. Herein, we focus on behavioral responses. For details on other animal adaption mechanisms, see Gaughan et al. [112].

Commonly observed responses to heat stress include reduced feed intake, shade seeking, increased sweating and panting, increased water intake and drinking frequency, increased standing time and decreased lying time, and reduced defecation and urination frequency.

It is noteworthy that domestic animals are rarely exposed to a single stress. Besides heat stress, under feeding, lack of water, and poor nutrition may occur together. The cumulative effects of multiple stressors may be multiplicative rather than additive [112]. Animals may not be able to fully adapt to climate stressors by themselves, and thus producers may need to help in order to sustain livestock production and profitability. However, one should note that climate change can be so large that it may not be possible overcome an effect and in such cases, more extreme actions, such as changes in land use, species, or abandonment, may be in order [114].

4.2. Human Adaptation Strategies

Human adaptation strategies involve breeding, production/management system modifications, and institutional and policy changes. Table 3 presents a brief summary of livestock management adaptation strategies, and a detailed discussion follows.

Table 3. Summary of human adaptation strategies.

Animal Genetics
•Choose species that are more heat-tolerant •Genetic selection to changed conditions
Physical modification
•Provide shade and sprinklers for outdoor animals •Improve/supply cooling systems indoors
Feed and pest management
•Modify diet composition and feeding time •Supplemental feeding •Adoption of integrated pest management
Livestock system
•Diversify livestock species •Adjust stocking rate •Integrate livestock system with forestry or crops

4.2.1. Animal Genetics

Breed selection has traditionally been used to improve livestock production efficiency and has facilitated a massive increase in livestock production. However, current species selected for higher production in some cases have higher metabolic heat production and hence can be more susceptible to heat stress [115]. As future climate is predicted to be hotter, with more frequent heat extremes, breeding techniques and breed type selection can also be an adaptation action. Genetic variation in heat stress response in livestock species has been observed and measured [116,117]. Some breeds are less affected by heat stress, such as smaller, lighter-colored animals [118], or breeds can show great physical and physiological adaptation to heat stress. If such trait is heritable, selective breeding for heat tolerance could be used to improve animal adaptation to climatic stress [119,120]. Producers can switch breeds, for example, using more Bos indicus cattle [121,122].

4.2.2. Physical Modification

Physical modification of the environment can also be undertaken and can be broadly divided into two groups: outdoor and indoor.

For animals kept outdoors on grasslands or pasture, one cost-effective adaptation method is shade provision. This lowers exposure to solar radiation and reduces heat stress [39,123]. Sprinklers and misters could also help to decrease body temperatures [124], and they are more effective in drier weather. Huynh [125] suggested the use of a combination of different methods as there exist interaction effects. For example, the combination of sprinkling and a covered pen without an outdoor yard leads to higher daily gain for hogs than the provision of sprinkling alone.

For livestock kept indoors, in buildings, physical modification options can involve use or addition of (1) ventilation systems, (2) heat reducing building materials (e.g., insulation and orientation), and (3) forced air velocity, fogging, misting, sprinkling, and pad cooling [126]. Air conditioning and pad cooling have been found to have the best performance

in terms of lowering heat stress [126], but the high initial investment and operating expense might make them impractical [127].

4.2.3. Feed and Pest Management

Feeding practices can be used to improve animal performance under heat stress. These involve modification of diet composition, changes in feeding time and/or frequency, and water management [120]. These practices help alleviate heat stress through increasing energy content, increasing nutrient and electrolytes or certain minerals intake, and maintaining water balance. Feeding modifications in cattle [128,129], hogs [130–132], and poultry [66,133,134] have all been investigated, and the general effect is positive.

Pest management has not been fully discussed as livestock adaptation, although researchers have noticed that future changes in precipitation patterns may affect the spread and quantity of some vector-borne pests [52]. There are several concerns related to livestock pest management. First, some pests will develop resistance to insecticides and drugs in a short time, which would limit the effectiveness of insecticides or drugs. Thus, in practice, it is suggested to use the rotation of insecticides with different modes of action [135]. Second, high-density or confined systems can encourage pests and disease outbreak, with poultry in particular suffering a lot from pest problems [136]. Third, drug residues in animal products due to inappropriate use of pesticides may be a potential threat to public health [137]. As a result of these considerations, integrated pest management is needed [138], as well as improved techniques in pesticides.

4.2.4. Livestock Management System

Livestock management adaptations can involve one or more of the following strategies:

(1) Diversification of livestock species: Multi-species farming enhances the producer's ability to cope with a changing climate and the associated change in rangeland conditions and can also improve the sustainability of livestock farms [139,140].
(2) Adjustment in stocking rates: Díaz-Solís et al. [141] found that adjusting stocking rate can be used to reduce the effect of drought on cow-calf in Mexican state of Coahuila. Mu et al. [142] found that in the U.S., the stocking rate of cattle decreases as THI increases and precipitation increases in summer.
(3) Integration of livestock system with forestry or crops: Because of their positive synergistic effects on soil properties and nutrient cycling, mixed crop–livestock or forestry–livestock can help with soil degradation, reduce chemical use, and generate economies of scale at the farm level [143,144].

5. Mitigation

There are mitigation measures that reduce livestock GHG emissions. Gerber et al. [7] indicated that livestock emission intensities vary greatly between production systems and regions and the mitigation potential lies in the gap between the management techniques that result in the lowest and highest emission intensities. They estimated that the emissions from the livestock sector can be reduced by 18% if producers in a given system, region, and climate adopt the practices currently applied by the top 25% of producers with the lowest emission intensity and 30% if using techniques employed by the top 10%. We summarize many potential mitigation options in Table 4 and discuss them below.

5.1. Land Resource Management

Substantial livestock mitigation lies in livestock management and land use. Thornton et al. [145] estimated that the maximum mitigation potential from livestock and pasture management is approximately 7% of the global agriculture mitigation potential to 2030. Possible strategies involve adoption of improved pastures, intensification of ruminant diets, changes in ruminant breeds, reductions in stocking rate, and lowering grazing intensity. Havlík et al. [146] indicated that significant emission reduction could be achieved through transitions to more efficient and less land-demanding livestock systems. They also found

that mitigation policies targeting land-use-change-related emissions are 5–10 times more efficient than policies targeting emissions from livestock only.

Table 4. Summary of mitigation strategies.

Land resource management
•Improve grazing management •Alter grazing intensity and or manure use to enhance Carbon sequestration
Enteric fermentation management
•Modify diet and nutrition for livestock • Genetic selection
Manure management
•Alter storage practices •Modify diet and nutrition for livestock
Fertilizer management
•Increase nitrogen efficiency •Offest commerial nitrogen use by using manure

Another land-use-related mitigation category deals with carbon sequestration, which mainly relates to feed crop production. Carbon sequestering actions include using conservation tillage, selecting to produce higher yielding crops, reducing deforestation, converting cropland to grassland, and improving grass species [3,103].

5.2. Enteric Fermentation Management

As discussed above, enteric fermentation is the main source of ruminant methane emissions. This emission source can be reduced through dietary management and genetics. Knapp et al. [147] found that nutrition and feeding strategies such as improving forage digestibility can reduce enteric methane emission by 2.5–15% per unit of milk produced and that more significant reductions can be achieved if combined with genetic and management approaches. Feed additives and supplements, such as antibiotics, lipids, grain, and ionophores, have also been shown to decrease enteric methane emissions [105,148].

5.3. Manure Management

Livestock manure generates both N_2O and CH_4 emissions, and most of these are related to storage and handling methods [3]. Altered manure storage practices can reduce manure GHG emissions. These include shortened storage duration, lowered storage temperature, solid–liquid separation, and less use of water [149,150]. Anaerobic digestion processes, in which microorganisms break down manure in the absence of oxygen, produce a mixture of biogas (mainly CH_4 and CO_2) and digestate that can be captured and used as bioenergy to generate heat or electricity. This also indirectly reduces GHG emissions by replacing emission-intensive fossil energy and by changing the composition of emissions from the traditional combination of N_2O and CH_4 into a combination of CO_2 and CH_4 [151]. Anaerobic digestion can lead to an over 30% reduction in GHG emissions compared to traditional manure treatment [152]. Dietary adjustment for animals can also be used to reduce manure emission as it could change the volume and composition of the manure.

5.4. Fertilizer Management

Fertilizer application in feed crop production contributes N_2O emissions attributable to the livestock sector. Associated mitigation strategies aim at increasing nitrogen application efficiency. Possible measures include the use of time-released nitrogen, precision application, organic fertilizers, plant breeding, genetic modifications, and changes in plant species [153,154]. However, it is complex to calculate the mitigation potential of increasing fertilizer efficiency on animal feed production, and this leaves a gap for future studies to discover.

Another possible practice related to reducing emission from feed production involves shifts in types of livestock feed. Pikaar et al. [155] analyzed the potential of using microbial proteins (MP) as a feed replacement, finding that it can replace 10–19% of conventional crop-based animal feed protein demand, which leads to a reduction by 7% in agricultural greenhouse gas emission.

6. Discussion

On the one hand, climate change can affect livestock production directly through increased heat stress and indirectly through impacts on the quantity and quality of forage and crop-based feeds, as well as land and water availability. Associated adaptation strategies could target direct animal responses, by adjusting their living environment and feed, or focus on the modification of production and management systems.

On the other hand, livestock production influences climate change by contributing to 14.5% of the global anthropogenic GHG emissions. Mitigation strategies from the livestock side could help address enteric emissions and improve manure management, along with more emission efficient feed production through reduced use of N-fertilizer and land carbon sequestration. Figure 3 provides an overview of the major impacts, emission types, and actions covered in this review.

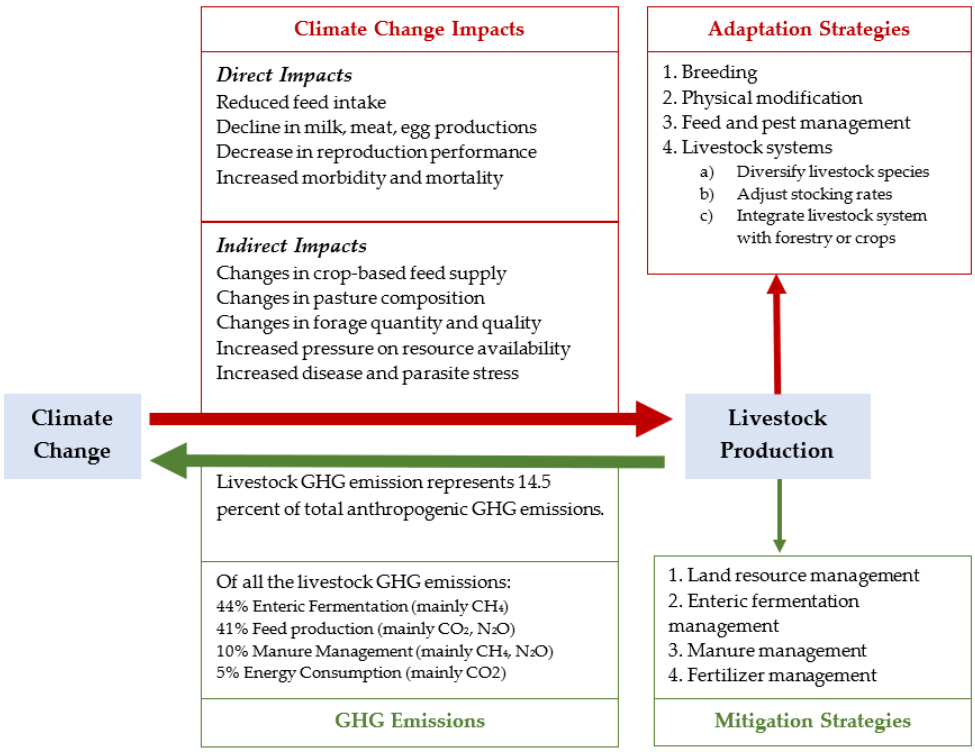

Figure 3. An overview of the relationship between climate change and livestock production.

Despite the numerous studies carried out in this field, there remain a number of research gaps. First, the literature mainly focuses on ruminants, with less coverage of other

species, such as hogs and poultry. These animals are also affected, and their productivity may even be more affected than that of ruminants [13]. Considering emissions on the basis of the per-unit protein produced, chicken meat, eggs, and pork have lower emission intensities compared to beef meat, and this could be exploited as a mitigation strategy [102]. Thus, research on non-ruminants is needed. Second, current publications have a strong focus on grassland-based livestock systems, while a mixed crop–livestock system produces half of the world's food and supports a large number of households in developing regions [156]. This additional research is needed on livestock in such production systems. Third, adaptation and mitigation strategies are not universally applicable, being place, species, and context specific. In addition, some options are too costly or resource intensive to be applied in a number of settings and the strategy potential is limited by the dietary needs for milk, meat, and eggs and by local conditions in terms of income, awareness of climate change impacts, experience, loan terms, and many other factors [157]. Research is needed to identify locally appropriate mitigation and adaptation strategies, especially in the context of developing countries, as well as policy approach for encouraging and implementing adoption. For doing this, better data, methods, and coverage are needed.

Author Contributions: Conceptualization, B.M. and C.F.; methodology, M.C.; writing—original draft preparation, M.C.; writing—review and editing, B.M. and C.F.; visualization, M.C.; supervision, B.M. and C.F.; project administration, B.M.; funding acquisition, B.M. All authors have read and agreed to the published version of the manuscript.

Abstract

This study evaluates the dynamics of soil organic carbon (SOC) under perennial crops across the globe. It quantifies the effect of change from annual to perennial crops and the subsequent temporal changes in SOC stocks during the perennial crop cycle. It also presents an empirical model to estimate changes in the SOC content under crops as a function of time, land use, and site characteristics. We used a harmonized global dataset containing paired-comparison empirical values of SOC and different types of perennial crops (perennial grasses, palms, and woody plants) with different end uses: bioenergy, food, other bio-products, and short rotation coppice. Salient outcomes include: a 20-year period encompassing a change from annual to perennial crops led to an average 20% increase in SOC at 0–30 cm (6.0 ± 4.6 Mg/ha gain) and a total 10% increase over the 0–100 cm soil profile (5.7 ± 10.9 Mg/ha). A change from natural pasture to perennial crop decreased SOC stocks by 1% over 0–30 cm (−2.5 ± 4.2 Mg/ha) and 10% over 0–100 cm (−13.6 ± 8.9 Mg/ha). The effect of a land use change from

forest to perennial crops did not show significant impacts, probably due to the limited number of plots; but the data indicated that while a 2% increase in SOC was observed at 0–30 cm (16.81 ± 55.1 Mg/ha), a decrease in 24% was observed at 30–100 cm (−40.1 ± 16.8 Mg/ha). Perennial crops generally accumulate SOC through time, especially woody crops; and temperature was the main driver explaining differences in SOC dynamics, followed by crop age, soil bulk density, clay content, and depth. We present empirical evidence showing that the FAO *perennialization* strategy is reasonable, underscoring the role of perennial crops as a useful component of climate change mitigation strategies.

1 | INTRODUCTION

Soils store approximately 1,550 Gt of organic carbon out of the 2,110 Gt of organic carbon estimated to be present in the biosphere (Lal, 2004). Thus, soil organic carbon (SOC) accounts for about 70% of total terrestrial carbon (C), and represents more than twice the 760 Gt of atmospheric C (IPCC, 2014). The size of the SOC pool means that land use and land use changes (LUCs) that cause soil disturbance can lead to substantial loss of SOC and greenhouse gas (GHG) emissions. Indeed, conversion from natural to agricultural ecosystems causes a major loss of SOC: up to 60% or 75% in temperate and tropical regions, respectively (Lal, 2004), and this C is released to the atmosphere as carbon dioxide, CO_2, a GHG source. Agriculture is practiced on 49% of the global ice-free land surface, 12% as cropland, and 37% as pasture, and is responsible for 12% of the total direct anthropogenic GHG emissions (IPCC, 2019). If, in addition, LUC and degradation are considered, the contribution of agriculture rises to one third of the total anthropogenic emissions (Wollenberg, Tapio-Bistrom, Grieg-Gran, & Nihart, 2011). Furthermore, the reduction in SOC causes soil degradation and hence reduces plant productivity and yield (Lal, 2006). Agriculture, however, is a basic human activity and a necessity, and as such, providing secure food and energy supply for rising global population while minimizing GHG emissions is one of the main challenges of humanity (Smith et al., 2010). The agriculture, land use, and forestry sectors are the only major sectors with the potential not only to reduce emissions but also deliver negative emissions in some cases (Ledo, Heathcote, Hastings, Smith, & Hillier, 2018). This is achieved via C sequestration (Smith, 2004) and/or offsetting through the supply of feedstock for energy production (Robertson et al., 2017).

It is estimated that agricultural lands have the potential to sequester up to a 66% of historical C loss, if managed properly (Lal, 2004). The "4 per mille" initiative (https://www.4p1000.org/), which aims to increase SOC relies mainly on the application of best agricultural practices and the reduction of deforestation. Tree planting is an effective method increasing SOC (Laganiere, Angers, & Pare, 2010). Another method for increasing SOC is the establishment of perennial crops, which may be applied without loss of productive area. This latter option might deliver food, fiber, energy feedstock, or other goods and ecosystem services including increasing SOC, and as such could represent a win–win scenario. In fact, the FAO has suggested "perennialization" of agricultural lands as a strategy to mitigate climate change, and to enhance food security and ecosystem service delivery (Glover, Reganold, et al., 2010). Nonetheless, to date there has been a lack of evidence about the capacity of perennial crops to store SOC (Ledo et al., 2019). Importantly, studies have been carried out in a range of locations, using different experimental designs and analytical methods, and for a wide variety of crops. Therefore, results are not directly comparable and conclusions on the effect of perennial crops on SOC and soil properties cannot easily be derived. This is a significant limitation and knowledge gap considering that, even currently, perennial crops comprise 30% of global croplands (Ledo et al., 2018). There is thus a clear need to collate and carry out standardized analysis and syntheses of results from these disparate studies in order to understand the global impacts of LUCs and conversions under such significant production systems and/or scale; as well as to identify critical information or data gaps.

Perennial crops in this study are defined as crops that are planted, but not replanted and/or fully harvested annually to obtain goods (this definition excludes naturally occurring perennials and grasslands but includes plants for which the above-ground biomass is annually harvested). Perennial crops can be divided in two main groups: woody plants, such as fruits and nut crops (e.g., apple trees, citrus, almond), beverage crops (e.g., coffee, tea, cocoa), oil crops (e.g., palms), or short rotation coppices (e.g., poplar, willow); and perennial grasses such as sugarcane, switchgrass, *Miscanthus*. They also have different end uses, such as food (e.g., fruits), fiber (e.g., cotton), bioenergy (e.g., *Eucalyptus*, *Miscanthus*). In perennial crop cultivation, tillage and soil disturbances are reduced since, by definition, perennial crops stay on the land for more than 1 year. Moreover, perennial crops ensure vegetation cover and thus photosynthesis all year around which increases the biomass that is produced and left on the site to become SOC. Thus, there is greater potential to maintain or sequester SOC relative to annual crops. Along with potential benefits for soils (Cox, Glover, Tassel, Cox, & DeHaan, 2006; Paustian, Six, Elliott, &

Hunt, 2000) and GHG emission reduction, perennial crops store biomass (Ledo et al., 2018) and/or may be used to displace fossil fuels for energy generation (Dondini, Hastings, Saiz, Jones, & Smith, 2009; Robertson et al., 2017).

LUC and competition for land are urgent challenges for humanity (Foley et al., 2005; Smith et al., 2010). Given current rates of global population growth, the ongoing change from natural to cultivated ecosystems is likely to continue in order to feed an increasing population. It has been documented that a change from a natural ecosystem, forest or grassland, to annual cropland will result in SOC loss (Deng, Zhu, Tang, & Shangguan, 2016; Don, Schumacher, & Freibauer, 2011; IPCC, 2014). However, changes from natural ecosystems to perennial crops have been documented only locally and results are not consistent, reporting SOC gain (Post & Kwon, 2000; Robertson et al., 2017), SOC loss (Crowther et al., 2016; Don et al., 2011) or no change (Fialho & Zinn, 2014; Qin, Dunn, Kwon, Mueller, & Wander, 2016). Moreover, little information is available about the effects on SOC following conversion from annual to perennial crops. Furthermore, the SOC stock changes during the subsequent cultivation of perennial crops are poorly quantified. Turnover of soil organic matter is a function of several interacting variables, such as moisture, temperature, clay content, soil porosity, soil cover, and the composition of the soil microbiota (Aguilera, Lassaletta, Gattinger, & Gimeno, 2013; Blagodatsky & Smith, 2011; Deng et al., 2016; Don, Böhme, Dohrmann, Poeplau, & Tebbe, 2017). However, the most important driver for SOC turnover and changes is the C input via root litter and exudates, above-ground litter, and organic amendments (Kutsch, Bahn, & Heinemeyer, 2009; Rasse, Rumpel, & Dignac, 2005). Differences among crops and geographic areas may be largely explained by differences in these variables. Furthermore, an increase in global temperatures may affect SOC dynamics and C input to the soil (Davidson & Janssens, 2006).

In this study, we have used the first global and harmonized dataset of perennial crops on SOC dynamics (Ledo et al., 2019) to explore, at a global level, SOC in perennial crops. We studied different aspects: First, the changes in SOC stocks after a transition to perennials over a 20-year period or more, from different land uses: annual crops, forest (both natural and secondary forest) and natural grasslands. Secondly, we also evaluated changes in SOC stocks during the lifespan of the perennial crops, between 1 and 20 years after transition. Finally, we explored SOC changes in different biogeographical regions and for different perennial crops in order to identify general or distinctive patterns of SOC dynamics. Our final goal was to provide an empirical model to predict changes in SOC as a function of the main drivers of SOC dynamics found in this study: crop, climate, soil properties, and land use.

2 | METHODS

2.1 | Database creation

We used a global dataset of paired observations containing information about changes in SOC under perennial crops (Ledo et al., 2019), freely downloadable from the figshare file, https://doi.org/10.6084/m9.figshare.7637210 (2019). In addition to the original dataset, we calculated extra fields which were required in this study. This updated dataset is reproduced in Table S1. Firstly, for those plots without bulk density (BD) or soil texture (sand, silt, clay) and/or pH values in the original studies, we gap-filled the missing values as described previously (Ledo et al., 2019). Secondly, in order to standardize the units of SOC we transformed all values of SOC given as C density (SOC_{den}; g/kg) to SOC stocks (SOC_{stock}; Mg/ha) as follows:

$$SOC_{stock} = SOC_{den} * BD * depth \quad (1)$$

where BD is the bulk density (g/cm^3) and depth (cm) was the maximum depth at each particular measured plot.

This transformation may introduce errors and/or bias (Poeplau, Vos, & Don, 2017) but was deemed necessary due to lack of equivalence in reporting. Thirdly, for those plots with values of SOC at different depths, we calculated a single, depth-integrated value per sampling point by adding the SOC values of each layer. Consequently, we created a second database containing a single value of SOC stock per measured plot, whereas the original dataset has points with values of SOC at different depths (from 1 to 200 cm). This second dataset is reproduced in Table S2.

Finally, we calculated the relative change in SOC (ΔSOC_{rel}) for each point i between two times, t_0 (first measurement in time) and t_1 (second measurement in time, more recent, of the paired data information) as:

$$\Delta SOC_{rel_i} = \frac{SOC_{i,t_1} - SOC_{i,t_0}}{SOC_{i,t_0}} \quad (2)$$

We used the values of SOC as provided in the original study, either as SOC stocks (Mg/ha) or as SOC density (g/kg), to minimize errors and bias. SOC_{t_1} is the recorded empirical value of SOC after LUC to perennial crop cultivation; and SOC_{t_0} is the SOC value either (a) on previous land use before conversion to a perennial crop for those plots containing paired observations on two land uses, or (b) the earlier of observations at two different time points for those plots containing paired information on temporal changes on SOC during perennial cultivation. Positive values therefore indicate an SOC gain and negative values SOC loss.

We additionally calculated the stock change for every point i between times t_0 and t_1 in Mg/ha as:

$$\Delta SOC_{stock_i} = SOC_{i,t_1} - SOC_{i,t_0} \quad (3)$$

A summary of the SOC stock values recorded in the dataset evaluated in different biogeographical regions and main crop groups can be found in Appendix S1. The biogeographical regions considered were temperate, tropical, and boreal. The crop types were perennial grasses, woody plants, and palms (Ledo et al., 2019).

2.2 | Effect of LUC to a perennial crop on SOC in a 20-year period

We evaluated the change in SOC stock (ΔSOC_{stock}, Equation 3) from forest, grassland, or annual crops to perennial crops, using paired data. To align with the IPCC standards and provide relative stock changes over a 20-year period, we selected and included in our analysis only those studies where conversion to a perennial crop occurred more than 20 years ago (n = 138 plots). For such observations, we calculated the mean and the standard error of the mean (*SEM*) of the SOC values before and after conversion (ΔSOC_{stock}) and the percentage of SOC stock change. Furthermore, to avoid introducing additional errors and/or bias, rather than unifying values of SOC at a particular depth, we selected those plots containing information on SOC at depths (a) 0–30 cm (n = 105) and (b) 0–100 cm (n = 33).

2.3 | Temporal change in SOC under perennial plantations during the first 20 years after conversion

We evaluated changes on SOC stocks (ΔSOC_{stock}, Equation 3) over a 20-year period, from crop age 1 year to crop age 20 years. We selected a 20-year period as in the previous subsection and for the same reasons. We also included in our analysis those plots with SOC measured at 0–30 cm (n = 111) and 0–100 cm (n = 10) aggregated over different perennial crop types. Additionally, we calculated temporal ΔSOC_{stock} for perennial grasses, woody plants, and palms separately.

2.4 | Model to estimate temporal changes in SOC under perennial crops

We fitted a model to explain and predict the changes in SOC stocks and to identify the most significant explanatory variables and rank their importance. The explanatory variables we considered were (a) climatic: mean annual temperature, annual accumulated precipitation, climatic water deficit defined in Chave et al. (2015), and the variables Bio17 (Isotherma), Bio16 (changes in seasonal temperature), and climatic PT10 parameter, Bio12/(Bio 1 + 10), from the WorldClim database; (b) topographic: elevation, slope, aspect, and roughness (concavity or convexity of the terrain); (c) soil parameters: BD, percent clay, percent silt, percent sand, and pH; and (d) plantation parameters: crops age, years since transition to perennials, previous land use (annual crop, fallow, grassland, or natural forest), and current land use (agroforestry, bioenergy grass, or food and bio-products). More details on these variables can be found in Ledo et al. (2019). The response variable of this model was the rate of change in SOC, ΔSOC_{rel}, and we chose to fit a parametric model to make further predictions feasible. Since the variable ΔSOC_{rel} contained both positive and negative values and was highly skewed, we added 2 to all values and log-transformed the resultant data. After this transformation all the values of the response variable were positive, and the distribution was approximately normal. We then modelled the transformed ΔSOC_{rel} with a generalized lineal mixed model (GLMM), with a Gaussian distribution as identity link function.

To this end, we formulated several GLMMs, including systematically different sets of covariates and combinations, using both a Gaussian and Gamma distribution as identity link functions. Continuous explanatory variables were mainly but not exclusively tested and included as fixed effects and categorical variables were tested mainly, but not exclusively, as random effects. We used a Bayesian inference framework, an approach that allowed us to get information of the dispersion of the fitted parameters. We used the INLA (integrated nested Laplace approximation) method (Rue, Martino, & Chopin, 2009). The INLA method is a computationally efficient method for fitting Bayesian models that speeds up parameter estimation substantially in comparison with the typical Markov chain Monte Carlo routine. To identify the best model, we selected the model with lower log-likelihood among those containing all the covariates that were significant and not highly correlated and which residuals diagnose was acceptable. Including different sets of covariates and checking those that were significant was a manual, stepwise process.

Secondly, we calculated the variance in the data, and the variance explained by the model and by each of the explanatory covariates. In this way, we were able to rank the effect of each variable over the others and assess the importance of all of them in explaining and potentially predicting changes in SOC.

The R code used for all the analyses in this study can be found in Data S1 Programming Code 1.

3 | RESULTS

3.1 | Effect of LUC to perennial crop on SOC in a 20-year period

Overall, a change from an annual to a perennial crop led to a 20% (±10) increase in the SOC average stock values over a 20-year period in the top 30 cm and an increase of 11% (±8) over 100 cm (Table 1). In contrast, SOC stocks decreased when changing from grassland to perennial cops. We observed an averaged 0.6% (±5.65, not significant) SOC stock loss when only the first 30 cm were considered and a −9.6% (±6.7) when 100 cm were analyzed (Table 1). While the C loss in the upper layers was not significant, the effect of SOC loss was more obvious when the entire soil profile was considered. For a change from forest to perennial crops, we observed a 2% (±6.9, not significant) increase in SOC stocks in the upper part of the soil, but a 24% (±9.3) decrease when the entire profile was considered (Table 1). However, only seven paired plots contained information on this kind of LUC and natural and secondary forest were merged.

TABLE 1 Mean values of SOC (soil organic carbon) stocks (Mg/ha) and standard error of the mean before and after conversion to perennial with land use change more than 20 years ago. Significant effects are in bold

Previous land use	SOC before conversion (Mg/ha)	SOC after conversion (Mg/ha)	ΔSOC_{stock} (Mg/ha)	Gain/ loss	% change
Depth 0–30 cm					
Annual crop	41.1 (±5.0)	47.1 (±6.3)	6.1 (±4.6)	**Gain**	**20 (±10.0)**
Grassland	58.7 (±7.4)	55.0 (±6.4)	−2.5 (±4.1)	Loss	−0.6 (±5.6)
Forest	84.5 (±40.8)	100.6 (±12.3)	16.8 (±55.1)	Gain	2.0 (±6.9)
Depth 0–100 cm					
Annual crop	139.0 (±44.9)	144.7 (±42.9)	5.7 (±11.0)	**Gain**	**11 (±8.5)**
Grassland	121.9 (±12.5)	108.3 (±11.8)	−13.6 (±8.9)	**Loss**	**−9.6 (±6.7)**
Forest	173.5 (±22.5)	133.4 (±28.2)	−40.1 (±16.8)	**Loss**	**−24 (±9.3)**

3.2 | Temporal change in SOC stocks during perennial plantation

Overall, an increase in SOC stocks over time after conversion to perennial crops in the upper soil layers was observed (Figure 1a), meaning a gain in SOC through the first 20 years after conversion to perennial crops. This trend was consistent for all crop types, although woody plants tended to accumulate progressively more SOC than grasses and palms (Figure 1b). However, the time lags in which the database contains information also differed between crop types, which was a confounding factor. Upon close observation, it was apparent that SOC stock dynamics did not follow a linear trend with time. After an initial SOC gain, a marked SOC loss particularly under perennial grasses could be observed (Figure 1c), followed by an increasing SOC pattern again. This pattern was also repeatedly observed for single sites with multiple observations (chronosequence), thus confirming this general observation. For depths 0–100 cm, a modest SOC gain during the 20-year period was discernible especially under perennial grasses (Figure 1d), although the temporal increment observed in the upper layers was not as clear and the number of studies was very limited (n = 10).

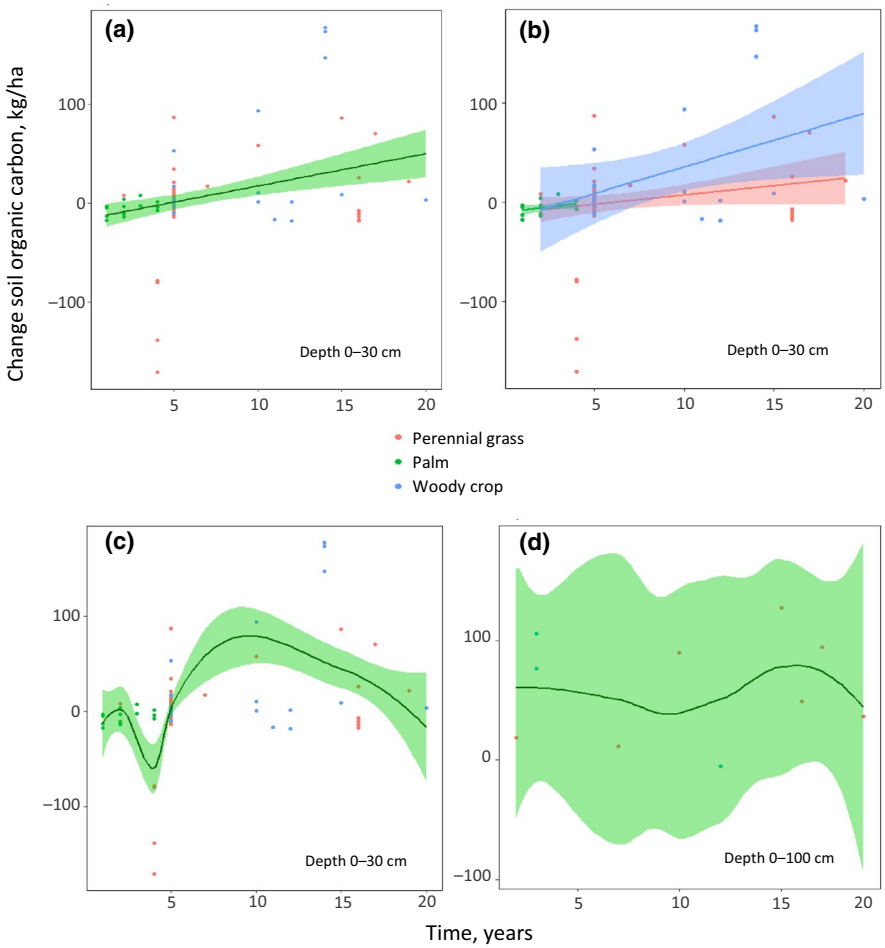

FIGURE 1 Empirical soil organic carbon (SOC) stock change values, in Mg/ha. Red, green, and blue dots are perennial grass, palm, and woody crop, respectively. (a) The green line is the linear trend of the mean value of SOC stock change including all the points (crop types) at depth 0–30 cm together, with the standard deviation in green shaded band. (b) The red, green, and blue lines are fitted linear models for perennial grasses, palms, and woody crop, respectively. (c) Actual empirical trend with the mean of SOC stock change as green line and the standard deviation of the mean in green shaded band, for depths 0–30 cm. (d) Actual empirical trend with the mean of SOC stock change as green line and the standard deviation of the mean in green shaded band, for depths 0–100 cm [Colour figure can be viewed at wileyonlinelibrary.com]

3.3 | Modelling temporal changes in SOC, considering the effect of climate, soil properties, and land use

Temporal changes in SOC were modelled using the GLMM formulations with a Gaussian distribution (a list of all the fitted models can be found in Table S5):

$$\Delta SOC_{rel} = -2 + e^{\zeta} \quad (4)$$

where

$$\zeta = \frac{1}{100}\left(\begin{array}{l} 78.584 - 0.533\,Temp - 0.189\,CropAge - 0.018\,Depth - 0.056 \\ PerClay + 5.352\,BD + |Previous\ land\ use| + |Current\ land\ use| \end{array}\right)$$

are the coefficients of the mean of the posterior fixed effects for: Temp, temperature, in Celsius; CropAge, the crop age (time since the crop was planted) in years; Depth, the profile depth in cm; PerClay, the percentage of clay; and BD, the soil bulk density. The coefficients for the mean posteriors of the random effects are given in Table 2.

The model explained 20% of the dataset variance, regardless of crop type. Although this means that a large proportion of the variance is not explained, this is, nonetheless, not a negligible percentage given the large heterogeneity in the data (including the different experimental methods, geographic regions, crop types, management practices, and ages) and the subsequently elevated Gaussian noise in the model. Of the explained variation, the main driver of the variation in SOC stock changes in perennial crops was temperature (Figure 2), which was negatively correlated with SOC changes. Crop age was second in importance, also negatively correlated with SOC change (Figure 2); changes in SOC were greater at the beginning of the crop establishment. Soil physical properties (BD, clay content) explained SOC changes to a lesser extent, with soils with greater BD and lower clay content showing greater changes in SOC. Depth and previous land use explained a minor proportion of the model variance, but these did improve the model fit (Table S5). Depth at the soil profile was negatively correlated with SOC changes, indicating that greater changes in SOC occurred at upper soil layers (Figure 2).

TABLE 2 Coefficients for the mean posteriors of the random effects of the ΔSOC empirical model

Previous land use			
Annual crop	Fallow	Grassland	Natural Forest
-5.431×10^{-05}	-2.178×10^{-05}	-2.832×10^{-04}	-2.733×10^{-04}
Current land use			
Agroforestry	Bioenergy grass	Food (and bio-products)	
-8.684×10^{-06}	-5.223×10^{-04}	5.647×10^{-04}	

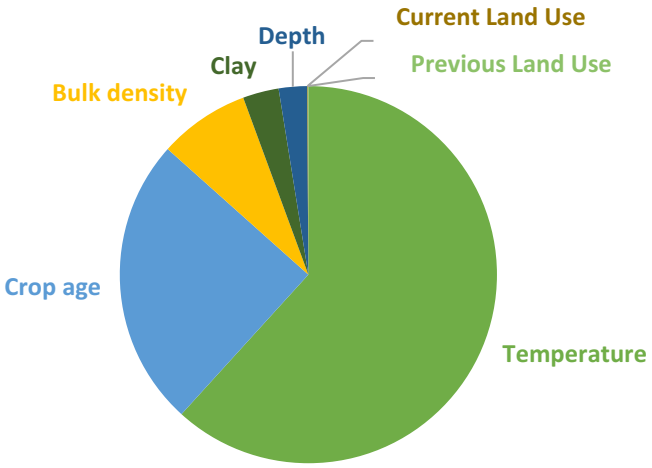

FIGURE 2 Percentage of variance explained by each of the soil organic carbon change model predictors. The previous land use categories are as follows: annual crop, fallow, grassland or natural forest; and the current land use ones: agroforestry, bioenergy grass or food, and bio-products [Colour figure can be viewed at wileyonlinelibrary.com]

4 | DISCUSSION

This study synthesizes the published, yet disparate, data on SOC changes at a global scale and provides for the first-time quantitative evidence about the effect of conversion to perennial crops on SOC relative to alternative land uses or cover types and over time. Specifically, it shows that a change from annual to perennial crops induces a SOC gain (Table 1) which indicates the potential to use perennials to sequester organic C across the cropland sector, especially where doing so has minimal trade-offs between SOC sequestration and food production. Besides, perennials increase the SOC stocks during crop life, at least up to 20 years (Figure 1). Climate, soil characteristics, and previous land use were identified as potential drivers of SOC dynamics in perennial crops at a global scale (Equation 4), with the average annual temperature playing a central role (Figure 2).

4.1 | Land conversion to perennial crops

A transition from an annual to a perennial to crop generally resulted in an average gain of a 20% (±10) in SOC (6.07 Mg/ha) after 20 years or more after conversion in the upper layers. In the 0–100 cm profile, the SOC gain was 11% (±8.5) a total of 5.66 Mg/ha in SOC. These slight differences between the 0–30 cm and 0–100 cm soil profile are partly likely due to the fact that the evaluated plots were different. If so, the information on the 30 upper centimeters is more reliable, since there are more data available (111 plots compared to 33). By contrast, a change from grassland to perennial crops appeared to cause a 1% loss of SOC in the top 30 cm the soil profile (although this is not statistical significant, therefore it should be taken with caution), the loss of SOC over 0–100 cm was more noticeable (−10%) and statistically significant. The effect of LUC from forest to perennials

on SOC varied with the soil depth; where comparisons are restricted to the top 30 cm soil a 2% (16.8 Mg/ha) gain in SOC is observed (the value was not statistically significant, and should be considered only as indicative). But a substantial loss of SOC was observed and was statistically significant (−24% or −40 Mg/ha) when the comparison is extended to the top 100 cm (see also Don et al., 2011). These findings highlight that when evaluating LUC effects on SOC stocks, it is imperative to consider a greater proportion of the soil profile affected by the root system to gain a fuller picture of impacts.

While the finding that a change from any land use to annual crops results in a loss in SOC is consistent among studies (Deng et al., 2016; Don et al., 2011), the effect of a change from a natural ecosystem to a perennial crops plantation is not that clear. Don et al. (2011) found a decrease of 30% in SOC when converting forest to perennials. This finding is not fully consistent with our study, we found a loss of SOC at the top 100 cm (−24%) but no significant effect at the top 30 cm (Table 1).

4.2 | Factors influencing SOC temporal dynamics in perennial crops

The first factor identified to affect SOC changes was crop age, or time after perennial establishment. After the initial LUC disturbance, SOC under perennials increases over 20 years, at an average of 0.05 Mg ha^{-1} $year^{-1}$ (Figure 1a) in the upper layers, 0–30 cm. This result is consistent with the patterns found in their analysis of SOC dynamics in perennial bioenergy crops in the upper soil layers by Ferchaud, Vitte, and Mary (2016). However, Ferchaud et al. (2016) observed a decrease in SOC in deeper horizons, which did not correspond to the findings in our evaluation. We observed that the increase in SOC is especially marked in woody crops where average gains of up to 0.1 Mg/ha (Figure 1b) were seen. However, this observed SOC gain was not constant: SOC increase was larger during the initial years after conversion to perennial crops after which a steady decline in SOC accumulation rate was observed (Figure 2c), consistent with the predictions of the GLMM (Equation 4). This supports the view that changes in SOC are greater at the beginning of the crop establishment and then decline until they reach a steady state (Smith, 2014). This pattern has also been observed in previous studies on SOC on perennial crops (Vicente-Vicente, García-Ruiz, Francaviglia, Aguilera, & Smith, 2016), and also reported for perennial woody crops in tropical savannas: In first cycle Eucalyptus plantations in Brazil, SOC losses after clearing of native vegetation were ascribed to decomposition of antecedent SOC at a faster pace than C was replenished in the young stands, but were reversed after harvest at age 7 years after planting and then by the ensuing coppice growth until age 14 years after planting (Zinn, Lal, & Resck, 2011).

Temperature and precipitation regimes are determining factors for the SOC balance, as they are strongly involved in processes responsible for both SOC inputs (i.e., litterfall production) and outputs (i.e., SOC decomposition, Davidson & Janssens, 2006). Therefore, differences in climate are probably one of the main causes explaining differences in SOC storage patterns among croplands in the world, as has been found for other ecosystems (Carvalhais et al., 2014; Doetterl et al., 2015). This study revealed temperature as one of the main factors affecting SOC changes in perennial crops globally (Figure 2, Equation 4). Temperature was negatively correlated with SOC changes, indicating that in warmer, tropical areas the relative change in SOC is lower than in temperate and boreal areas. We found temperature to be the main predictor of SOC changes over precipitation and over other climate indicators that combine temperature and precipitation together. This suggests that temperature exerts a stronger influence in soil respiratory processes than in plant growth and soil C input processes (which might be co-limited by other factors), thus limiting the potential for a more positive SOC balances in warm regimes. Soil physical properties were also significant in explaining SOC changes in the GLMM model: soils with greater values of BD showed greater changes in SOC, agreeing with the findings in Don et al. (2011), but this merely reflects the large weighting of BD in the calculation of SOC density. Soils with higher BD and lower SOC content are likely to have higher saturation deficit (Six, Conant, Paul, & Paustian, 2002)—the difference between maximum and minimum SOC that could be achieved—and thus may have higher potential to increase the SOC stocks (Vicente-Vicente, Gómez-Muñoz, Hinojosa-Centeno, Smith, & Garcia-Ruiz, 2017). The cultivated crop is a confounding factor in this study, and even with more data this limitation may remain, since some crops have a limited environmental range and are therefore only cultivated in certain climates. Nonetheless, woody crops showed a larger SOC gain on the whole than perennial grasslands (Figure 1).

In addition to the abovementioned factors, there are multiple, possibly interacting factors which affect SOC dynamics beyond the ones analyzed in this study, as indicated by the substantial unexplained variance in our data (Equation 4). Large variability among studies dealing with perennials has also been observed in previous studies (Aguilera et al., 2013; Vicente-Vicente et al., 2016). Some of the potential factors that are also likely to have impact and may improve the predictive capability of the model are management related: fertilizer application (type and rate), plant density, tillage, cover cropping, and other soil disturbances, but these could not be accounted for since there was not sufficient information across the dataset to model their effects. Along these lines, Vicente-Vicente et al. (2016) found that just by allowing the growth of spontaneous plant cover in the inter-row area and applying minimum tillage in Mediterranean orchards, an extra tonne of SOC per hectare and per year could be accumulated. Furthermore, the application of organic fertilizers and shredded pruning debris could increase this value by a factor of 3 to 4. The behavior of the perennial crop type in terms of above-ground biomass input production is also an important factor. Such as in Guava (*Psidium guajava*), leaf fall, bark fall, and also fruit falls in rainy season supply larger C input to soil in addition to the input from roots which helps in accumulation of 133 Mg/ha SOC stock in the top 2-m soil depth in a 31-year-old orchard situated in reclaimed sodic soil of northwest India (Datta, Basak, Chaudhari, & Sharma, 2015).

4.3 | SOC GLMM model caveats

The residuals from the GLMM showed an elevated Gaussian noise, but this was expected due to the large heterogeneity of the data, regarding experimental methods, biogeographic regions, crop types, and age among others. Yet, the predictors explained 20% of the dataset variance, across all crop types, indicating the difficultly associated with predictions of SOC at a global scale based on a purely empirical model with the currently available data. The available data are not only largely heterogeneous; in the light of our results, it becomes clear that more key information such as soil depth and management, which unfortunately are not always reported in studies (Aguilera et al., 2013).

We deliberately chose not to include crop type as a random effect, which indeed accounted for a notable proportion of the variance. There are two main reasons for this consideration; first, the intent was to derive a global/generic model to explain patterns of SOC changes under perennials, and not individual crop types. The dataset contains information on 58 crops at 709 locations (Ledo et al., 2019). Adding a random effect with 58 levels seems unreasonable. Second, and more importantly, many of the crops in the dataset were not duplicated (Ledo et al., 2019; Table S1), specifying crop type as random effect would be an obvious confounding factor.

The large heterogeneity of our dataset and neglecting some potentially important factors has not prevented us from revealing the robust observation that the SOC stocks under perennials are greater than under arable crops. In particular, we were not able to analyze changes in BD after and before perennials since those data were missing from the original dataset (see Ledo et al., 2019 for further details). We thus had to assume a fixed BD, while recommending that future experimental studies record BD before and after transition. Future data and studies might help to refine the estimates and regional distribution as driven by climatic, soil physico-chemical, and management differences across regions and crop types.

4.4 | Potential mechanisms of SOC accumulation in perennial crops

There are two ways of increasing C stock, either via increasing inputs or decreasing outputs. Soils that transition from annual to perennial crops may likely benefit from both: perennials produce more plant residues than annual crops (Ferchaud et al., 2016) and this extra organic matter consequently returns to the soil. Besides, soils under annual crops experience annual tillage or other frequent mechanical disturbances (Powlson et al., 2014), which allows faster decomposition of the SOC in upper layers. Perennials, in contrast, are disturbed usually only at the beginning of the life cycle and not during (Ledo et al., 2018), thus potentially avoiding SOC lost by mechanical soil treatments.

Perennials not only produce more plant residue than annual crops (Ferchaud et al., 2016) but also have the potential additional plant inputs from management interventions such us pruning and on-site retention of litter (Ledo et al., 2018). Rasse et al. (2005) assert that SOC is mainly derived from root C, from root exudates and fine root turnover. The fine root biomass, which typically has a fast turnover, is likely to be soon lost to the atmosphere as CO_2 (Glover, Culman, et al., 2010). However, perennial crops develop larger roots that penetrate and develop fine roots deeper in the soil. Root residues at deeper horizons are less subject to oxidation and thus more likely to remain as SOC in the soil. Additionally, root penetration changes soil texture (Reynolds, Bowman, Drury, Tan, & Lu, 2002) and thus potentially creates a larger and deeper rhizosphere which in turn may increase root exudates and thus soil microbial interactions (Huang et al., 2014), resulting in more C being captured in soil aggregates (Kutsch et al., 2009; Stockmann et al., 2013). In addition, the rhizomes of perennial grasses are known to be important contributors of organic matter and exudates to the soil (Zatta, Clifton-Brown, Robson, Hastings, & Monti, 2014), which would result in an increase in SOC.

The linear trend of SOC stock changes shows an increasing trend (Figure 1a). However, it can be seen that a minor SOC gain is followed by SOC loss for a period of a few years, and only after this does SOC start to consistently accumulate year-on-year (Figure 1c). This observed SOC gain has a subsequent levelling off of SOC accumulation rate and a decline when it stabilizes and reaches a steady state (Figure 1c), which is consistent with the acknowledged patterns of SOC accumulation (Smith, 2014), and also observed in agroforestry systems (Feliciano, Ledo, Hillier, & Nayak, 2018). This might be attributed to the so-called priming effect (Thiessen, Gleixner, Wutzler, & Reichstein, 2013; Wutzler & Reichstein, 2013), or to the disturbance produced when planting perennials (Smith, 2004) or a combination of both, since these are not mutually exclusive.

Another of the conclusions of our study is that the lack of annual soil disturbance contributes to SOC increase. The lack of frequent mechanical interventions may not only reduce SOC losses, but also C inputs to the soil may increase if the herbaceous layer is not removed. However, the soil of some woody cropping systems is kept permanently bare, and if this is the case, it reduces SOC even in no-till treatments (Aguilera et al., 2013). Furthermore, SOC protection mechanisms should also be considered. The physical protection (i.e., organic C within soil microaggregates) isolates the organic C from the activity of the soil microorganisms, preventing its mineralization. SOC physical protection is also affected by tillage (Vicente-Vicente et al., 2017), because of the disruption of the macroaggregates, precursors of soil microaggregates (Six, Bossuyt, Degryze, & Denef, 2004). This may be another mechanism that favors SOC accumulation under perennial crops, due to the lack of mechanical intervention. Another protection mechanism is chemical protection (Six et al., 2002). However, the chemical protection depends mainly on the chemical soil properties (e.g., pH) and, therefore, the management is supposed not to have a large effect on it and may not be a different between annual and perennial crops in this regard.

4.5 | Emission factor of LUC, potential of perennials as climate change mitigation tools, and food security allies

The IPCC (2014) guidelines for preparing GHG emissions inventories provide a default value of 1 as the relative stock change in SOC over a 20-year period in the top 30 cm after conversion from any land use to perennials crops (volume 4, section 5 croplands, tables 5.5 and 5.10), with an uncertainty of 50%. Results from this study suggest that this value can be refined to 1.12, since overall perennial crops accumulate SOC (Figure 1), leaving 50% uncertainty to be conservative. To be more precise, it should be 1.12 for woody plants and 1.06 for perennial grasses (Figure 2; Appendix S1). Furthermore, this study revealed a relative stock change of 1.2 in the case of a change from annual to perennial crop (Table 1). This is not, strictly speaking, a change in land use, since the land use is arable in both cases. However, as the 1.2 value is relevant and important, we suggest that a subcategory may be added and considered in further assessments and recommendations. Similarly, the default value from grasslands and forest would be 1, since we did not find significant differences (Table 1).

A second recommendation for GHG factors and C stock benchmarks is to consider using a soil profile of 0–100 cm depth in future assessments. This study highlights the importance of the SOC stocks stored deeper than 30 cm. This considering only the top 30 cm may favor practices and crops which concentrate SOC in the top 30 cm rather than sequester C across a more relevant profile.

Overall, perennial crops accumulate SOC through time (Figure 1), and a change from annual to perennial crop will lead to a SOC increase during at least 20 years (Table 1). Furthermore, perennial crops have been suggested as a tool to increase food security and ecosystem functioning (Glover, Reganold, et al., 2010). Aside from increasing SOC stocks, perennials could also contribute to reducing soil erosion (Glover, Culman, et al., 2010), and with the potentiality to contribute to food security improvement (Lal, 2004). A significant reduction in soil erosion has been reported when the main crop is accompanied by a cover crop and thus bare soil is avoided (Aguilera et al., 2013; Gómez et al., 2011). A second important climate change mitigation option in perennial crops is adding crop residues back to the ground; perennials produce more plant residues than annual crops (Ferchaud et al., 2016) which inputs extra organic C to the soil. Alongside, bioenergy crops aside from being climate change mitigation tools in the field by increasing SOC (Dondini et al., 2009; Robertson et al., 2017), they usually have an overall GHG reduction benefit favorable when compared with other crops (Whitaker et al., 2018), and also they bring an extra GHG reduction when they are used to replace fossil fuels and may thus contribute to the transition to a low C economy (Qin et al., 2016).

Perennial crops have therefore the potential to be a climate change mitigation, by resulting a negative C balance system or at least storing some C in the ground and thus reducing atmospheric CO_2 concentration. Nonetheless there are some important limitations and the C gain cannot be considered as a universal statement and recipe for C sequestration by itself. Additionally, while some management practices such as reduced- or no-tillage may reduce SOC losses, additional agricultural practices may be required so the full life cycle needs to be considered (Schlesinger & Amundson, 2019). Plant residue management is also important, that is, burning tress at the end of the crop cycle results in net GHG emissions (Ledo et al., 2018). In this case, the C stored in the ground during the perennial plantation may be lower than the C and other GHGs emitted during the combustion, thus resulting in net positive emissions from the plantation. In contrast, using perennials in restoration of degraded agricultural lands, either on their own or in agroforestry combination, can provide additional benefits via coproducts, thus potentially contributing to food security and local economies.

ACKNOWLEDGEMENTS

This study was initially funded by the NERC project (NE/N017854/1). It was further developed and finished thanks to the support of the SEPE-Madrid to A.L. The input of P.S. contributed to the following projects: DEVIL [NE/M021327/1], U-GRASS [NE/M016900/1], Assess-BECCS [funded by UKERC], Soils-R-GRREAT [NE/P019455/1], and the CIRCASA project which received funding from the European Union's Horizon 2020 Research and Innovation Programme under grant agreement no. 774378. Global patterns of the effects of land-use changes on soil carbon stocks

Lei Deng, Guang-yu Zhu, Zhuang-sheng Tang, Zhou-ping Shangguan *

State Key Laboratory of Soil Erosion and Dryland Farming on the Loess Plateau, Northwest A&F University, Yangling, Shaanxi 712100, China

HIGHLIGHTS

- Soil C sequestrations varied in different land use change types.
- Soil C sequestration dynamics were not determined by age at the global level.
- Globally, land use conversions have significantly reduced soil C stock.

ABSTRACT

Despite hundreds of field studies and at least a dozen literature reviews, there is still considerable disagreement about the direction and magnitude of changes in soil C stocks with land use change. This paper reviews the literature on the effects of land use conversions on soil C stocks, based on a synthesis of 103 recent publications, including 160 sites in 29 countries, with the aims of determining the factors responsible for soil C sequestration and quantifying changes in soil C stocks from seven land use conversions. The results show that as an overall average across all land use change examined, land use conversions have significantly reduced soil C stocks (0.39 Mg ha^{-1} yr^{-1}). Soil C stocks significantly increased after conversions from farmland to grassland (0.30 Mg ha^{-1} yr^{-1}) and forest to grassland (0.68 Mg ha^{-1} yr^{-1}), but significantly declined after conversion from grassland to farmland (0.89 Mg ha^{-1} yr^{-1}), forest to farmland (1.74 Mg ha^{-1} yr^{-1}), and forest to forest (0.63 Mg ha^{-1} yr^{-1}). And after conversion from farmland to forest and grassland to forest, soil C stocks did not change significantly. Globally, soil C sequestration showed a significant negative correlation with initial soil C stocks ($P<0.05$), and the

effects of climatic factors (mean annual temperature and mean annual precipitation) on soil C sequestration varied between the land use conversion types. Also, the relationships between soil C sequestration and age since land use conversion varied in different land use change types. Generally, where the land use changes decreased soil C, the reverse process usually increased soil C stocks and vice versa. Soil C sequestration dynamics were not determined by age since land use conversion at the global level when all land use change types were combined.

1. Introduction

The terrestrial biosphere can act either as a source or as a sink for atmospheric CO_2, both the vegetation and the soil may play a part in the residual terrestrial uptake (IPCC, 2000; Guo and Gifford, 2002). Organic carbon stored in the world's soils is the largest terrestrial pool of carbon, and is at least three times larger than the pool of atmospheric carbon dioxide (Jobbágy and Jackson, 2000; Amundson, 2001). It has long been recognized that land-cover change and management can alter the amount of organic carbon stored in the soil (Laganière et al., 2010; Deng et al., 2014a), and this in turn affects both soil fertility and atmospheric carbon dioxide (CO_2) concentrations (Powers et al., 2011). Although the contributions of land-cover change to anthropogenic CO_2 atmospheric emissions have recently been revised downward, the estimated current annual contribution of 1.2 Pg, or about 12%–15% of total anthropogenic fluxes, is still significant (Van der Werf et al., 2009). Therefore, a new challenge in the context of climate change mitigation is the management of terrestrial ecosystem to conserve existing carbon stocks and to remove carbon from the atmosphere by adding to stocks.

Land use change can cause a change in land cover and an associated change in carbon stocks (Bolin and Sukumar, 2000; Deng et al., 2014a,b). The change from one ecosystem to another could occur naturally or be the result of human activity. Each soil has a carbon carrying capacity, and an equilibrium carbon content depending on the nature of vegetation, precipitation and temperature (Jobbágy and Jackson, 2000). The equilibrium between carbon inflows and outflows in soil is disturbed by land use change until a new equilibrium is eventually reached in the new ecosystem (Guo and Gifford, 2002). During this process, soil C stocks would have been changed, either as a carbon source or as a carbon sink. Despite hundreds of field studies and dozens of literature reviews, there is still considerable disagreement on the direction and magnitude of changes in soil C stocks with land-use change (Van der Werf et al., 2009). Indeed, the current knowledge remains inconclusive on both the magnitude and direction of C stock changes in mineral soils associated with land use type, management and other disturbances, and cannot support broad generalizations (IPCC, 2006).

Recently, some studies have reviewed the effects of certain land use changes on soil C stocks, for example, Post and Kwon (2000) found an average rate of soil C accumulation after afforestation of former farmlands with the value of 0.338 Mg ha^{-1} yr^{-1} although values vary greatly among studies, however, Vesterdal et al. (2002) observed that afforestation of former farmlands did not lead to increase of SOC in three decades. In addition, for a tropical regions study, the conversion of forests to farmland reduced soil C stocks by an average of 15.4% or 18.5%, respectively. Interestingly, both the conversions of forests to grassland and grassland to secondary forests increased soil C stocks, and the establishment of perennial tree plantations on lands that were previously grazed or cropped increased soil C stocks, but the conversion of unmanaged forests, or grasslands to plantations had no effect (Powers et al., 2011). Globally, although Guo and Gifford (2002) concluded that soil C stocks significantly increased after the conversion from farmland to grassland (19%), tree plantation (18%) and secondary forest (53%), they uses a relative percentage change. In order to understand how C stocks change after land use conversions, the changes need to be recalculated as absolute values to meet the challenge of managing soil C stocks world-wide and to help understand the contribution of carbon emissions due to land use change to the global climate change.

In addition, understanding the factors that govern the size of the current land carbon stock and the balance between plant carbon inputs and soil carbon losses is crucial to predicting the effects of future land use change on the net greenhouse gas balance, and to the development of policy for 'carbon conscious' management of the land surface. Although several authors (Post and Kwon, 2000; Paul et al., 2002; Laganière et al., 2010) have analyzed the factors determining soil C stocks during the establishment of perennial vegetation, a consensus on the relative significance of these factors has yet to be achieved. While Paul et al. (2002) found that climate is one of the most important factors influencing soil C change after cropland conversion, Laganière et al. (2010) concluded that climate had a smaller effect on soil C accumulation during afforestation when compared to previous land use, tree species planted, soil clay content and preplanting disturbance. However, at a global scale, we had difficulties in getting access to many factors that may influence the soil C stock after land use change from the existing field studies, except for climatic factors, so this paper mainly analyzed the effects of mean annual precipitation and temperature on soil C sequestration after land use conversions, as was done by other national or global studies (Guo and Gifford, 2002; Paul et al., 2002; Yang et al., 2011).

The objectives of this study were: (1) explore the effect of various land use changes on soil C sequestration; (2) establish the temporal pattern of soil C sequestration for different land use changes; and (3) study those factors driving the changes in soil C. To achieve these objectives we synthesized the findings of 103 recent publications from the literature in which

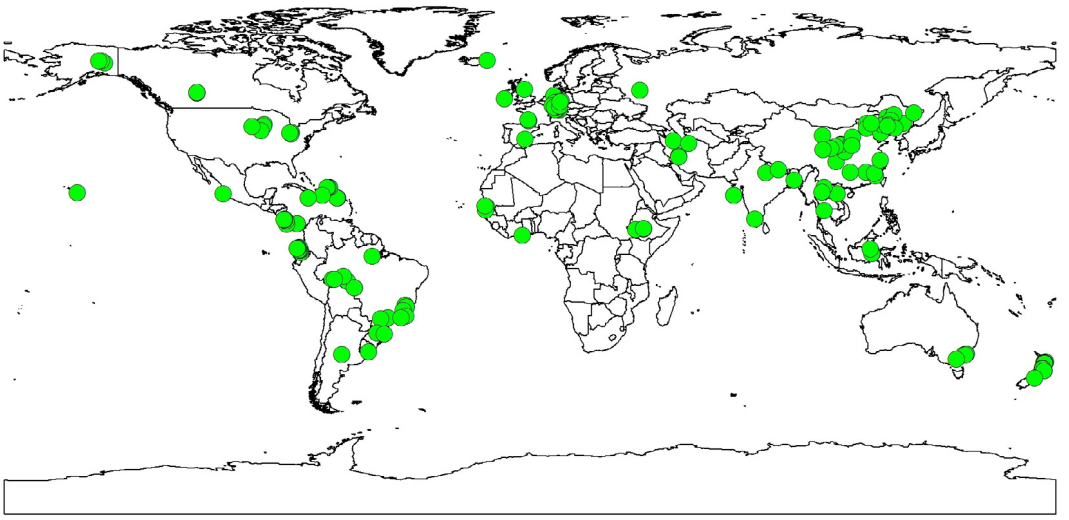

Fig. 1. Global sampling sites distribution of observed soil C change after land use conversions in the collected dataset.

seven land use conversions (from farmland to forest, from forest to farmland, from farmland to grassland, from grassland to farmland, from grassland to forest, from forest to grassland, from forest to forest) were related to changes in soil C values.

2. Materials and methods

2.1. Data preparation

We compiled data from the literature on the influence of land use change on soil C stocks and characterized each study according to the following categories of land use change: from farmland to forest, from forest to farmland, from farmland to grassland, from grassland to farmland, from grassland to forest, from forest to grassland, from forest to forest. The following criteria were used to select papers for synthesis: soil C stocks were provided or could be calculated based on SOC or SOM concentration, bulk density and soil depth; there were data on both the immediate land use (LUn) and the prior land use (LU0); the experiments used paired sites, chronosequences or retrospective designs, had similar soil conditions for both LUn and LU0; the number of years since land use conversion were either clearly given or could be directly derived. In the studies, only the first rotation of land use conversion was considered and data for 0–20 cm soil layers were extracted (Appendix Dataset S1). In addition, studies were excluded if they lacked replications or if the paired sites or sites of chronosequence were confounded by different soil types. In total, the final dataset comprised 103 studies (Appendix Table S1) most of them published between 2000 and 2014, and three studies published in 1994, 1997 and 1999, respectively, including 424 observations at 160 sites in 29 countries (Appendix Table S2) (Fig. 1). In the current study, the definition of forest is native forest before it is cleared for other land use. Pasture is land used for grazing purposes including natural grassland. Farmland includes lands cultivated for food products. The current forest is the plantation forest by human establishment. The ages of land use conversions were divided into four groups, as follows: 0–10, 11–20, 21–30, and >30 yr.

The raw data were either obtained from tables or extracted by digitizing graphs using the GetData Graph Digitizer (version 2.24, Russian Federation). For each paper, the following information was compiled: sources, location (longitude and latitude), climatic data (mean annual temperature and precipitation), land-use conversion types (including both prior and current land use types), age (years since land use conversion), soil depth from soil surface, soil bulk density, and amount of SOC or soil C stocks in each layer of 0–100 cm soil (Appendix Dataset S2).

2.2. Data calculation

If the samples reported only had SOM, their SOC were calculated by the relation between SOM and SOC. The formula for the calculation is as follows (Guo and Gifford, 2002):

$$\mathrm{SOC} = \mathrm{SOM} \times 0.58 \tag{1}$$

where SOC is the soil organic carbon and SOM is the soil organic matter.
The SOC stocks was calculated using the following equation (Guo and Gifford, 2002):

$$C_s = \frac{\mathrm{SOC} \times \mathrm{BD} \times \mathrm{D}}{10} \tag{2}$$

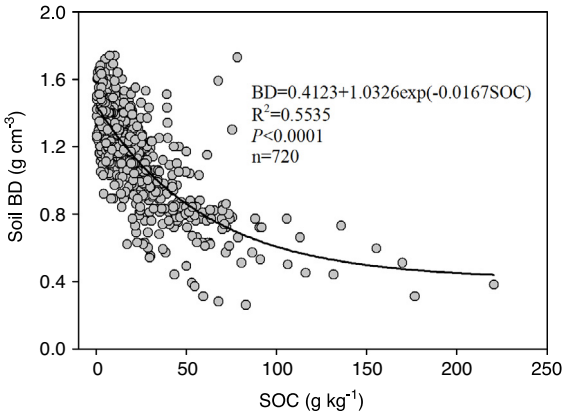

Fig. 2. Empirical functions for estimating the missing soil BD based on data from studies reporting SOC concentration and soil BD.

in which, C_s is soil organic carbon stocks (Mg ha^{-1}); SOC is soil organic carbon concentration (g kg^{-1}); BD is soil bulk density (g cm^{-3}); and D is soil thickness (cm).

Soil BD estimates are critical for calculations of C_s, but many studies did not measure this attribute. We established an empirical relationship between soil BD and SOC concentration with the reported values from the Appendix Dataset S2 (Fig. 2). Then, the missing values of soil BD were interpolated using the predicted values from the empirical functions in Fig. 2. The formula for the calculation is as follows (Eq. (3)):

$$\mathrm{BD} = 0.4123 + 1.0326e^{-0.0413\mathrm{soc}}. \tag{3}$$

Although it is desirable to compare changes in soil C stocks between land uses based on common soil mass rather than on volume because of compaction, it is impossible for us to correct data for all these studies, as not all the studies reported bulk densities, especially bulk densities for different soil depths. Thus, similar to other meta-analysis (Guo and Gifford, 2002; Laganière et al., 2010; Powers et al., 2011), we did not adjust reported data to a common mass, but we used mass-corrected soil C stocks when authors presented them. Not adjusting for an equivalent mass of soil could only result in a slight bias in the estimation of changes in soil C stocks, which is supported by our data and also by other studies (Laganière et al., 2010).

To increase the comparability of data derived from different studies, the methodology adopted by Yang et al. (2011) was used in the present study. The original soil C data were converted to the soil C stocks in the top 20 cm using the depth functions developed by Jobbágy and Jackson (2000) according to the following equations:

$$Y = 1 - \beta^d \tag{4}$$

$$X_{20} = \frac{1-\beta^{20}}{1-\beta^{d0}} \times X_{d0} \tag{5}$$

where Y represents the cumulative proportion of the soil C stocks from the soil surface to depth d (cm); β is the relative rate of decrease in the soil C stocks with soil depth; X_{20} denotes the soil C stocks in the upper 20 cm; $d0$ denotes the original soil depth available in individual studies (cm); and X_{d0} is the original soil C stocks. For soil C, although Jobbágy and Jackson (2000) provided the depth distributions for 11 biome types globally, there was no significant difference ($P > 0.98$), ANOVA LSD test using PASW 18 (SPSS Inc., Chicago, IL, USA) in the depth distribution among biome types or between individual biomes and the global average. Therefore, in this study, the global average depth distributions for C were adopted to calculate the value of β (0.9786) in Equations.

It should be noted that potential uncertainties may be introduced by this dataset standardization, mainly as a result of the difference in C distribution over the soil profile between prior land use types and immediate land use sites, and among different stages of vegetation (forest, shrub and grassland) development. However, as has been stated, there was no significant difference among the 11 biome types included in Jobbágy and Jackson (2000) or between individual biomes and the global average in terms of the soil C distribution with depth. The same method (i.e., converting the original C stocks to the stocks in the top 20 cm using the depth functions in order to increase comparability) was used by Yang et al. (2011) and Li et al. (2012), and it was concluded that depth correction did not alter the overall pattern of soil C stocks dynamics during vegetation development.

C sequestration rate is estimated depending on the changes of soil C stocks in different time sequences of time. The study set the C stocks of prior land use types as the baseline for calculating the rate of C stocks change in the restoration process after land use conversions. We first calculate the carbon sequestration (Mg ha^{-1}) in every site after land use conversion (Eq. (6)),

$$\Delta C_s = C_{LUn} - C_{LU0} \tag{6}$$

in which, C_{LUn} is represent soil carbon stocks at immediate land use sites (Mg ha^{-1}), and C_{LU0} is soil carbon stocks of prior land use types before land use conversion (Mg ha^{-1}).

We used mean annual absolute rate of change in soil C stock to indicate soil C sequestration rate (R_s, Mg ha^{-1} yr^{-1}). The calculated equation is as follows:

$$\text{Soil C sequestration rate (Mg ha}^{-1}\text{ yr}^{-1}) : R_s = \frac{\Delta C_s}{\Delta Age}. \tag{7}$$

In order to reflect the dynamics of soil C stocks, soil C sequestration were summed for each category. In this case, a methodology reported previously (Luo et al., 2006, 2009) was used to calculate 95% CI of means for soil C sequestration, as shown in Eqs. (8) and (9):

$$SE_{total} = \sqrt{\frac{V_S}{N}} \tag{8}$$

$$95\%\ CI = 1.96 \times SE_{total} \tag{9}$$

where SE_{total} denotes the standard error of the relative change in soil C stock. V_S and N are the variance of relative soil C stock change and the number of observations, respectively. In this study, the 95% confidence interval (CI) was calculated for the overall data and for each category. And the observed effect sizes are considered statistically different from zero if the 95% CI does not include zero, and the grouping factors are considered significantly different from each other if their 95% CI does not overlap.

2.3. Data analysis

ANOVA results of the effects of land use conversions, years since land use conversion (Age), and their interactions on soil C sequestration in different land use conversion types with general linear model (GLM) tests. Differences were evaluated at the 0.05 significance level. Stepwise regression analysis was used to analysis the relationship between soil C sequestration (ΔC_s) and mean annual temperature (MAT), mean annual precipitation (MAP), age since land use conversions (Age), and initial soil C stocks (I) in each land use conversion types. Pearson correlation coefficients between soil C sequestration and various other factors (Age, I, MAT, and MAP) were determined following land-use conversions. All statistical analyses were performed using the software program SPSS, ver. 17.0 (SPSS Inc., Chicago, IL, USA).

3. Results

3.1. Global patterns of soil C stock changes due to land use conversions

As an overall average across all land use change examined, land use conversions had significantly reduced soil C stock (−2.52 Mg ha^{-1}, rate = 0.39 Mg ha^{-1} yr^{-1}) (Fig. 3). However, not all land use conversions have reduced soil C stock. Soil C stocks significantly increased after the conversion from farmland to grassland (+6.16 Mg ha^{-1}, rate = 0.30 Mg ha^{-1} yr^{-1}), forest to grassland (+11.53 Mg ha^{-1}, rate = 0.68 Mg ha^{-1} yr^{-1}) (Fig. 3). Soil C stocks had significantly declined after the conversion from grassland to farmland (−12.45 Mg ha^{-1}, rate = 0.89 Mg ha^{-1} yr^{-1}), forest to farmland (−21.05 Mg ha^{-1}, rate = 1.74 Mg ha^{-1} yr^{-1}) and forest to forest (−12.28 Mg ha^{-1}, rate = 0.63 Mg ha^{-1} yr^{-1}) (Fig. 3). The highest soil C stock increases occurred in land-use conversions from forest to grassland, and soil C stocks declined the most after conversion from forest to farmland. After conversions of farmland to forest and grassland to forest, soil C stocks did not change significantly (Fig. 3).

3.2. Temporal patterns of soil C stocks after land use conversions

Overall, after land use conversions, the differences in soil C sequestration were not significant among different age groups ($P > 0.05$) (Table 1), but soil C sequestration changes fluctuated over time (Fig. 4). With the land-use change from farmland to grassland, soil C sequestration change was not significant during 0–10 years, and then it was significantly increased (Fig. 5(A)). Soil C sequestration had significantly difference among different age groups ($P < 0.01$) (Table 1). With the land-use change from grassland to farmland, soil C sequestration had not significantly difference among different age groups ($P > 0.05$) (Table 1). Soil C stocks had been reducing in the first 30 years (0–30 yr), and then soil C stock began to increase (>30 yr) (Fig. 5(B)), however, soil C stock still reduced compared to the initial soil C stock. With the land-use change from farmland to forest, soil C sequestration had significant differences among different age groups ($P < 0.01$) (Table 1). Soil C sequestration was significantly reduced in the first 10 years (0–10 yr), and then it was significantly increased (>10 years) (Fig. 5(C)). With the land-use change from forest to farmland, soil C sequestration had no significant difference among different age groups ($P > 0.05$) (Table 1). Soil C stock was similar to the conversion from grassland to farmland that soil C stocks had been reducing in the first 30 years (0–30 yr), and then soil C stock began to increase (>30 yr) (Fig. 5(D)). With the land-use change from grassland to forest, soil C sequestration had significant differences among different age groups

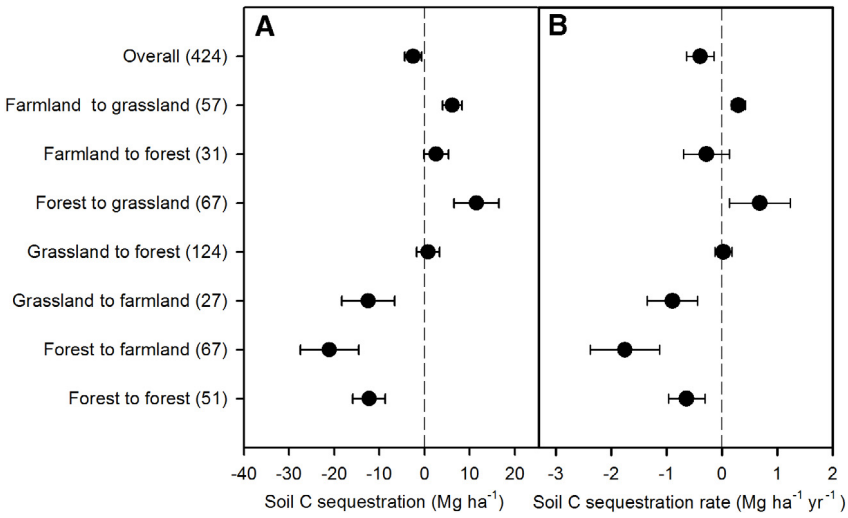

Fig. 3. The effects of the land use changes on soil C sequestration and soil C sequestration rate. Note: dots with error bars denote the overall mean values and the 95% CI, and numbers of observations are in the parenthesis. The dash line indicates $x = 0$.

Table 1
ANOVA results of between-subjects effects of years since land use conversion (Age), and their interactions on soil C sequestration in different land use conversion types (LUE) with general linear model (GLM) tests.

Land use change types	Source	df	F	Sig. (P)
Farmland to grassland	Age	3	11.793	0.000**
Grassland to farmland	Age	3	0.973	0.422
Farmland to forest	Age	3	13.535	0.000**
Forest to farmland	Age	3	1.331	0.272
Grassland to forest	Age	3	4.451	0.005**
Forest to grassland	Age	3	2.883	0.043*
Forest to forest	Age	3	3.953	0.014*
	LUE	6	27.565	0.000**
Overall	Age	3	2.307	0.076
	LUE × Age	18	2.361	0.001**

Note: Age were divided into four groups, as follows: 0–10, 11–20, 21–30, and >30 yr.
* Indicates significant at $P < 0.05$.
** Indicates significant at $P < 0.01$.

($P < 0.01$) (Table 1). Soil C stock was not significantly reduced in the first 10 years, and then it was significant increased (11–20 yr), but it also tended to significantly reduce from 21 to 30 years, and then increase after 30 years (Fig. 5(E)). With the land-use change from forest to grassland, soil C sequestration had significant differences among different age groups ($P < 0.05$) (Table 1). Soil C stock was increased after land use conversion (Fig. 5), especially after conversion for more than 30 years, soil C stock increased 24.40 Mg ha^{-1} compared with the initial soil C stock (Fig. 5(F)). With the land-use change from forest to forest, soil C stock was reduced especially after more than 30 years (−19.45 Mg ha^{-1}) (Fig. 5(G)). And soil C sequestration had significant differences among different age groups ($P < 0.05$) (Table 1).

3.3. Factor effects on soil C stocks

Pearson correlations analysis showed that in different age groups, the factors affecting soil C sequestrations were different (Table 2). However, after land use conversions, soil C sequestration had significant negative correlations with the initial soil C stocks in every land use conversion type ($P < 0.05$) (Table 2). In addition, after the conversion of farmland to grassland and forest, soil C sequestration also had significant positive correlations with the age since land use conversion, but it showed negative correlations after the conversion of forest to forest (Table 2). For the conversion of grassland to forest, soil C sequestration also had significant positive correlations with MAT (Table 2).

Stepwise regression revealed that different land use conversion types had different impact factors (Table 3). The age since land use conversion had significant effects on soil C sequestration after the conversion of farmland to grassland, farmland to forest, and forest to forest (Table 3); the initial soil C stock was the main factor affecting soil C sequestration after the conversion of grassland to farmland, forest to farmland and grassland to forest (Table 3); and climatic factors (MAT and MAP) were the main factors affecting soil C sequestration after the conversion of forest to grassland (Table 3). However, for

all land use conversions, the initial soil C stocks and climatic factors had significant effects on soil C sequestration after land use conversions, particularly the initial soil C stocks (Table 3).

Table 2
Pearson correlation coefficients between soil C sequestration and factors: age after land use conversion (Age), initial soil C stocks (I), mean annual temperature (MAT), mean and annual precipitation (MAP) following land-use conversions.

** Indicates significant at $P < 0.01$.

4. Discussion

4.1. Effects of land use changes on soil C stocks

Globally, land-use change can cause a change in soil C stock (Fig. 3). As an overall average across all land use change examined, land use conversions had significantly reduced soil C stock (-2.52 Mg ha^{-1}) (Fig. 3(A)). Similarly, Guo and Gifford (2002) reported land use changes reduced soil C stocks by 9%, but their study only showed the relative percentage change, not the absolute change in soil C sequestration after land use conversions, so our study fills this gap. Guo and Gifford (2002) also reported that soil C stocks decline after land use changes from grassland to plantation (-10%), native forest to plantation (-13%), native forest to farmland (-42%) and grassland to farmland (-59%), and soil C stocks increase after land use changes from native forest to grassland ($+8$%), farmland to grassland ($+19$%), farmland to plantation ($+18$%), and farmland to secondary forest ($+53$%). In our study, soil C stocks significantly increased after the conversion from farmland to grassland ($+6.16$ Mg ha^{-1}) and forest to grassland ($+11.53$ Mg ha^{-1}) (Fig. 3(A)), and soil C stocks significantly declined after the conversion from grassland to farmland (-12.45 Mg ha^{-1}), forest to farmland (-21.05 Mg ha^{-1}) and forest to forest (-12.28 Mg ha^{-1}) (Fig. 3(A)). In addition, after conversion of farmland to forest and grassland to forest, soil C sequestration had no significant change, (Fig. 3(A)), which is similar with the study of Powers et al. (2011), which reported that the conversion of unmanaged forests, grasslands, or savannas to plantations had no effect in the tropical regions. And Powers et al. (2011) also reported that the conversion of forests to shifting cultivation or permanent crops reduced soil C stocks by an average of 15.4% or 18.5%, respectively, and interestingly, both the conversions of forests to pastures and pastures to secondary forests increased soil C stocks, and the establishment of perennial tree plantations on lands that were previously grazed or cropped increased soil C stocks. Generally, where the land use changes decreased soil C, the reverse process usually increased soil C stocks and vice versa.

In addition, despite the considerable soil C sequestration potential that afforestation offers, many studies have reported contradictory findings. Afforestation resulted in either a decrease (Farley et al., 2004) or an increase in soil C stocks (Lemma et al., 2006), or had a negligible effect (Smal and Olszewska, 2008). Also, at the global scale, we found similar patterns (Fig. 3): decline (forest to forest); increase (farmland to forest), and unchanged (grassland to forest). At the national scale, Deng et al. (2014a) calculated the average soil C sequestration rate in the top 20 cm soil to be 0.33 Mg ha^{-1} yr^{-1} following perennial vegetation establishment (mainly forest and shrub) from cropland in China. In addition, the global average soil C sequestration rates following the conversion of cultivated land to forest, shrub and grassland are 0.45, 0.47 and 1.1 Mg ha^{-1} yr^{-1}, respectively (IPCC, 2000; Vleeshouwers and Verhagen, 2002; Shi et al., 2013). In contrast, after the conversion from forest to farmland, a significant decline in soil C stocks was found in many studies (Guo and Gifford, 2002; Murty et al., 2002; Wei et al., 2014). For example, Wei et al. (2014) reported that the largest decrease in soil C stocks was observed in temperate regions (-52%) followed by tropical regions (-41%) and boreal regions (-31%), and for the global scale, soil C stocks declined about 43.1% compared to prior forest land; and the 30% decrease observed by Murty et al. (2002). Also, with the conversion from grassland to farmland, similar pattern was observed, where soil C stocks declined after land use conversion (Fig. 3).

4.2. Temporal changes in soil C stocks after land use conversions

Globally, as an overall average across all land use changes examined, the changes in soil C sequestration with age were not significant ($P > 0.05$). For a specific land use conversion type, in contrast, age since land use conversion can effect soil C sequestration. In our study, soil C sequestration was significant different among different age groups in 5 of 7 land use conversion types (Table 1). Deng et al. (2014a) reported after the conversion from farmland to forest, soil C stocks showed an initial loss in soil during the first few years ($\sim$5 yr), followed by a gradual return of C stocks to levels comparable to those in the control agricultural soil, and then increasing to generate net C gains in some cases; similar temporal patterns of soil C stock changes following farmland conversion have been reported in a number of studies (Turner et al., 2005; Ritter, 2007; Karhu et al., 2011). The duration of the initial decrease in C was reported to last for 3–35 years following agricultural abandonment and there was a significant net accumulation of soil C by 30 years after afforestation (Paul et al., 2002). Nevertheless, Wei et al. (2014) observed that the conversion of forests to agricultural land caused a rapid initial decrease in SOC stocks, followed by a slow decline. In addition, with afforestation on grassland, soil C stocks showed the trend of declined–increased–declined–increased following time (Fig. 5(E)). The possible mechanism was that due to afforestation activity, soils of the previous grassland suffered human disturbance, leading to soil C loss due to strong soil respiration, and following forest development, soil C input into the soils was increased, especially understory vegetation biomass input into the soils, then the forest coverage increased, understory vegetation biomass decreased, so leading to soil C loss again, but then forest litter and dead roots input into the soil were increased, so soil C stocks increased again. In contrast, after the forest was converted to grassland, soil C stocks have been increased on the whole (Fig. 5(F)). However, after afforestation on native forest, soil C stocks were always lower than the values in a comparable natural forest, which agrees with the finding of Smal and Olszewska (2008). For the conversion from farmland to grassland, soil C stocks have been increased after farmland abandonment, which was supported by some studies (Mensah et al., 2003; Nelson et al., 2008; Deng et al., 2013; De Baets et al., 2013; Deng et al., 2014b,c). For example, De Baets et al. (2013) found a logarithmic increase since farmland abandonment. On the contrary, after the conversion from grassland to farmland, soil C stocks had been reducing

in the first 30 years (Fig. 5(B)). The temporal patterns were similar to the conversion from forest to farmland (Fig. 5(D)). Houghton (2003) indicated that clearing forests for new agricultural land caused a release of carbon to the atmosphere. The carbon initially held in trees and other vegetation is released through decomposition of above- and below-ground plant material left in the soil at the time of clearing. Even if the productivity of the new farmland is as high as it was in the forest or grassland, less of the crop production accumulates as litter, most of it is harvested and subsequently consumed or respired. Hence, the process of the conversion from forest or grassland to farmland and management afterward reduces carbon input from litter and enhances the carbon output via breaking the protection of soil organic matter (Guo and Gifford, 2002). For example, Aslam et al. (1999) found that adoption of no-tillage could protect soils from biological degradation and maintain soil quality as compared with plow tillage management after land use change from grassland (pasture) to farmland. However, through long term tillage management, such as increased organic fertilizer input to the topsoil, soil C stock did not always decline. It could reach a new equilibrium point and gradually accumulate at a slower rate (Guo and Gifford, 2002). As in our study, after forest or grassland converted to farmland, soil C stock began to increase after 30 years of cultivation (Fig. 5(B), (D)).

4.3. Factors affecting soil C stocks

Soil C sequestration due to land use change is likely to be affected by multiple factors such as climatic condition, soil texture, site preparation and management, vegetation type, land use history, etc. (Post and Kwon, 2000; Paul et al., 2002; Vesterdal et al., 2002; Guo and Gifford, 2002; Laganière et al., 2010; Li et al., 2012; Shi et al., 2013; Deng et al., 2014). Many studies have reported that age since land use changes plays a consistent and key role in estimated soil C stocks (Guo and Gifford, 2002; Laganière et al., 2010; Li et al., 2012; Shi et al., 2013; Deng et al., 2014). For example, Shi et al. (2013) found that stand age can play an important role in carbon sequestration after afforestation of agricultural sites in the globe. Deng et al. (2014a) have reported that restoration age was the main factor affecting soil C stock change after cropland conversion in China. In our study, our results showed that after the conversion of farmland to grassland and forest, the age since land use conversion also had significant positive correlations with soil C sequestration, but also negative correlations with soil C sequestration after the conversion of forest to forest (Table 2), and for grassland to farmland, forest to farmland, grassland to forest, and forest to grassland, soil C sequestration had no significant correlations with the age since land use conversion (Table 2). Wei et al. (2014) have reported that soil C sequestration has significantly positive correlations with the age. Therefore, these results showed that the relationships between soil C sequestration and age since land use conversion varied between study scales and land use change types.

Climate may affect soil C accumulation through biotic processes associated with the productivity of vegetation and decomposition of organic matter (Li et al., 2012). At the global scale, the restoration of soil C stocks after afforestation was found to vary with climate (Laganière et al., 2010). Post and Kwon (2000) found a tendency for rates of soil C accumulation to increase from temperate regions to subtropical regions, and they inferred that the amounts of organic matter inputs which increased with temperature and moisture were the major factors determining the rate of accumulation. Our results show that soil C sequestration at a global scale had no significant correlation with mean annual temperature and precipitation ($P > 0.05$), but soil C sequestration is positively correlated with MAP, demonstrating that precipitation increases the magnitude of soil C sequestration after land use change, and negatively correlated with MAT, which may be because higher temperature leads to higher losses of soil carbon through decomposition of soil organic matter (Deng et al., 2014b). In addition, our results revealed that the effects of climatic factors (MAT and MAP) on soil C sequestration were closely related to the land use conversion type (Table 3). For example, soil C sequestration had significant positive correlations with MAT for the conversion of grassland to forest (Table 2), and MAT and MAP were the main factors affecting soil C sequestration after the conversion of forest to grassland (Table 3).

Moreover, for all land use conversions in the globe, soil C sequestration showed a significant negative correlation with initial soil C stocks ($P < 0.05$) (Table 2), which was the same with the studies on soil C sequestrations since farmland conversion (Zhang et al., 2010; Deng et al., 2014a). However, in a smaller study scale, i.e. the Loess Plateau, soil C sequestration showed a significant positive correlation with initial soil C stocks ($P < 0.05$) (Deng et al., 2014b). This may be related to the different decomposition rates to be found under the varying nutrient conditions associated with different climate regimes (Zhang et al., 2010; Deng et al., 2014b). The synthesis revealed that initial soil C stocks had strong relations with MAT and MAP (Zhang et al., 2010; Deng et al., 2014b). Also, in our study, we found that the initial soil C stocks and climatic factors (MAT and MAP) had significant effects on soil C sequestration after land use conversions, and were mainly affected by the initial soil C stocks (Table 3), a finding from which Vesterdal et al. (2002) had earlier inferred that slower rates of decomposition might make soil carbon storage increase faster in more nutrient-poor soils following afforestation, and vice versa.

4.4. Uncertainty analysis

This synthesis offers the most accurate estimate on soil carbon sequestration following land use change across the entire global. Strict accuracy is limited due to the uneven distribution of data collected in each category (Age group and land use change types). Additionally, many of the studies have no long term observations and consequently, these measurements may add to the uncertainty. In addition, in our study, we ignored the effect of bulk density substituting Eq. (3) (Fig. 2), i.e.,

the will be equal as long as SOC is the same. In reality, however, bulk density would not only be significantly different among different sites but also experience significant change after land use conversion within a site. Soil types also a limiting factor effecting on the relationship between SOC and soil bulk density. In spite of that, the concern of only the upper soil layer and soil carbon sequestration in the deeper soils also changed due to land use changes, so the problem of the only upper layer consideration have a high influence on the quantity of the result. In future, we should focus on the effects of land use change on deeper soil carbon sequestration to build a functional relationship between topsoil carbon sequestration and deeper soil carbon sequestration.

Abstract: The restoration of soil organic matter (SOM, as measured by soil organic carbon (SOC)) within the world's agricultural soils is imperative to sustaining crop production and restoring other ecosystem services. We compiled long-term studies on the effect of management practices on SOC from Iowa, USA—an agricultural region with relatively high-quality soil data—to highlight constraints on detecting changes in SOC and inform research needed to improve SOC measurement and management. We found that strip-tillage and no-tillage increased SOC by 0.25–0.43 Mg C ha^{-1} yr^{-1} compared to losses of 0.24 to 0.46 Mg C ha^{-1} yr^{-1} with more intensive tillage methods. The conversion of cropland to perennial grassland increased SOC by 0.21–0.74 Mg C ha^{-1} yr^{-1}. However, diversifying crop rotations with extended rotations, and supplementing synthetic fertilizer with animal manure, had highly variable and inconsistent effects on SOC. The improved prediction of changes in SOC requires: the use of methods that can identify and disentangle multiple sources of variability; looking beyond total SOC and toward systematic collection of data on more responsive and functionally relevant fractions; whole-profile SOC monitoring; monitoring SOC in long-term studies on the effect of multiple conservation practices used in combination; and deeper collaboration between field soil scientists and modelers.

1. Introduction

International efforts to limit global warming to 1.5 °C by 2100 are falling short of targets [1], leading to an increasing focus on CO_2 removal to meet climate goals [2,3]. Soil organic carbon (SOC) is an important component of the global carbon (C) balance, and increasing SOC is a form of CO_2 removal, though of limited durability (<100 years) [2]. Some argue that efforts to increase SOC for climate mitigation are misplaced given limitations on measuring and managing this pool [4], but the pace and impacts of anthropogenic climate change requires the consideration of all options. Furthermore, the low capacity and high price of more durable CO_2 removal technologies (e.g., direct air capture and C capture and storage) results in nearly all of the current estimated 2 Gt yr^{-1} of CO_2 removal being due to land management [2].

SOC associated with croplands is highly relevant because of the global extent of agriculture, which covers between 10% and 15% of the total ice-free land area of the Earth, and because these lands are already highly managed. Furthermore, increased SOC can improve the resilience of croplands to extreme weather events associated with anthropogenic climate change [5]. Increasing SOC storage can meet both climate change mitigation and crop production goals, and is aligned with farmers' long-term interests. Yet,

farmers' ability to simultaneously manage for both crop production and SOC storage has largely been undervalued until recently [6]. The importance of measuring, managing, and monetizing SOC is coming into clearer focus with the development of numerous private sector C programs [7–9], corporate net-zero claims requiring documentation of supply chain (i.e., Scope 3) emission reductions [10], USDA initiatives such as the Climate-Smart Commodities Partnership program [11], and provisions of the Inflation Reduction Act [12], such as tax incentives (45Z) for biofuel producers to lower their C intensity, including C impacts of their feedstocks.

SOC is the dominant constituent of soil organic matter (SOM) and C typically accounts for more than half of SOM's dry mass [13]. SOM affects the physical, chemical, and biological properties and functions of soil [14–16]. SOM increases the capacity of soils to store and provide water and nutrients to support plant growth [17]; influences soil structure, soil erosion, water quality, and food security; and decreases the negative impacts of human activities to ecosystems [14]. Paradoxically, some of the key benefits of SOM, such as supplying nitrogen to plants, rely on its continued degradation rather than its accumulation [18–20]. This paradox highlights the ongoing challenge of optimizing soil management with respect to increasing SOM. Developing scientifically sound recommendations for managing these dynamic processes and pools requires long-term experiments and large amounts of high-quality data.

There are numerous challenges and opportunities in achieving, maintaining, and measuring increases in SOC to achieve climate goals and restore soil functions. Our objectives were to consolidate and summarize data from previously published studies on the baseline SOC stocks and the long-term effect of common conservation practices on carbon sequestration as SOC in Iowa, USA, including the ability to detect change and rates of change in SOC, and compare these results to the global literature on SOC response to agricultural management. A further goal was to summarize key issues and associated challenges and opportunities to achieve the reliable, measurable, and sustainable storage of carbon in these soils. Our hope is that knowledge generated from Iowa, a relatively data-rich portion of the world, can facilitate more informed SOC data collection strategies elsewhere.

2. Iowa Soils and Agriculture

The US state of Iowa is widely known for its highly productive, high-organic-matter soils (Table 1, Figure 1). This soil environment has been produced by a nearly ideal intersection of climate, soil parent material, and native vegetation. The state has a humid continental climate with hot summers and cold winters. Mean annual precipitation ranges from 590 to 900 mm, and mean annual temperatures range from 6 °C to 10 °C. Much of the geologic parent material from which the soil was formed has a high silt content (median = 61%; [21]), resulting in soil textures that are silt loam, silty clay loam, or an adjacent texture class. A loamy soil, especially with silt's ideal particle size, provides abundant water-holding capacity at pressure potentials that are readily available for plant uptake. The silty and fine-textured particle size distributions of Iowa soils may also be partly responsible for large SOM stocks, as finer particle sizes promote more persistent SOC [22,23]. Before the 19th century, the native vegetation across much of the state was tallgrass prairie, dominated by diverse and deep-rooted grasses and forbs.

Table 1. Descriptive statistics for silt content (%), soil organic matter (%), and bulk density (g cm^{-3}) in Iowa from 0 to 30 cm as mapped in the USA's Soil Survey [21]. SOC stock was calculated by assuming a 2:1 ratio of SOM and SOC. Although SOC is known to exist below the topsoil (A horizon), this estimation of SOC stock focuses on the thickness of soil with visibly evident organic carbon accumulation as indicated by "mollic" colors.

Measure	Min	Max	Mean	STD	Median	90th Percentile
Silt (%)	1	90	54	15	61	71
Sand (%)	0	96	19	17	9.5	41
Clay (%)	0	60	27	6	28	34
SOM (%)	0	85	4	3	3	6
Bulk Density (g/cm^3)	0.2	1.7	1.3	0.1	1.3	1.5
Mollic Thickness (cm)	0	203	45	36	43	94
SOC Stock (Mg/ha)	0	2309	120	132	95	294

Note: Silt, sand, clay, SOM, and bulk density are based on 0–30 cm data. Mollic thickness and SOC stock are variable, with stock being variable with thickness.

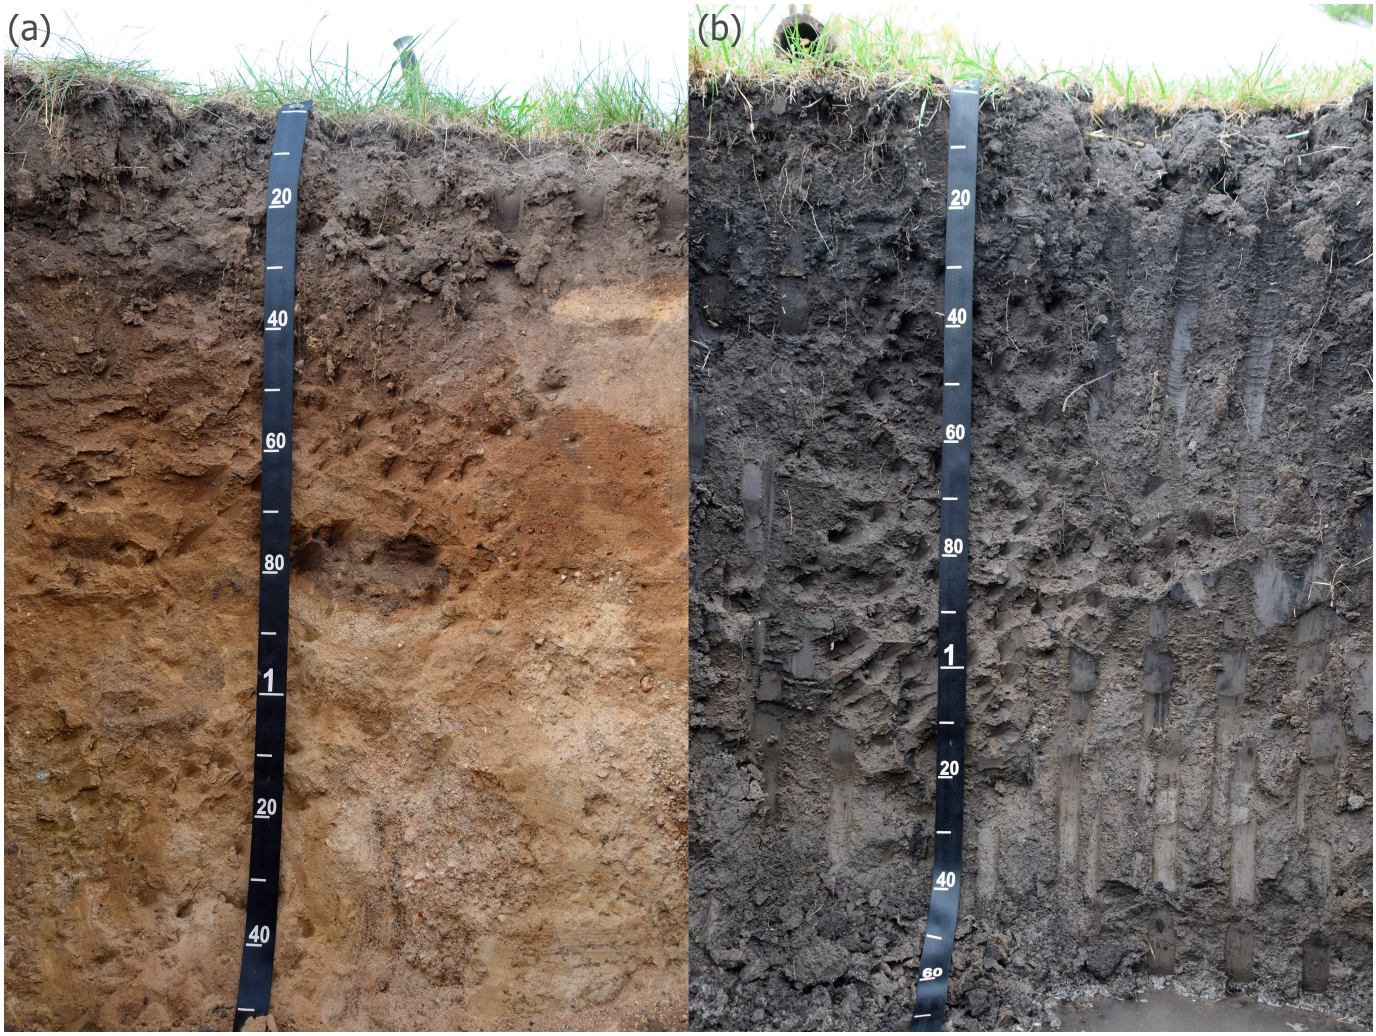

Figure 1. Variable thickness of mollic colors for two common soil series from the intensively drained Des Moines Lobe Landform in north-central Iowa. The (**a**) 30 cm mollic colors profile is a Clarion (fine-loamy, mixed, superactive, mesic Typic Hapludoll), and the (**b**) 60 cm mollic colors profile is a Webster (fine-loamy, mixed, superactive, mesic Typic Endoaquoll). Photos by BA Miller, Iowa State University.

Information about Iowa's soils is a result of over a century of investment from county, state, and federal levels of government. Although many more soil observations were made as part of this cooperative effort, a database of over 8000 deep (>1 m) soil cores documents this work [24]. By combining field experience with aerial photography and then field verification, soil scientists produced soil survey maps at cartographic scales of 1:15,840 and 1:12,000 [25]. These soil maps are among the most detailed in the world, especially for covering such a large extent. The maps were produced county by county (~2330 km^2), with teams of four soil scientists dedicated to surveying each county over a four-year period (Fenton, personal communication).

Iowa's soil and climate conditions are conducive to high yields of summer annual crops. The landscape is dominated by the cultivation of maize and soybeans, used for livestock feeds, vegetable oils, sweeteners, and biofuel feedstock [26,27]. Humans have lived in North America since as early as 5000 BCE, practicing various forms of agriculture [28–30]. Since Euro-American settlement in the 19th century, however, Iowa's topsoil has been drastically altered by the conversion to field crop production. A substantial portion of topsoil has been redistributed by wind, water, and tillage erosion. Even on gently rolling landscapes such as those of north central Iowa, the loss of organic-matter-rich topsoil from some landscape positions is evident [31]. One study based on remotely sensed data has suggested that 37% of Iowa's agricultural fields have no remaining topsoil [32], but this does not account for local sediment movement and deposition. Considering the thickness of topsoil in prairie remnants, spatial modeling suggests that the SOC stock in Iowa soils before Euro-American settlement was about 1.47 billion Mg [9]. A similar analysis calculated from the gSSURGO database [21] suggests the present stock is about 990 million Mg (Figure 2), which indicates a loss of about 32%. Losses and gains are a function of landscape position, with the largest losses measured in the backslope [31]. Preliminary data also suggest a loss of C from upland swales and depressions. Despite slow but continued increases in the adoption of soil conservation practices by farmers [33], the estimated annual statewide average soil loss is 13 Mg ha^{-1} yr^{-1} [34].

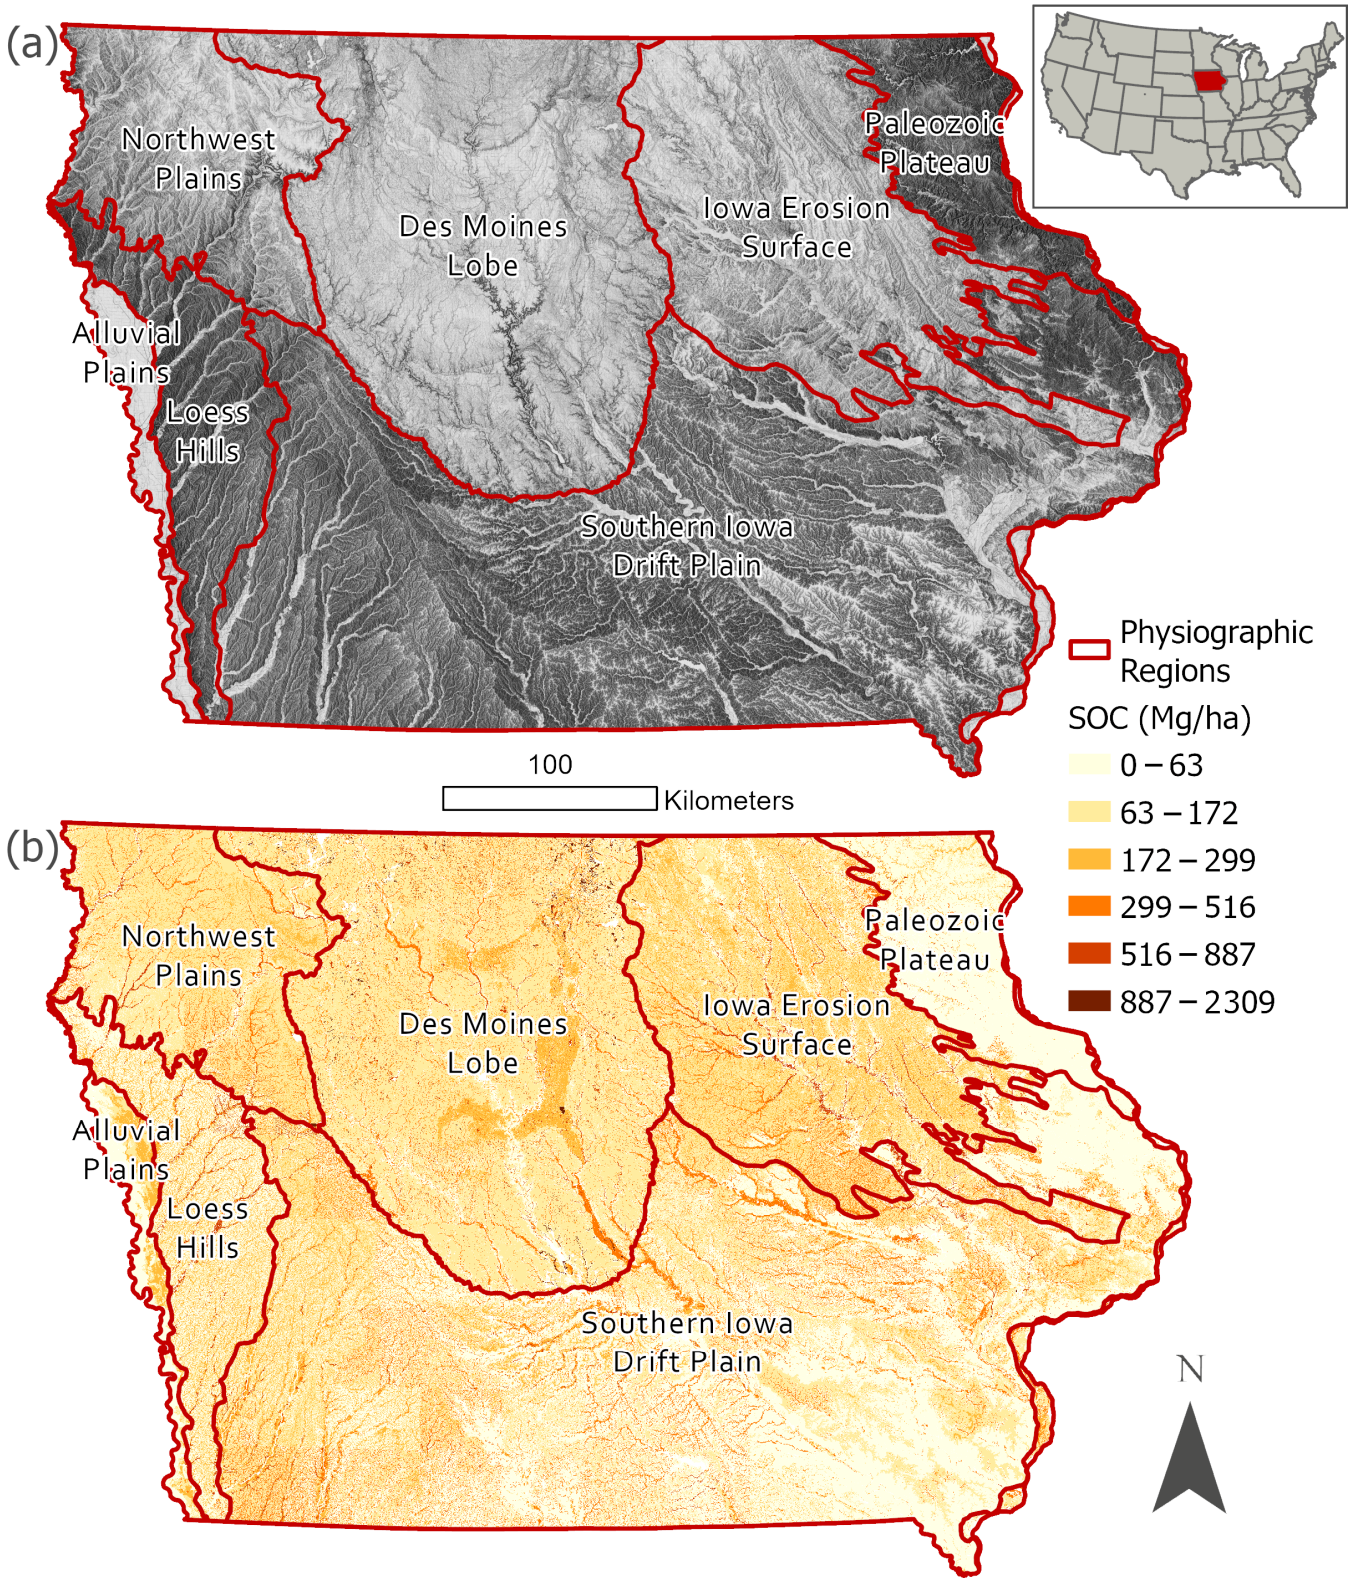

Figure 2. (**a**) The relief of Iowa, USA, displayed by a hillshade model derived from LiDAR elevation data (State of Iowa, 2009), which heavily influences the distribution of (**b**) soil organic carbon (SOC). Estimates of SOC content is based on gSSURGO data [21]. The depth included is variable and is based on the thickness of soil with visible evidence of organic carbon accumulation (i.e., "mollic" colors, a standard for indicating soil most enriched by organic matter). For some soil areas, this thickness may be up to 2 m.

3. Agricultural Management Practices and Soil Organic Carbon: Long-Term Studies in Iowa

On a worldwide basis, SOC stocks have declined by 133 Pg C since the beginnings of cultivation, with the "Corn Belt", of which Iowa is the center, among the areas of greatest loss [35]. While we cannot point to one cause, this SOC loss can be attributed to soil-tillage-induced erosion, extensive tile drainage, improper soil fertility, and increased soil temperatures [36,37]. A long-term study on SOC loss from 23 counties in Iowa reported a net loss of SOC from 0 to 100 cm depth (−10.8%) but gain at 100 to 150 cm (of +1.5%) between the years of 1959 and 2007 [31]. This study represents the status of most Iowa farms regarding SOC, and we do not expect this rate of loss from the upper soil profile to have slowed since the 2007 sampling.

As in other locations around the world, Iowa researchers and farmers have looked toward multiple practices to increase SOC. These include (but are not limited to): reduced tillage [38], residue management [39], diversified crop rotations [40,41], manure or other organic carbon amendments [38,42], using winter cover crops [43], growing perennial crops [44,45], using a living mulch or perennial groundcover [46], and full or partial land conversion to perennial vegetation [47]. These practices reliably reduce soil erosion and improve water quality, but long-term data from these studies suggest that consistent measurement of absolute changes in SOC remains challenging. Here, we summarize patterns in extensive, relatively long-term SOC datasets associated with three practices and collected in Iowa (Table 2).

Table 2. Summary of approaches and methods used in long-term studies of three practices intended to increase soil organic carbon (SOC) in Iowa, USA.

Practice Intended to Increase SOC	Number of Sites/Studies	Length of Studies' SOC Monitoring (years)	Sampling Depth (cm)	Approach	Treatments	References
Reduced Tillage	7	12	0 to 60	Sampled annually, with baseline *	1. Moldboard Plow 2. Chisel Plow 3. Deep Rip 4. Strip Tillage 5. No Tillage	[48]
Diversified Crop Rotations	3	10–12	0 to 30–90	Sporadic sampling, no baseline *	1. Maize-Soybean 2. Maize-(Maize)-Soy-Oat-Alfalfa	[40,41,49–53]
Conversion to Perennial Vegetation	4	7–40	0 to 15–30	Various, chronosequence, most without baseline *	1. Cropland 2. Restored Prairie 3. Native (or Remnant) Prairie	[45,47,54,55]

* Baseline refers to sampling before, or shortly, after practice change. Without baseline sampling, determining net SOC loss/gains is more challenging (see ref. [56]).

3.1. Reduced Tillage

Although the use of no-till in Iowa has increased significantly since the 1980s, full-width tillage is still used on the majority of cropland in Iowa for at least part of the crop rotation [57,58]. Intensive tillage transiently decreases soil bulk density and increases soil aeration, mixes crop residues with mineral soil, and breaks soil aggregates and crop residues into smaller pieces—all of which increase decomposition (and loss of SOC as CO_2). Tillage also dries and warms soils more rapidly in springtime by increasing aeration and decreasing albedo. These soil microclimate benefits and increased decomposition of residues are why many growers in Iowa continue to till—converting to no-tillage has been shown to have a 7.6% maize yield penalty according to a global meta-analysis [59]. However, the SOC benefits to reducing tillage in Iowa are compelling [48] (Figure 3).

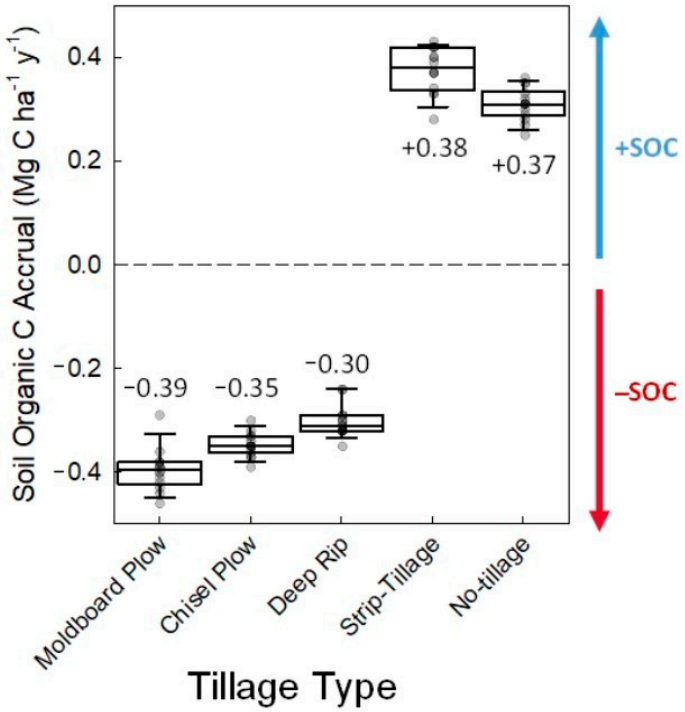

Figure 3. Five tillage types and impact on soil organic carbon (SOC) at 0–60 cm depth from 2002 to 2014. Boxplots include seven sites spread throughout Iowa and two rotations (maize-soybean and maize-maize-soybean) for a total of $n = 14$. Mean state-wide averages are shown with the boxplots. Data from [48].

Al-Kaisi and Kwah-Mensah (2020) [48] compared five tillage methods—moldboard plow, chisel plow, deep rip, strip-tillage, and no-tillage, over a 12-year period across seven locations in Iowa (Figure 3). Soils were sampled and analyzed for SOC in increments to a depth of 60 cm. Prior to the initiation of the study, all sites had been in row crop production using common conservation tillage methods for at least 50 years.

Averaged across seven locations and two rotations, no-tillage and strip-tillage systems added 0.25 to 0.43 Mg SOC ha^{-1} y^{-1} to a depth of 60 cm. Conversely, chisel plow, deep rip, and moldboard plow had losses ranging from −0.24 to −0.46 Mg SOC ha^{-1} y^{-1} over the 12-year study (Figure 3). SOC gains and losses predominantly occurred in the upper 30 cm. Interestingly, there was no tillage interaction with crop rotation or location, despite varying climates and soils [48]. Taken together, this comprehensive Iowa study indicates that reducing tillage improves SOC storage, with a reasonable expectation that, if no-tillage and strip tillage systems replaced more intensive tillage systems across Iowa, SOC stocks in the upper 60 cm of soil could increase at an average net rate of approximately 0.7 Mg SOC ha^{-1} yr^{-1} ([average SOC increase with strip-tillage or no-tillage] + [average avoided SOC loss caused by more intensive tillage systems]).

Globally, the majority of studies have also consistently documented the positive impact of reducing or eliminating tillage on SOC stocks, at least in the upper 30 cm. This is probably best illustrated via meta-analyses, which document a range from <0.1 to 0.57 Mg C ha^{-1} y^{-1} increase in SOC [60–63]. For Iowa climate and soil conditions, Ogle et al. [64] reported a 0.33 Mg C ha^{-1} y^{-1} increase in SOC in the 0–60 cm soil depth following conversion to no-till. While there is some scientific debate, [65–68], most data syntheses point to net SOC accrual (e.g., [63,69,70]). In addition to soil depth, the other many relevant factors affecting SOC response to adopting no-till include climate, soil type, cropping system, and duration [60,61,63,64,69,71]. The potentially nonlinear temporal response of SOC to no-till conversion also poses particular challenges to the accurate measurement and interpretation of results [60].

In addition to increasing SOC, reduced tillage provides multiple environmental co-benefits. Several studies have demonstrated reduced erosion from no-tillage or reduced tillage [72–74]. Soil infiltration [75], structure and porosity [69,76], and microbial biomass and activity [77] also improve. Conversion to no-till also reduced nitrate-nitrogen leaching by 14 ± 10% at a site in northwestern Iowa [78].

3.2. Diversified Rotations

Diverse crop rotations that include small grains and forage crops were widely used across much of Iowa until the 1950s, after which intensive monocultures of continuous maize and maize-soybean became increasingly dominant [79]. A concern with this increased specialization in crop production is the potential negative effects on SOC and other aspects of soil health. Three long-term crop rotation experiments examined the effects (Table 2).

These three experiments compare a conventional maize-soybean rotation with a diversified maize-soybean-oat-alfalfa rotation. The Kanawha experiment was established in 1954 in northern Iowa (42°94′ N, 93°17′ W); the Nashua experiment was established in 1979 in northeast Iowa (42°95′ N, 92°54′ W); and the Marsden experiment was established in 2002 in central Iowa (42°01′ N, 93°47′ W). Detailed information on site history, management, and soil sampling for SOC can be found in several publications [40,41,50,80]. Tillage and fertilization vary somewhat for the three sites, but full-width tillage was used at all sites. Animal manure was incorporated after the alfalfa phase of the rotation at the Marsden site to simulate a diversified, integrated crop-livestock system [80].

Unlike reduced and no-tillage, there are no clear trends in the impacts of crop diversification on multiple soil measures. The coefficients of variation for bulk density, SOC concentration, and SOC stock are high (medians range from 5 to 8%) for both maize-soybean and diversified rotations (Figure 4). Although yield data and allometric equations suggest that below-ground inputs of carbon were 20–35% greater in the diversified rotations compared to the maize-soybean rotation, SOC increases within the total soil profile were minor [41]. Although changes in SOC stock were not consistently observed, changes in certain C fractions were noted. For example, C stored in particulate organic matter (POM), microbial biomass C, and salt-extractable organic carbon were significantly increased with diverse rotations [52,53]. One reason for the lack of a clear trend in SOC may be fertilization: Russell et al. [50] found that nitrogen fertilization tends to negate the effect of increased below-ground inputs of carbon in diverse rotations (SOC increases are maximized at the agronomic optimum nitrogen application rate in Iowa intensive maize and maize-soybean rotations [81]). Furthermore, the formation of mineral-associated organic matter (MAOM) requires substantial amounts of nitrogen, which could pose another limitation for its accumulation [82].

Meta-analyses report SOC increases for both diversified crop rotations [83] and manure inputs [84]. The lack of SOC response to diversified rotations in Iowa is puzzling but similar to recent findings from Wisconsin, a neighboring US state, where the researchers found even 29 years of diversified management was not enough to detect SOC changes between conventional cropping and diversified crop rotation [85]. Climate or soil conditions may make SOC slow to respond to cropping system diversification in this region, if there is a response at all.

Even though changes in SOC stock are difficult to discern, there are a plethora of additional benefits of diversified cropping systems. The four-year diversified rotation in the Marsden experiment dramatically lowered synthetic nitrogen inputs (−86%), herbicide use (−50%), and energy use (−65%); improved many metrics of soil health including reduced soil erosion (−62%); increased crop yields (maize +5%, soybean +20%); and even improved air quality [52,53,86,87].

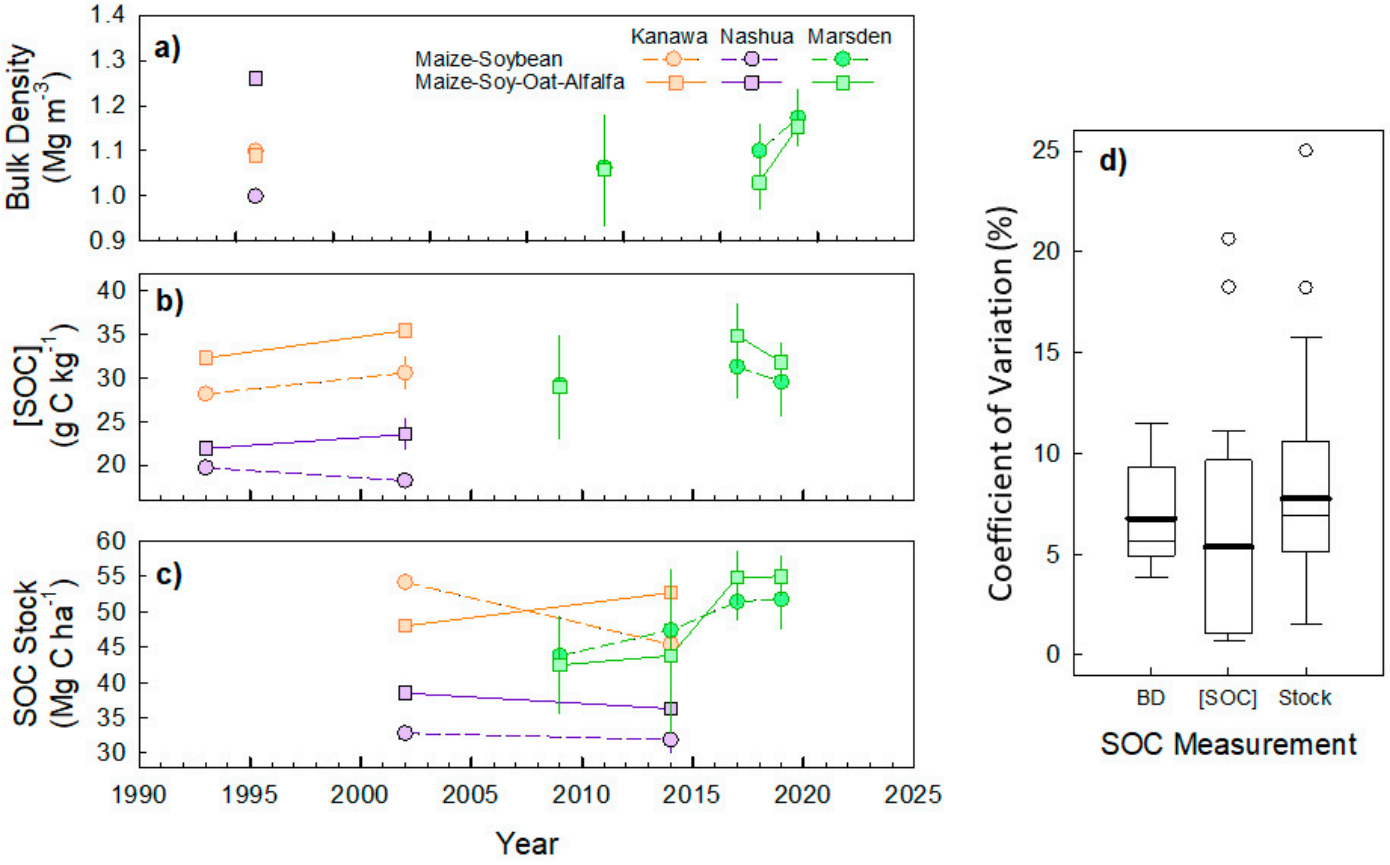

Figure 4. (**a**) soil bulk density, (**b**) soil organic carbon (SOC) concentration, (**c**) calculated SOC stock, and (**d**) the coefficient of variation for all three soil measurements at 0–15 cm depth across time from three long-term crop diversification experiments. Means and standard deviations are compiled from [40,41,49–53], and the coefficient of variation was calculated by treatment and year (n = 6 for BD, n = 10 for [SOC], and n = 12 for SOC stock). The thick dark lines in boxplots are the means.

3.3. Converting Cropland to Perennial Vegetation

Perennial grasslands, called "prairie," once covered 70–80% of Iowa's landscape, but now comprise < 1% [88]. Remnant prairies average 30–60% greater SOC than adjacent cultivated cropland [55,89], suggesting a massive potential sink for SOC with conversion of cropland to native prairie. Numerous environmental benefits have been shown to accrue with the restoration of even modest areas of prairie within Iowa's cropland landscapes, including increased biodiversity, reduced runoff, and increased retention of nitrogen and phosphorus [90]. Converting cropland to perennial grassland vegetation may be particularly beneficial on soils that are marginally productive for annual crops [91], and can be economically feasible if farmers and/or farmland owners receive federal or state cost-share to assist with establishment and management costs, and enroll in a private sector C program [92].

Long-term studies of the effect of conversion of cropland to perennial grassland on SOC in Iowa (Table 3) have included three approaches: (i) a chronosequence approach, sometimes called space-for-time substitution because it involves sampling different fields (ideally under very similar soils and climates) that have been converted to perennial vegetation [47,54,55], (ii) randomized complete block designs that ideally measured SOC at baseline or beginning of the conversion and some years later [45], and (iii) sampling through long time frames (>50 years) and monitoring SOC loss [31].

Table 3. Summary of four studies conducted in Iowa, USA on the effect of cropland conversion to perennial grassland on soil organic carbon stocks and change (at 0–15 cm).

Study Citation	Region in Iowa (Nearest City)	Soil Texture	Classification Based on USDA's Soil Taxonomy	Years since Conversion	Cropland SOC (Mg C ha^{-1})	Restored Perennial Grassland SOC (Mg C ha^{-1})	Native Prairie Remnant SOC (Mg C ha^{-1})	SOC Accrual Rate (Mg C ha^{-1} y^{-1})	Significant Difference between Crop and Restored Grassland
[47]	Central (Prairie City, IA)	Silty clay loam	Aquertic and Typic Argiudolls	14	44	35–39	55	0.74	Variable
[54]	Central (Prairie City, IA)	Silty clay loam	Oxyaquic, Aquertic, and Typic Argiudolls	21	25	40	58	0.59	NA
[45]	Central (Boone, IA)	Clay loam	Typic Endoaquoll, Aquic Hapludoll	7	55	60	NA	0.71 †	No
[55]	North central (Various)	Various	Various	40	49	54	60	0.21	Yes

†: Prairie biomass is harvested. Also had fertilized prairie that increased at 0.29 Mg C ha^{-1} on average (not significantly different at $p < 0.05$). Larger differences between years than between treatments.

The SOC accrual rate in these four long-term studies ranged from 0.21 to 0.74 Mg C ha^{-1} y^{-1}, but SOC in the grasslands was not always significantly greater than in cropland (Table 3). Even after multiple decades (up to 40 years), SOC did not reach levels of nearby undisturbed prairies [47,54,55]. These findings highlight the slow recovery of SOC, and the patience needed to observe "statistically significant" differences between the annual croplands and re-established grasslands. Also, it is important to note that in none of the studies did the perennial grassland reach the SOC stocks measured in the remnant prairie benchmark (Table 3).

The reason for slow and variable recovery of Iowa's SOC from conversion to perennial vegetation, sometimes resembling something like native vegetation, is unclear (Table 3). Variability in soil properties, like clay concentration, limited the ability to detect significant differences in switchgrass plantations compared to other covers [93]. Tile drainage of somewhat poor, and poorly drained sites may promote residue decomposition by aerating the soils for longer periods than under native conditions. Warm-season grass residues may decompose faster than those of cool-season species [92]. Ten-month laboratory incubation studies of central Iowa soils have shown that root residues from unfertilized reconstructed prairie plots dominated by warm-season grasses decomposed rapidly and did not lead to carbon storage in the soil [94]. Reducing soil erosion and increasing the duration of living plant roots and the quantity of other root-derived C inputs are likely the main factors that increase SOC under perennial vegetation [95]. Furthermore, the speed at which the SOC concentrations increases when tilled soils are converted to grassland can be dependent on hillslope position [55]. The more eroded, shoulder-slope positions tended to accrue SOC faster than positions lower down the hillslope [55], perhaps because the change in SOC concentration was easier to discern from the lower background concentration on the eroded sites. Changes in inorganic carbon are often not considered, but impacts can be significant. Conversion from cropland to grassland reduced soil inorganic C by 14.4% [96].

Global meta-analysis has indicated that the conversion of cropland to pasture resulted in increased SOC stocks, especially in the upper soil horizons, but the increases do not reach that of the native conditions on the timescales of most scientific studies [97]. Kristersen et al. [98] note the potential role of incorporating large herbivores in establishing increased and resilient stocks of SOC in grasslands globally. Research interest in understanding potential applications in Iowa is increasing, but data on net GHG impacts and SOC changes in grazed systems in Iowa are scant [9]. Overall, Fargione et al. (2018) [99] estimate modest potential contributions from grassland restoration to climate mitigation as compared to avoided grassland conversion.

4. Implications for Soil Organic Carbon Measurement and Management

The results of these studies suggest that, in Iowa soils, SOC responds slowly to management and has a high variability, such that changes in SOC are difficult to detect with statistical certainty. Here, we discuss the implications of these findings for SOC measurement and management within our broader understanding of soil science literature. We focus on SOC measurement, spatial and temporal variation in SOC, and other considerations.

4.1. What to Measure and Why

Detecting changes in SOC is difficult. Even long-term, well-controlled studies reflect this challenge for some management practices, as we show here for diversified rotations and conversion from cropland to perennial grassland. Several factors influence our ability to detect and interpret SOC changes based on soil management, including the depth measured, bulk density, and the influence of different SOC fractions including highly persistent fractions (naturally occurring or added "biochar").

4.1.1. Soil Depth

The majority of Iowa research studies on the effect of management practices on SOC have focused on the upper 0–15 or 0–30 cm, leaving substantial uncertainty on impacts to deeper layers and changes in whole profile stocks [9]. Of the long-term studies summarized here, only two assessed SOC deeper in the soil profile. Al-Kaisi et al.'s [48] measured to a depth of 60 cm and established a positive influence of no-tillage on SOC across seven study locations. Poffenbarger et al. [41] did not find a consistent effect of cropping system on the vertical distribution of SOC within the soil profiles among three long term trials. More studies including measurements of deeper soil layers may help establish more consistent patterns, especially patterns of SOC that might be stable over long periods of time. Soil carbon sampling protocols and programs are generally focused on SOC changes in the upper 30 cm [8], but we note that subsurface horizons warrant considerable additional investigation because stocks of subsoil C may be substantial in some soils. Those deeper stocks may still be influenced by soil management at the soil surface, and the biochemical and physical processes that stabilize C in subsoils proceed at different rates from those in topsoils [100].

4.1.2. Bulk Density

Bulk density (dry mass per volume) is an essential parameter for the calculation of changes in SOC stocks, but it is difficult and time-consuming to obtain accurate measurements. Uncertainties associated with bulk density measurements are related to both spatial variability and the variety of methods that can be used. These uncertainties can easily exceed those associated with SOC measurement [9]. Automated in-situ tools such as multi-sensing penetrometers that predict bulk density rapidly and to multiple depths have been developed (e.g., [101]), but their use in soils with coarse fragments, gravel, or rocks is uncertain. There has been little testing of these tools in Iowa soils.

4.1.3. SOM Fractions

The components of SOM differ in both chemical and physical characteristics, and their functions and behaviors in soils also differ. Therefore, soil scientists have long investigated ways to chemically, physically, biologically, or through a combination of the three approaches, fractionate total SOM to better understand soil C and explain its behavior. Separating SOM according to its size (and sometimes density) into particulate organic matter C (POM-C) and mineral-associated organic matter C (MAOM-C) has proven useful for this purpose, given that these fractions broadly differ in their persistence, formation pathway, and soil function [102–104]. The POM fraction represents organic particles, usually partially decomposed fragments of plant tissue, that are >50–63 μm in diameter (depending on the specific protocol that is followed). MAOM is empirically defined as organic matter that is finer than 53–63 μm. POM may be located freely between soil

particles or occluded in large aggregates [104]. MAOM comprises organic compounds that may be chemically bound with soil minerals or could be located within micropores or small aggregates (<50–63 μm). The degree of its close physical association with silt and clay particles in an undisturbed soil is likely to be highly variable and dependent on clay type and concentration, pH, metal oxides, and exchangeable cations, as well as faunal activity that intimately mixes organic and inorganic components. In most fractionation schemes, MAOM includes microbial biomass and necromass. Soil organisms—both fauna and microorganisms—that decompose organic residues and environmental conditions regulate the formation and decay of these fractions. Understanding the complex interactions between these SOM pools, the environment, and decomposers is key to choosing the best management strategies to optimize SOM storage [105].

In Iowa croplands, the majority of SOC (>90%) is stored as MAOM-C [41]. Some of the organic matter in this fraction can persist in the soil for long periods (e.g., decades or longer) due to its attachment to or occlusion by minerals, but some MAOM compounds are also readily accessible to microbially derived enzymes and are decomposable. Some soil minerals with a low specific surface area can become saturated with MAOM-C [106–108]. To the extent that MAOM is composed of microbial biomass and necromass, its formation depends on the availability of nitrogen, which could pose another limitation for its accumulation [82]. When the mineral phase of a soil becomes saturated with C-containing compounds, additional C inputs can be stored as POM [107]. Thus, in such situations, it may be recommended to focus on managing POM (e.g., by cultivating crops that add low-quality residues to the soil) [105]. However, determining the C saturation limit for particular soils remains challenging and is subject to ongoing debate [109].

On the other hand, labile fractions like POM have been suggested as useful indicators of soil health compared to total SOM, because they exhibit greater sensitivity to changes in land use and management [110]. Results from a three-year study of different crop systems across a topographic gradient in Iowa indicated that while total SOC stocks remained unchanged, POM-C increased [111]. Additionally, soil aggregation showed a positive correlation with POM stocks, suggesting that improving soil structure enhances the protection of POM against decomposition. Similar findings were obtained when comparing different cropping systems in Iowa: POM-C exhibited changes while total SOC did not [52]. Utilizing data from this study, we also discovered a positive correlation between POM-C concentration and potentially mineralizable nitrogen (Figure 5). These results emphasize the importance of POM in defining soil properties and functions. While MAOM is also significant in certain soil functions, particularly nutrient storage and provision [112], it has received less attention [113].

Some forms of soil organic matter are inherently resistant to decomposition. When plant residues are heated at a high temperature in the absence of oxygen (i.e., pyrolyzed), some of the C present is not combusted but is condensed into chemical structures that resist further decomposition. The solid-phase product of pyrolysis is called char or biochar and can be produced at backyard to industrial scales to create a long-lasting soil carbon amendment [114–116]. In addition to removing C from the atmosphere for decadal to centuries-long periods, biochar soil amendments have been shown to enhance beneficial soil properties like cation and anion exchange capacities and water-holding capacity in soils (e.g., [117–120]).

Some soils already have measurable concentrations of such persistent C. These are hypothesized to be the legacy of naturally occurring fires, of fires created by Indigenous hunters to drive game, of localized and intentional soil amendments by Indigenous farmers before modern agriculture, or of crop residue burning to facilitate the subsequent planting of crops. Studies of Iowa soils have reported that 29–36 percent of the C in surface horizons was composed of such "recalcitrant" forms [121]. This fraction represents SOC that is likely to remain stable in the soil for long periods under many variations of soil management practices—as long as the soil is not eroded. The concentration of such recalcitrant C, which

is not quantitatively known for most soils, also has a significant impact on the uncertainty of predictions of soil C stocks that are made using dynamic models [122].

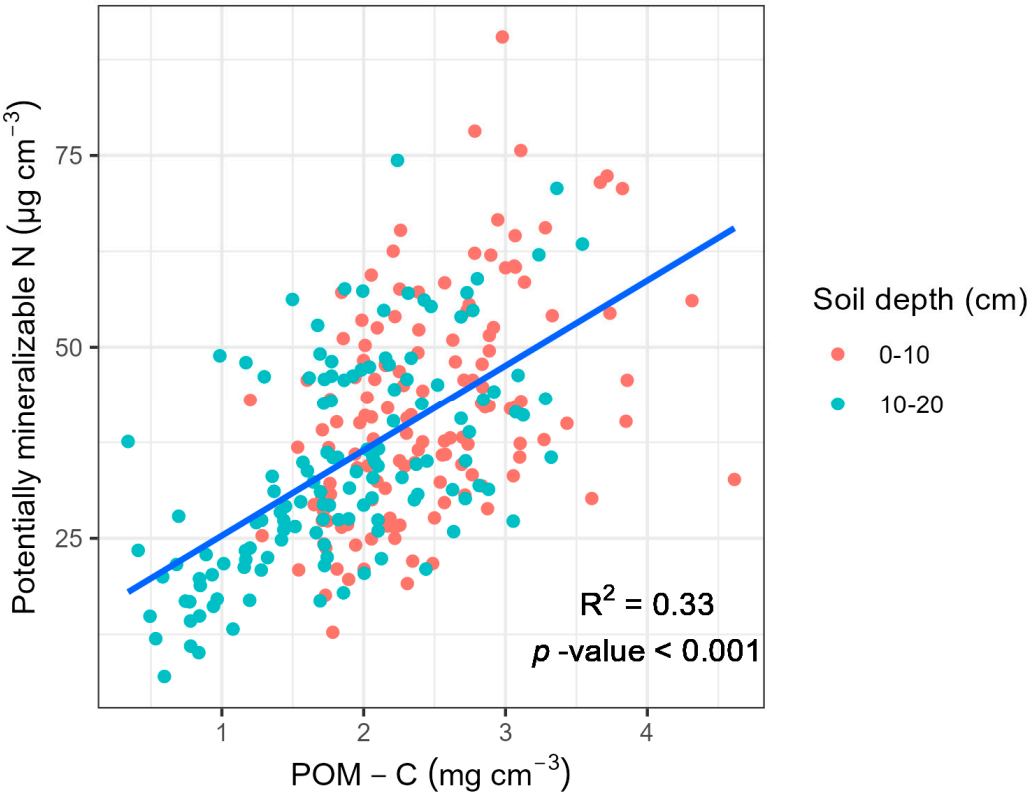

Figure 5. Particulate organic matter carbon (POM-C) relationships with potentially mineralizable nitrogen from Marsden Agricultural Diversification Experiment mentioned in previous section (data from [52]).

There are other soil C pools, usually either measured with an extraction or laboratory incubation, that are implicitly included in MAOM-C. This includes microbial biomass C, or C that is contained in living microorganisms, typically measured using chloroform fumigation-extraction or substrate-induced respiration [123]. Microorganisms in soil constantly reproduce and die at rates that depend on temperature and the availability of water and nutrients. While it is difficult to quantitatively differentiate the carbon associated with living versus dead microorganisms, recent research has estimated that in many cultivated and grassland soils the total necromass can account for as much as 50% of the total organic C in the soil [124,125]. Much bacterial biomass and necromass occurs in the clay size fraction, but fungal biomass also extends to the silt size fraction. Microbial biomass is dominated by the cell walls of the organisms, and those walls are composed of polymers of amino sugars. The breakdown of these polymers provides low-molecular-mass organic compounds that other microorganisms and plants use for energy, respiring the carbon as CO_2. In addition, the N in those polymers serves as an important source of mineralized inorganic N that both plants and soil organisms require. The importance of MAOM components like microbial biomass and necromass in N mineralization has recently been reported [126].

Also, the low-molecular-weight organic C that can be extracted with water (WEOC) has received some recent attention as it is one of three components in the "Haney Test" used in the Midwest US for soil health assessments [127,128]. Yet another way to fractionate SOC is to use soil biota themselves to produce CO_2 in a laboratory incubation—this method of re-wetting dry soils produces a "biologically active" C pool that is typically < 10% of SOC and has been used to predict soil nitrogen supply to crops [129–131]. These methods all

show promise as either proxies for measuring some soil function, like the ability to supply nitrogen, or as indicators of soil health [132,133].

POM has sometimes been treated as a "leading indicator" of long-term changes in organic matter concentrations that result from a change in management practice such as cover crops or reduced tillage. While changes in POM concentrations are more likely to occur over periods of a few years than are changes in total organic matter concentrations, only a minor fraction of POM C will remain unmineralized in most cultivated soils [134]. Thus, predicting the impacts of a management practice on long-term carbon storage by its impact on POM concentrations is problematic. It is also important to note that the most widely used dynamic process models to predict gains or losses of soil organic C are not based directly on POM and MAOM measurements. Models that are based on the CENTURY/DayCent framework (e.g., COMET-Farm, https://comet-farm.com/Home, accessed 17 August 2023) make assumptions about the litter pool (which includes particulates larger than POM), the microbial biomass pool, and the total soil organic matter pool. More recent academic models that include measured POM and MAOM values as input variables have been developed [135–137], but their ability to predict outcomes of soil management practices on soil C has not been tested.

4.2. Spatial and Temporal Variation in SOC

Many factors complicate the accounting of SOC stocks, including spatial and temporal variation. Soil samples are intended to represent a soil landscape, which has spatial connectivity. This condition presents challenges and opportunities. For example, lateral movement challenges assumptions made when comparing repeated location samples. Conversely, the fact that SOC stock is a spatially continuous variable presents opportunities to utilize geographic concepts to reduce uncertainty in SOC estimation for a given area.

The spatial modelling of soil carbon stocks uses auxiliary information such as spatial autocorrelation and remotely sensed covariates to improve the representation of the entity [138,139]. Using this additional information can lessen the uncertainty in assessment of carbon stocks compared to using sampling alone [140]. Similar to the question of how much precision is needed from lab measurements for detecting change, spatial modeling methods also contribute to the uncertainty in calculation of SOC stocks. To illustrate the range of outcomes possible by using different methods to assess the amount of SOC in a field, a variety of spatial modeling approaches were applied to a set of 143 soil samples from a 16-ha field in northern Iowa (Figure 6). Differences among the maps illustrate the potential variability in stock estimation resulting from differences in spatial modeling method and sampling density. The impact of the spatial modeling method is expected to increase for areas with higher variability of SOC stock due to the higher magnitude of spatial differences as the method interacts with the spatial pattern. The combination of field data with remotely sensed data dramatically improves the spatial resolution of prediction. These more highly resolved datasets can inform the precision management of SOC, particularly with regard to the strategic spatial integration of perennial crops or conservation cover [141]. As previously discussed, some portions of a field are likely to have a greater potential to accrue SOC than others.

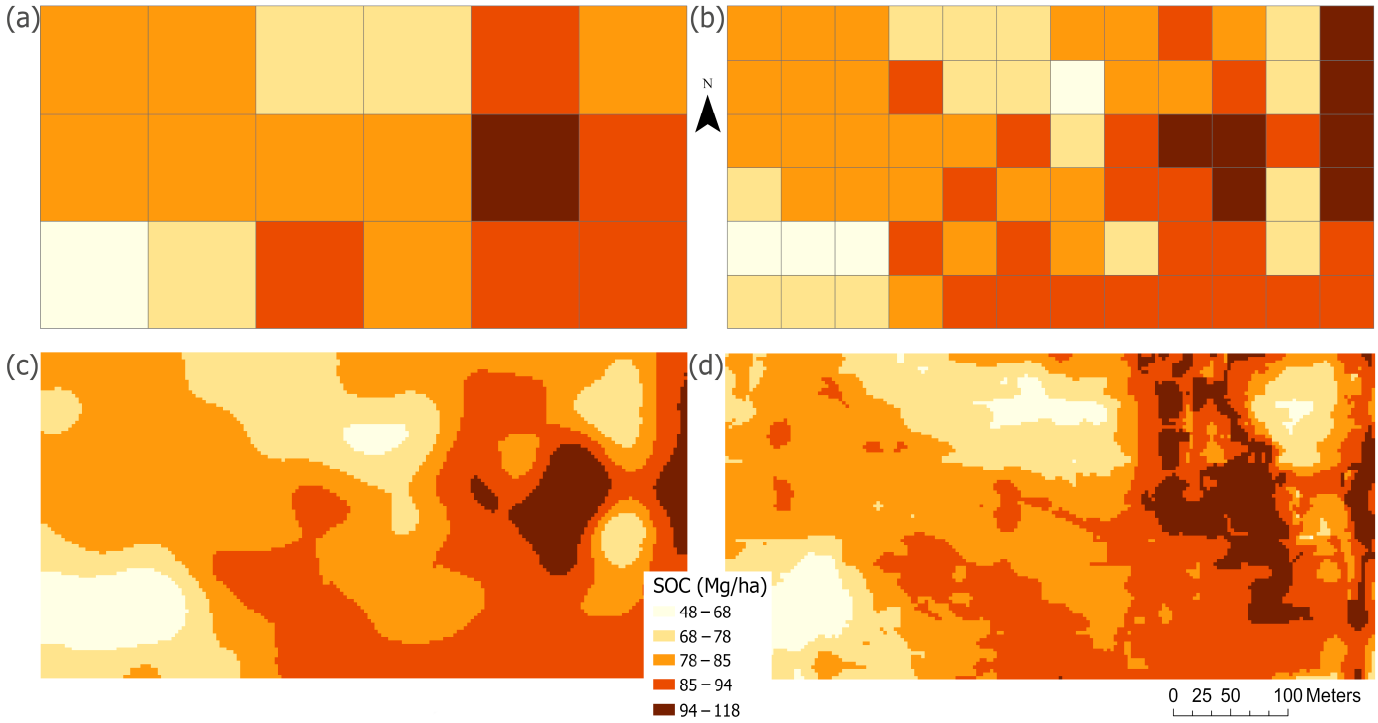

Figure 6. SOC stock maps generated from 143 samples (**a**) "composited" to a 0.4-ha (1-ac), (**b**) "composited" to a 0.1-ha (0.25-ac) grid, (**c**) interpolated using ordinary kriging, and (**d**) used to train a machine learning model with Cubist [142] and remotely sensed covariates.

Appropriate choices for soil sampling design depend on the intended use of that data. If they will be used estimate a field mean, then the goals of representing variability and having enough samples for statistical significance will be the most important. In terms of representing variability, the sampling design should be cognizant of equally representing zones versus the spatial weighting of those zones. A grid sampling design is inherently spatially weighted. If a stratified sampling design is applied, such as landscape position or soil map unit, then a strategy for spatially weighting those stratification zones will be needed for estimating the spatially weighted mean. For example, a field with a skewed distribution of SOM could be represented as a normal distribution with strategic sampling.

The number of samples needed also depends on how that data will be used to represent the field and how much uncertainty is tolerable. When the field is modelled by estimating a mean, field variability will often drive the need for a high number of samples to be able to detect significant change [93,143]. Other approaches to model a field can use geographic principles to spatially predict C stocks in unsampled locations. Spatial interpolation methods (e.g., kriging) rely on spatial autocorrelation to fill in values for the field. Spatial regression methods utilize other, more readily measured variables that tend to covary with the target variable to infer values for the complete field. In theory, the inclusion of additional information should reduce uncertainty in the accounting of soil properties in a field. However, the methods for estimating uncertainty differ among these approaches. More work is needed on comparing these methods and determining which are best suited for monitoring soil carbon stocks.

Temporal variation in SOC accrual rates also complicate accounting. As noted earlier in the context of POM and MAOM fractions, some scientists have hypothesized that soils have an intrinsic, "saturation" limit, that is a steady state status beyond which carbon stocks will not increase; in other words, the rate of carbon addition will be equal to the rate of its loss [105,107,144]. The carbon saturation concept is focused not on how much total carbon can accumulate in a soil, i.e., stored carbon, but on how much might be sequestered or stabilized for long periods, which depends mainly on clay-size minerals—if all other factors

are held constant. Scientists promoting the saturation concept reason that the primary control over the amount of carbon that is stabilized and not subject to loss is the mineral surface area that protects organic matter from being broken down by microbial enzymes. This hypothesis has been used to explain why increasing carbon stocks can be fast in some soils and very slow in others. However, there are some soils in Iowa almost entirely composed of organic matter with little mineral material (Histosols). These soils suggest that, under the right conditions, there is no limit to how much carbon can accumulate in some parts of the landscape.

While the protection of organic matter in association with minerals is one way C can be stabilized, some organic matter associated with clay and silt particles remains susceptible to oxidation. The period required to reach stable carbon stocks will vary not only with the quality and quantity of organic matter inputs but also with soil management practices (e.g., tillage, fertilization), changing climate, and vegetation. Soil amendments of organic matter in forms that are already resistant to decomposition, such as pyrolyzed biochar, will increase SOC in a soil beyond its saturation limits defined by texture. Digestate solids that result from the breakdown of organic matter through anaerobic digestion are also very slow to breakdown after land application and could increase SOC beyond typical saturation limits [145]. These soil management strategies require more research, especially through long-term replicated field trials in which several management factors are investigated in combination.

One concern moving forward is that studies of the past effect of management practices on SOC may not be predictive of future carbon storage given climate change. Climate change has likely contributed to increased maize and soybean yields in Iowa in recent decades due to the timing of humidity, rainfall, and heat [146]. Moreover, Iowa has had the good fortune of not experiencing the same level of warming to date as the global trend (aka, "the warming hole"). This is due in part to a buffering effect on peak summer and early fall temperatures as a result of crop evapotranspiration of spring and early summer rainfall and the high water holding capacity of Iowa's soils [147]. This advantage may be diminishing, as increasing spring rainfall often delays planting and increases soil erosion, and rising humidity increases the growth of molds and fungi [146]. Under a business-as-usual scenario in terms of global emissions, Iowa is likely to experience severe droughts in between high rainfall years from the present to ~2050, and subsequently, high temperatures, heat stress, and reduced growing season rainfall will tend to significantly constrain crop yields [146,148,149]. These changes will likely adversely impact the ability of Iowa soils to sequester carbon. Integration of the DAYCENT model with various Intergovernmental Panel on Climate Change (IPCC) climate models for central Iowa suggests declines in SOC in the latter part of 21st century, largely due to harvest losses, despite increases in net primary productivity [150].

The SOC benefits of converting areas of row crops to perennial grasses are likely to continue, even if slowly. However, profitable uses of perennial grasses are desperately needed to combine this clear SOC benefit with economic viability [151]. There is some nascent research on using perennial grain crops like Kernza® to concomitantly obtain the combined outcomes of grain production and SOC benefits [152,152]. Further research is underway on using perennial, native grasses as plant biomass feedstock for anaerobic digestion [151]. A clear path for recovering SOC, and sustainable agriculture, will likely require cropping systems that maintain continuous living cover, whether through integrating winter crops or through perennial plants: grain crops, forage crops, biomass crops, or restored native grassland species.

4.3. Other Considerations

Another major factor that may affect long-term SOC storage in Iowa soils is artificial drainage. Tile drainage has been used in Iowa since the 19th century to lower water tables and to remove excess soil water to allow earlier planting and to reduce nitrogen loss by denitrification during the growing season. Today, close to 60% of Iowa's cropland

is tiled [58,153,154]. Artificial drainage may also have an impact on the storage of soil carbon because it increases aeration and soil temperatures [155], potentially leading to the increased microbial oxidization of organic carbon [154,156,157].

Cropland soils in low-lying topographic positions tend to have higher soil carbon stocks [158] (e.g., the poorly-drained Webster soils vs. well to moderately well-drained Clarion soils in the same landscape (Figure 1)) because organic-matter-rich eroded sediments accumulated there or because decomposition rates of plant biomass were slow before agricultural exploitation. Subsurface drainage systems can release soil carbon from soils in these positions as CO_2 by lowering the water table, aerating the soil, and promoting decomposition of organic matter. Carbon markets have started to recognize the impacts: adding or improving drainage after the start of a project is not allowed in common soil carbon protocols (e.g., [159]). While subsurface drainage may promote soil carbon loss as CO_2, modeling studies suggest that artificial drainage could, in some years, reduce direct nitrous oxide (N_2O) emissions from maize cropping systems and may thus lead to lower net cumulative GHG emissions [154]. This is important to consider alongside carbon programs because one ton of N_2O traps 265 times more heat in the atmosphere than one ton of CO_2 over a 100-year period [160].

The emission of N_2O is most likely when soils are nearly but not completely saturated with water and the level of oxygen in the soil is low. Long-term measurements from typical maize/soybean rotations on poorly and somewhat poorly drained soils in central Iowa indicate that N_2O emissions from soil can be a significant contribution to atmospheric greenhouse gases [161,162], and they can release more N_2O than well-drained soils in other parts of the Midwest where previous research has been conducted [163]. Water-filled pores in an otherwise unsaturated soil can host microorganisms capable of biochemically reducing oxidized forms of nitrogen, like nitrate, to N_2O gas. Other studies suggest that N_2O emissions associated with practices like no-till, cover crops, and rotations are not likely to offset the lowered warming potential that results by CO_2 removal using those practices (e.g., [164]). More field research is needed to accurately predict N_2O emissions from soils under a greater variety of management regimes. The most important management practices to limit N_2O emissions from Iowa soils are already well known, however, and include (1) timing application of nitrogen fertilizers to crop growth periods when nitrogen is most needed, and (2) effective and timely drainage of somewhat poorly and poorly drained soils during spring snow melt and during the growing season.

Given the cost of data field collection, SOC cannot be sampled and understood at spatial and temporal resolutions sufficient to fully inform each management decision—predictions are necessary. Simulation models play a crucial role by providing a mathematical framework to represent our understanding of SOC dynamics and make predictions under various environmental conditions. Voluntary carbon credit programs rely on such simulation models, and sometimes also on sophisticated statistical analysis, to defensibly align sampling and analysis costs with carbon market values [8,9]. Agroecosystem models now are reasonably adept at prediction of maximum and minimum values from practice changes, but providing predictions of variability at field scale is less robust [9]. While soil measurements from Iowa are more extensive than many regions of the world, data to support model development and use are still limited in several respects. They are limited in both spatial resolution, including depths below 30 cm, and temporal resolution. They are particularly scant regarding the impacts of artificial drainage and newly emerging practices including multispecies cover crops and soil amendment with biochar or digestate [9].

Additional research is needed to improve SOC models. There is further need for models to provide more holistic predictions, integrating other crucial factors, including robust estimates of changes in GHG emissions, crop yield, etc., along with changes in SOC stocks [9]. Collaboration among modelers with researchers who generate empirical data is particularly essential, as the empirical data obtained from experiments is not always the most suitable for these models, and vice versa [165]. For instance, traditional SOM simulation models typically divide SOC into different conceptual pools (usually 3–5 pools,

depending on the model) to represent SOC heterogeneity (e.g., [166,167]); however, most of these pools do not correspond to the readily measurable fractions. This limitation significantly impacts the model's application, calibration, and validation since values for the input variables are assumed from limited and legacy empirical data rather than from contemporary measurements. A new generation of SOC models based on measurable fractions [135–137] and aimed at addressing this issue, represents an example of improved communication between modelers and experimental scientists.

5. Conclusions

There is growing interest in improving the measurement and management of SOC in agroecosystems due to its linkages to soil health and crop productivity, agroecosystem resilience under climate change, developing voluntary C markets, and Scope 3 emissions documentation. In assessing results from long-term studies on the effect of agricultural management on SOC stocks in Iowa—a relatively well studied part of the world—we found increases in SOC of 0.25–0.43 Mg C ha^{-1} yr^{-1} with adoption of strip-tillage and no-tillage compared to losses of 0.24 to 0.46 Mg C ha^{-1} yr^{-1} with more intensive after tillage methods; highly variable and inconsistent effects of diversifying crop rotations with extended rotations on SOC; and increases in SOC of 0.21–0.74 Mg C ha^{-1} yr^{-1} with conversion of cropland to perennial grassland. Results further indicate that SOC is highly variable spatially and responds slowly to management changes, and that changes under some management practices are difficult to detect with statistical certainty. While these general conclusions are not scientifically surprising, they are of increasing importance as society grapples with managing atmospheric CO_2 levels alongside feeding eight billion people and delivering other important ecosystem services. Given this constellation of factors, we suggest improved prediction of changes in SOC requires the development and use of new methods that can identify and disentangle multiple sources of variability; looking beyond total SOC and toward systematic collection of data on more responsive and functionally relevant fractions (including but not limited to POM-C and MAOM-C); monitoring the effects on SOC of multiple conservation practices used in combination in long-term studies; whole-profile SOC monitoring; and deeper collaboration between field soil scientists and modelers, which can help design the long-term studies needed to fill knowledge gaps.

Author Contributions: Conceptualization, J.J., M.M., B.A.M., M.T. and L.A.S.; Data curation, M.M., B.A.M. and M.T.; Writing—original draft, J.J., M.M., B.A.M., M.T., S.V. and L.A.S.; Writing—review & editing, J.J., M.M., B.A.M., M.T., S.V. and L.A.S. All authors have read and agreed to the published version of the manuscript.

Soil carbon maintained by perennial grasslands over 30 years but lost in field crop systems in a temperate Mollisol

Check for updates

Clarissa L. Dietz[1] ✉, Randall D. Jackson[1], Matthew D. Ruark[2] & Gregg R. Sanford[1,2]

To mitigate climate change, some seek to store carbon from the atmosphere in agricultural soils. However, our understanding about how agriculture affects soil organic carbon is muddied by studies (1) lacking longitudinal data, (2) ignoring bulk density changes, or (3) sampling only surface soils. To better understand soil organic carbon trends, here we measured changes over 30 years in density-corrected, full-soil-depth (90 cm) soil organic carbon stocks under 6 cropping systems and a restored prairie in a Mollisol of southern Wisconsin, USA. Cash-grain systems and alfalfa-based systems lost soil organic carbon. Prairie and rotationally-grazed pasture maintained soil organic carbon. Average soil organic carbon losses for cash-grain and alfalfa-based systems were −0.80 (±0.12) and −0.54 (±0.13) Mg C ha^{-1} yr^{-1}, respectively. Sensitivity analysis showed that incomplete methodologies overestimated soil organic carbon improvements. Our findings using more comprehensive methods demonstrate the inadequacy of row-crop systems and the need for well-managed grasslands to protect soil organic carbon in productive agricultural soils of the Upper Midwest USA.

A politically popular strategy to mitigate agriculture's contributions to climate change is drawing down carbon dioxide (CO_2) from the atmosphere and storing it in agricultural soils via soil organic carbon (SOC) sequestration. SOC sequestration is central to programs such as the "4 per mille Soils for Food Security and Climate" initiative launched at the COP21 and the agricultural aspects of many countries' pledges to the Paris Agreement[1]. Despite its popularity, however, the real potential to sequester substantial SOC through agriculture remains uncertain, in part because of the ubiquitous use of flawed or incomplete methods to measure changes in SOC.

To start, long-term studies are necessary to understand if a practice truly sequesters SOC. Without careful and spatially precise sampling, it can be difficult to delineate short-term SOC changes from natural variation[2]. Further, if SOC gains are temporary, they do not mitigate climate change in the long-term. To truly mitigate climate change, SOC gains must be maintained for decades or more[3]. Among the few long-term studies that track SOC, ubiquitous but incomplete methods have muddied our understanding of the true impact of agricultural management on SOC. Despite decades of research highlighting their flaws, studies still may over- or underestimate SOC change by using common C-accounting methods: (1) comparisons lacking longitudinal baseline data, (2) failing to correct for bulk density (ρ_b) changes, and (3) sampling only surface soils[2,4–6].

Many studies lack longitudinal data and instead compare concurrent SOC stocks, substituting a difference over time with a difference over space ("space-for-time") and assuming implicitly or explicitly that any difference indicates SOC increases in the improved management scenario. However, unless the SOC stocks of the control treatment in such "space-for-time" studies remain constant over time (an unlikely situation in a warming climate[7]), these studies cannot demonstrate C sequestration[8]. Relative differences in SOC stocks can be found in scenarios where the control and improved management treatments are both gaining or both losing SOC, telling us little about the actual rates of SOC accrual in either treatment[6,9].

Further exacerbating these accounting issues, SOC data is often limited to the surface soil (15 or 30 cm deep). Though there are statistical (strongest signal) and logistical (time, equipment) reasons to sample only surface soils, exclusively relying on surface soils may obscure overall SOC effects. For example, if a treatment increases surface SOC while losing more SOC at unsampled depths, it does not actually increase SOC or drawdown atmospheric CO_2[10].

Changes in ρ_b over time also may obscure SOC accrual. Many studies treat depth from the soil surface as a constant through time and between treatments, despite significant soil expansion or compaction as a result of changing management[11,12]. These ρ_b changes can directly affect how much of the soil profile is sampled, making comparisons between treatments difficult[5]. For example, Guillaume et al. (2022) found a 16% underestimation of treatment effect on SOC when changes in ρ_b were ignored[13]. To account for these changes, we must convert depth-based

[1]University of Wisconsin–Madison, Department of Plant and Agroecosystem Sciences, 1575 Linden Drive, Madison, WI 53706, USA. [2]University of Wisconsin–Madison, Department of Soil Science, 1525 Observatory Dr, Madison, WI 53706, USA. ✉e-mail: cdietz2@wisc.edu

measurements to an unchanging reference system, such as equivalent soil mass (ESM). Institutions such as the IPCC and FAO have emphasized the importance of ESM corrections[14,15], but standardization remains lacking in SOC crediting methods[4].

When studies use more comprehensive methodologies (change over time, deep sampling, and ESM corrections) while estimating SOC stock changes, they often demonstrate different magnitudes or even directions of SOC change compared to studies using incomplete methods. One such 8-year study by Liu et al. (2022), investigating the effects of no-till and straw retention on SOC in wheat-maize systems, found that tillage redistributed C through the soil profile but did not lead to significant changes in SOC stocks, while straw retention increased SOC stocks regardless of tillage[16]. These results are inconsistent with those of Al-Kaisi and Kwaw-Mensah (2020) using depth-based methods or Powlson et al. (2014) evaluating only surface soils[17,18]. Both reported potential for SOC gains in no-till systems, a contradiction potentially explained by using incomplete methods.

While we theoretically understand how these methods may affect results, we have a limited understanding of the general effects and relative impact of using them on real data. The few studies that use more comprehensive methods and report the sensitivity of results to incomplete methods tend to address only one cropping system or method, which limits the generalizability of their results. To truly test the impact of incomplete methods on results, we must compare the results of using them versus comprehensive methods on data from multiple cropping systems in an otherwise controlled study.

While accurate accounting of SOC is important for all major soil types, of particular interest are Mollisols, the high-C, fine-textured grassland soils that support much of global intensive agriculture[19]. In the Upper Midwest U.S. and elsewhere, Mollisols are used primarily for the production of commodity cash-grains (maize, soybean, wheat) or forages for livestock (maize for silage, alfalfa, pasture), while a common conservation practice is restoration to grassland. To assess the potential of C sequestration in agricultural Mollisols, we assessed SOC over 30 years at the long-term Wisconsin Integrated Cropping Systems Trial (WICST). Our goals were to (1) explore changes in SOC among three cash-grain systems, three dairy-forage systems, and a restored prairie using comprehensive assessment methods and (2) assess how partial methodologies (using space-for-time methods, omitting ESM corrections, and limiting analysis of SOC stocks to surface soils) affect SOC estimates.

Results

SOC change from baseline in years 20 and 30

A general linear mixed effect model of total 0–90 cm SOC stocks from 1989–2019 (ΔSOC 1989–2019) indicated a significant cropping system effect ($p = 0.03$). For all cropping systems except Management-Intensive Rotation Grazing (MIRG) and Prairie, we estimated a net loss of SOC ($p < 0.05$) (Fig. 1). Of the five cropping systems that lost SOC, the cash-grain rotations, Maize, Maize-Soy (MS), and organic Maize-Soy-Wheat (org. MSW) lost the most SOC (−0.78 Mg ha^{-1} yr^{-1}, −0.70 Mg ha^{-1} yr^{-1}, and −0.93 Mg ha^{-1} yr^{-1}, respectively) (Table 1). We found evidence for SOC loss in all depths in Maize, MS, and MSW ($p < 0.005$). The alfalfa-based dairy-forage systems lost SOC slower than the annual systems with rates of −0.56 Mg ha^{-1} yr^{-1} ($p = 0.0004$) and −0.52 Mg ha^{-1} yr^{-1} ($p = 0.0053$) for Maize-alfalfa-Alfalfa-Alfalfa (MaAA) and organic Maize-oats/alfalfa-Alfalfa (org. Mo/aA), respectively (Table 1). In both, lack of evidence for change in surface 0–15 cm SOC stocks belied the significant ($p < 0.05$) losses in lower depths. In the perennial systems, MIRG and Prairie, there was no evidence for change (+0.11 Mg ha^{-1} yr^{-1}, $p = 0.7$ and +0.24 Mg ha^{-1} yr^{-1}, $p = 0.55$, respectively) in SOC in the 0–90 cm soil profile (Fig. 1). Gains in MIRG's 0–15 cm depth (0.25 Mg ha^{-1} yr^{-1}, $p = 0.0086$) were offset by losses in the 15–30, 30–60, and 60–90 cm depths, despite those losses being nonsignificant ($p > 0.1$) (Table 1). Likewise in Prairie, surface 0–15 cm gains (0.35 Mg ha^{-1} yr^{-1}, $p = 0.024$) were offset by nonsignificant losses in lower depths. We found similar results for

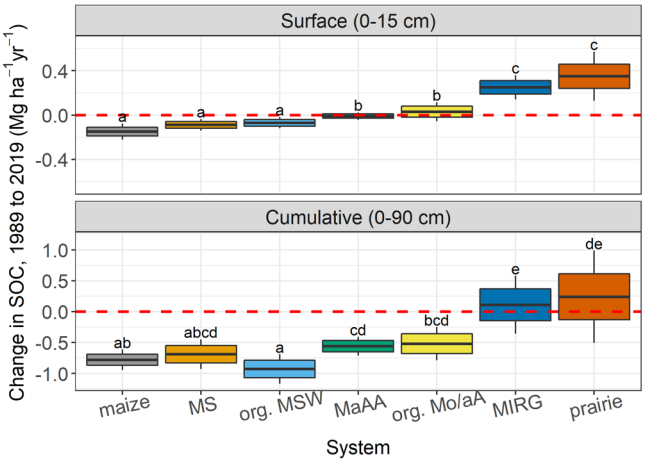

Fig. 1 | ΔSOC in the 0–15 cm and 0–90 cm soil profile from 1989 to 2019. Center bar represents change in soil organic carbon (ΔSOC) between 1989 and 2019 estimated by the linear mixed effects model. Boxes represent +/- the standard error. Whiskers represent upper and lower 90% confidence limits. Letters represent results of pairwise comparisons within each depth at alpha = 0.1. Treatment abbreviations are as follows: *maize*, cropping system of continuous maize; *MS*, minimum tillage cropping rotation of maize to soybean; *org. MSW*, organic cropping rotation of maize to soybean to winter wheat with cover crop; *MaAA*, cropping rotation of maize followed by 3 years of conventional alfalfa; *org. Mo/aA*, organic cropping rotation of maize followed by oats/alfalfa followed by alfalfa; *MIRG*, management intensive rotationally grazed pasture seeded to red clover, timothy grass, smooth bromegrass, and orchardgrass; *prairie*, cool-season grassy waterways established in 1990 planted to soy in 1998 and to warm-season grass mixes in 1999.

$\Delta SOC_{1989\text{-}2009}$ as Sanford et al. in 2012 (Table 1, see Sanford et al.[20] for their 20 year analysis).

SOC change between years 20 and 30

Total 0–90 cm SOC did not significantly change between 2009 and 2019 (Supplementary Information, Table S1) with the exception of org. CSW which experienced continued system wide loss of SOC (−0.71 Mg ha^{-1} yr^{-1}, $p = 0.0389$). Other systems experience changes within depths. In both Maize and MS, losses continued in the 15–30 cm depth (−0.74 Mg ha^{-1} yr^{-1}, $p = 0.0244$, and −0.24 Mg ha^{-1} yr^{-1}, $p = 0.0348$ respectively). Surface gains (0–15 cm) occurred in both the org. Mo/aA and Prairie systems (0.24 Mg ha^{-1} yr^{-1}, $p = 0.044$ and 0.79 Mg ha^{-1} yr^{-1}, $p = 0.0067$ respectively). No horizon-specific significant changes were detected below 30 cm for any of the systems.

Effects of alternative methods

The simulated use of alternative, less comprehensive methods resulted in marked changes to the estimated total $\Delta SOC_{1989\text{-}2019}$ of each system (Fig. 2). These changes were not consistent in magnitude across systems. The space-for-time, shallow sampling, and depth-based methods, compared to the comprehensive results, affected the $\Delta SOC_{1989\text{-}2019}$ by ranges of −0.35–0.62, 0.08–0.58, and −0.10–0.16 Mg ha^{-1} yr^{-1}, respectively.

Incomplete methods altered the trends emerging from the data. Using space-for-time, with 2019 MaAA SOC stocks as the baseline rather than 1989 SOC stocks by location, the losses estimated by the comprehensive assessment in Maize, MaAA, and org. Mo/aA were no longer statistically different from zero (a change of 0.62, 0.58, and 0.33 Mg ha^{-1} yr^{-1}, respectively), and gains in MIRG appeared statistically significant (a change of 0.57 Mg ha^{-1} yr^{-1}) (Supplementary Information. Table S2). Shallow sampling (0–30 cm) rather than sampling to 90 cm had a positive impact on apparent $\Delta SOC_{1989\text{-}2019}$ across systems, with an average increase of 0.33 Mg ha^{-1} yr^{-1}. It also reduced variation in $\Delta SOC_{1989\text{-}2019}$, especially for the perennial systems MIRG and Prairie. The effect of depth-based sampling without ESM corrections was marginal for the cumulative soil

Table 1 | ΔSOC (1989–2009 and 1989–2019) estimated by the linear mixed effects model

profile, but more pronounced in the 0–15 cm depth (Fig. 2), which had experienced greater changes in ρ_b. Within the 0–15 cm depth, losses in Maize, MS, and org. MSW, as well as gains in MIRG were no longer evident in the depth- based scenario (a change of 0.16, 0.08, 0.12, and −0.02 Mg ha^{-1} yr^{-1}, respectively).

Discussion

All cropping systems lost SOC over a 30-year period except MIRG and Prairie. The maintenance of SOC in MIRG and Prairie may stem from high C inputs (above- and below-ground, see Sanford et al.[20]) and absence of tillage, providing an ideal environment for soil aggregation and subsequently SOC protection from loss to the atmosphere[21,22]. Relatedly, Rui et al.[23] reported greater carbon use efficiency (CUE) and lower oxidative enzyme activity in MIRG than the other non-Prairie systems at WICST (Prairie was not included in their analysis), suggesting a greater proportion of the C metabolized by the microbial communities in MIRG was assimilated into microbial biomass rather than respired[23]. Microbial necromass is responsible for much of the C found in mineral-associated organic matter, one of the slowest cycling SOC pools[24]. Rui et al.[23] found that MIRG had more mineral-associated organic carbon than the other non-Prairie systems.

The lack of evidence for SOC change below 15 cm in MIRG and Prairie may reflect limited sample size ($n = 12$ and $n = 6$, respectively), leading to greater uncertainty in our estimates of SOC stocks. The experimental design at WICST results in more plots dedicated to the multiple-phase systems such as MaAA and org. Mo/aA than the single-phase systems such as Maize, MIRG, and Prairie. The low number of

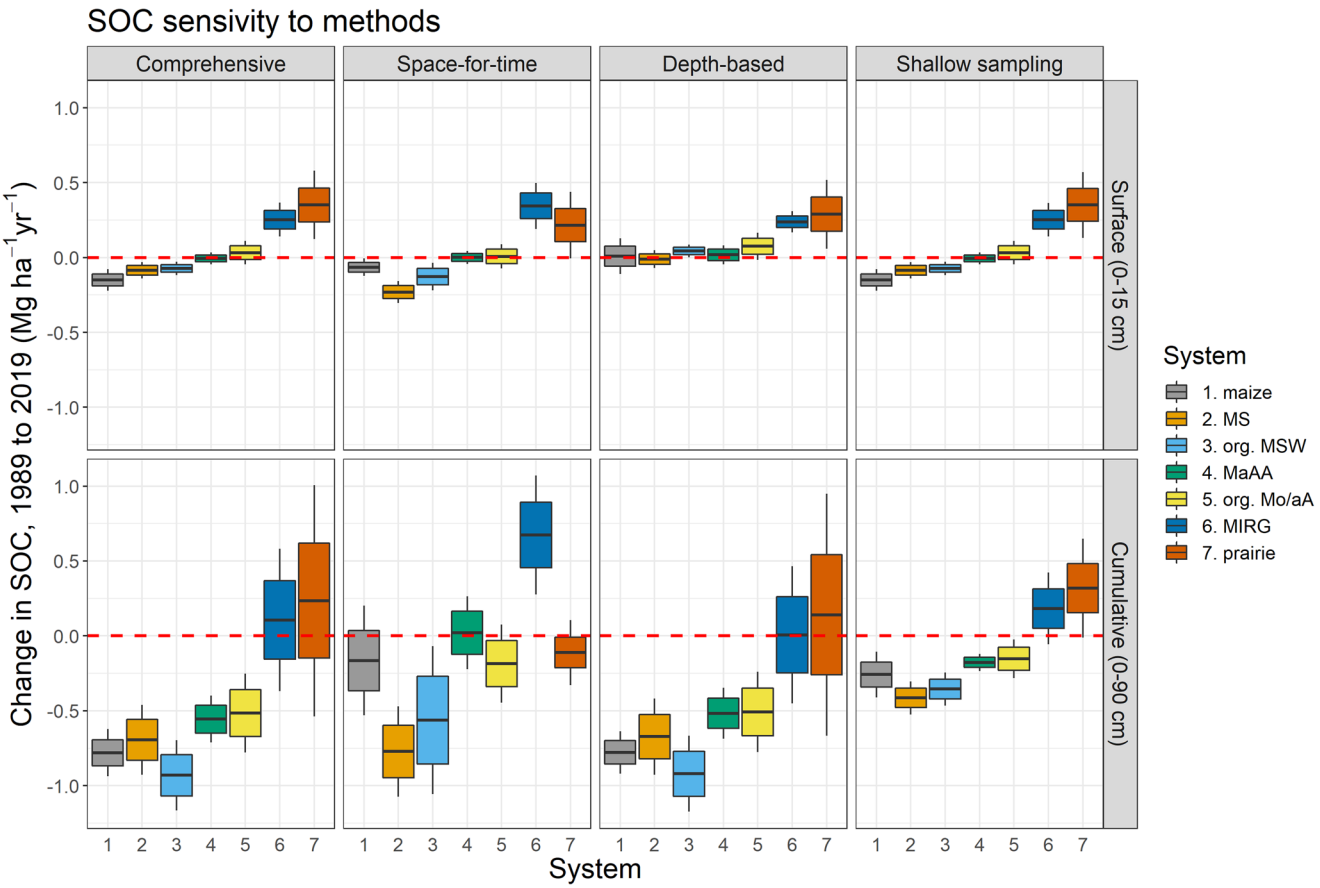

Fig. 2 | ΔSOC in the 0–15 cm and 0–90 cm soil profile from 1989 to 2019 for different data collection and analysis methods. Center bar represents change in soil organic carbon (ΔSOC) between 1989 and 2019 estimated by a linear mixed effects model. Boxes represent +/- the standard error. Whiskers represent upper and lower 90% confidence limits. Treatment abbreviations are as follows: Maize cropping system of continuous Maize, *MS* minimum tillage cropping rotation of Maize to soybean, *org. MSW* organic cropping rotation of Maize to soybean to winter wheat with cover crop, *MaAA* cropping rotation of maize followed by 3 years of conventional alfalfa, *org. Mo/aA* organic cropping rotation of Maize followed by oats/alfalfa followed by alfalfa, *MIRG* management intensive rotationally grazed pasture seeded to red clover, timothy grass smooth bromegrass and orchardgrass, Prairie cool-season grassy waterways established in 1990 planted to soy in 1998 and to native warm-season grass mixes in 1999.

samples taken for Maize ($n = 12$ yr^{-1}), MIRG ($n = 12$ yr^{-1}), and Prairie ($n = 18$ in 1989 and 2009, $n = 6$ in 2019) complicates comparisons with the other systems. That said, the lack of evidence for change in deep SOC in MIRG and Prairie may come from true SOC maintenance, as C inputs may balance outputs in those systems. Deep C inputs may come from exudation and turnover of the deeper, more extensive root systems of perennial grasslands[25,26]. Dissolved organic carbon, thought to be a major precursor of SOC[27], also may be percolating through the soil from the C inputs above, given the improved water infiltration associated with perennial grasslands[28].

In contrast to the perennial grass systems, we found significant losses in all depth increments below 15 cm of all field crop systems (e.g., Maize, MS, org. MSW, MaAA, and org. Mo/aA). Soil warming driven by a changing climate may be responsible for the release of this deeper SOC, as both laboratory and in situ studies have shown that soil warming can induce SOC loss[7,9,29]. Globally, loss of subsoil SOC has been observed in both agricultural and natural systems in the past several decades, suggesting a widespread cause such as warming[6,30,31].

Additionally, our results imply that reduced tillage alone is insufficient to build or maintain SOC stocks in systems with low C inputs. For example, the minimum-tillage cropping system MS lost a significant amount of SOC despite a lack of soil disturbance, likely from the combination of relatively shallow roots and limited biomass returned to the system during the soybean phase. Others have shown that no-till systems require both leguminous cover crops and double cropping to generate C inputs sufficient to offset losses at depth[18,32].

The lack of significant changes between 2009 and 2019 in most systems and depths may have several causes. It is possible that, despite ongoing SOC fluxes, a decade was insufficient to accrue detectable changes on these C-rich Mollisols[33]. Another possibility is that SOC accrual is slowing as these systems approach equilibrium. For MIRG and Prairie, this explanation would align with a meta-analysis of perennial crop age and SOC that found a slowing of SOC gains in perennial systems around 20 years[34]. Using this 20-year benchmark, MIRG should have approached SOC equilibrium around 2009, while the Prairie treatment (established in 1999) should have approached equilibrium around 2019, explaining both the maintenance of SOC in MIRG's upper depths and the ongoing accumulation in Prairie's surface 15 cm.

The use of space-for-time, shallow sampling, or depth-based methods generally resulted in overestimation of ΔSOC. In the case of space-for-time, most systems' ΔSOC were overestimated, although org. MSW and Prairie were underestimated. Space-for-time studies rely on two assumptions. One, that the baseline system (here, MaAA) is at equilibrium, and two, that SOC stocks across systems were reasonably similar at the beginning of the experiment. Our longitudinal data undercuts the first assumption, since MaAA lost SOC at a rate of about −0.56 Mg ha^{-1} yr^{-1} since the start of the experiment. As for the second assumption, despite our randomized complete block design, baseline 1989 SOC stocks for each system were quite

variable (Supplementary Materials, Table S3), which may explain why systems were impacted differently by the switch to the space-for-time method. Using the space-for-time method, one may conclude that MIRG was sequestering SOC, Maize and MaAA were SOC-stable, and only MS, org. MSW, and org. Mo/aA were losing SOC, trends that have been noted in many space-for-time studies[6,35,36]. However, using the comprehensive longitudinal data, we arrived at less sanguine conclusions.

If we had only sampled to 30 cm depth instead of 90 cm, we would have overestimated ΔSOC for all the systems, for an average increase in ΔSOC of −0.258 Mg ha^{-1} yr^{-1}. Under this sampling scheme, estimated losses, especially in Maize, MaAA and org. Mo/aA are reduced, making these annual and semi-perennial systems appear more climate-smart than the comprehensive analysis indicates. Losses of SOC below 30 cm may represent a blind spot in climate models and C market ventures, many of which assume SOC stocks are stable or increasing on agricultural land with improved management (see Mathers et al.[37]), such as minimum-tillage (MS), organic management (org. Mo/aA), and/or cover crops (org. MSW)[38].

If we had neglected to account for changes in bulk density (ρ_b) using ESM conversions, and instead relied on depth-based measurements, the changes in the total 0–90 cm ΔSOC would have been marginal, ranging from −0.10 Mg ha^{-1} yr^{-1} in MIRG to 0.04 Mg ha^{-1} yr^{-1} in MaAA. Within the 0 –15 cm depth, which was most likely to experience change in ρ_b due to management, the use of depth-based measurements had divergent effects on Prairie versus the rest of the systems (Supplementary Materials, Table S2). This divergence likely occurred because Prairie's ρ_b decreased where all other systems' ρ_b increased. Increased ρ_b correlates with increases in ΔSOC when switching to a depth-based method since increased ρ_b leads to more soil (and thus more SOC) sampled[5].

Sensitivity of our comprehensive results to commonly-used incomplete methods, especially space-for-time, demonstrates the importance of long-term, longitudinal, compaction-adjusted studies that measure the entire soil profile. Relying solely on less comprehensive methods, as many studies do, may lead to overestimations of C sequestration. This suggests that C sequestration in agricultural soils may not be as effective in mitigating climate change as previously thought, and other tactics (e.g., reducing combustion of fossil fuels) should be pursued.

The common field crop systems evaluated in this study were sources, not sinks, of atmospheric CO_2. Common SOC accounting methods (space-for-time, depth-based, and shallow sampling) obscured the magnitude of SOC losses in these soils, and in the case of space-for-time, suggested SOC gains in rotationally-grazed pastures where more comprehensive methods showed none. While C sequestration in productive, agricultural soils may not be possible, our work aligns with others suggesting that permanently restored and well-managed perennial grasslands are the best options to mitigate agricultural soils' CO_2 emissions.

Methods

Site description and history

We conducted this work at the University of Wisconsin-Madison's Arlington Agricultural Research Station, in Arlington, WI (43°18'N, 89°20'W) on soils classified as Plano Silt loam (fine-silty, mixed, superactive, Mesic Typic argiudolls). These are relatively deep (about 1 m), well drained soils with little relief that developed under tallgrass prairie vegetation (see Curtis, 1959[39]) in loess deposits over calcareous glacial till. Mean annual temperature and precipitation between 1991 and 2020 were 7.8 °C and 902 mm, respectively[40].

Conversion of tallgrass prairie vegetation to row-crop agriculture (primarily wheat), began in the 1840s with the attempted removal of Indigenous peoples such as the Ho-Chunk by northern Europeans. Between the 1860s and the middle of the 20th Century, after wheat yields crashed due to soil degradation and pest pressure, crops for dairy cattle feed (e.g., alfalfa, clovers, maize, oats) predominated. While agricultural practices shifted substantially following the Green Revolution, dairy forage systems remained dominant at the site, and from the 1960s until the establishment of WICST in 1989, maize (*Zea mays* L.), alfalfa (*Medicago sativa* L.), and soybeans (*Glycine max* (L.) Merr.) were the main crops grown, with dairy manure applied for fertility (see Posner et al., (1995) for additional historical details[41]).

In 1989, maize was planted across the 24-ha site to improve soil uniformity and allow for baseline measurements (crop yield and soil parameters), which were used to determine the boundaries of each block in the core experiment's four-block randomized complete block design[41]. In 1990, six cropping systems were initiated in a staggered start beginning with the legume phase of each rotation (if present). To reduce the potential confounding influence of yearly weather variability, every phase of every cropping rotation is present in one plot per block every year. For example, continuous maize (Maize) has one plot per block, while maize followed by 3 years of alfalfa (MaAA) has four plots per block. These rotations represent three cash-grain and three dairy-forage systems common to the Upper Midwest U.S.

The three cash-grain systems include high-input, or chemically and mechanically intensive, continuous maize (Maize), moderate-input minimum-tillage maize-soybean (MS), and organically managed maize-soybean-winter-wheat with a cover crop (org. MSW) (Table 2). The Maize system represents a conventional, continuous maize rotation, using synthetic fertilizer, tillage and herbicides for weed control, and top-yielding maize hybrids with advanced genetic traits such as herbicide resistance and insecticide (Bt) production. The MS system represents a maize-soybean rotation using minimum tillage, synthetic fertilizers, herbicides for weed control, and top-yielding maize hybrids and soybean varieties with advanced genetic traits. Soybeans are no-till drilled into maize stover, and maize is strip-till planted in soybean stubble. The org. MSW is managed

Table 2 | Wisconsin Integrated Cropping Systems Trial (WICST) experimental cropping system descriptions

Cropping system	System description	Species	Replicate plots
maize	Continuous maize with high inputs of synthetic fertilizers and pesticides.	Maize (*Zea mays* L.)	4
MS	Maize-soybean with minimum tillage and high inputs of synthetic fertilizers and pesticides.	Maize, soybean (*Glycine max* L. Merr.)	8
org. MSW	Organic maize-soybean-winter wheat with clover cover crop	Maize, soybean, winter wheat (Triticum *aestivum* L.), red clover (*Trifolium pratense* L.)	12
MaAA	Maize followed by three years of conventional alfalfa	Maize, alfalfa (*Medicago sativa* L.)	16
org. Mo/aA	Organic maize followed by oats/alfalfa followed by alfalfa	Maize, alfalfa, oats (*Avena sativa* L.)	16
MIRG	Management intensive rotationally grazed pasture seeded to red clover, timothy, smooth bromegrass, and orchardgrass	Timothy (*Phleum pretense* L.), bromegrass (*Bromus inermis* L.), orchardgrass (*Dactlyis glomerata* L.), red clover	4
prairie	Cool-season grassy waterways planted to soy in 1998 and to warm-season grass mixes in 1999. Burned every 2–3 years in spring.	See Liang et al. (2016) for full list of species[46].	6

according to the USDA's National Organic Program Standards. Fertility comes from biologically fixed N, composted poultry manure, and potassium sulfate. Weeds are controlled via tillage and cover crops. High-yielding organically-certified maize hybrids and organically-certified soybean and soft red winter wheat varieties are planted. Following wheat harvest mid-summer, a berseem clover and oats cover crop is planted and grows until terminated the following spring before maize is planted.

The three dairy-forage systems include high-input maize-alfalfa (MaAA), organic maize-oats/alfalfa-alfalfa (org. Mo/aA), and management-intensive rotationally grazed pasture (MIRG) (Table 2). The MaAA system represents a high-input, high-yielding dairy forage rotation, with fertility derived primarily from the application of dairy manure, weed control via herbicides, and top-yielding maize hybrids and alfalfa varieties with advanced genetic traits. Typically, two forage harvests occur during the alfalfa seeding year and between three and four harvests occur during other years of the alfalfa phases of the rotation. The org. Mo/aA system is managed according to the USDA's National Organic Program Standards. Fertility comes from the application of dairy manure, weeds are controlled with tillage, and organically-certified top-yielding maize hybrids and organically-certified leaf hopper resistant alfalfa varieties are planted. Oats are planted with alfalfa to suppress weeds and assist alfalfa establishment in the alfalfa seeding year. Typically, two forage harvests occur during this establishment year; a first harvest of primarily oat biomass with a second harvest of primarily alfalfa biomass later in the growing season. Between three and four alfalfa-only harvests occur during the 2nd year of the alfalfa phase of the rotation. The MIRG system is designed to represent a heifer-raising operation. Heifers rotationally graze the pasture plots from May to October, with a new subsection of the pasture available each day. Fertility comes from biologically fixed N and manure as well as synthetic fertilizer applied according to University-recommended best management practices. Red clover is seeded as necessary to maintain 35% legume levels in the cool season grass pasture.

Plots are relatively large (~0.3 ha, 18 × 156 m) and all fieldwork is carried out with production scale farm equipment, with fertilizer, pesticides, and other inputs applied according to University-recommended best management practices. Additional details on the design of WICST were presented in Posner et al.[41]. In 1990, grassy waterways were established where precipitation preferentially flows in the field. In 1998, these grassy waterways were chisel-plowed, sprayed with glyphosate, and planted to 1 year of soybeans. In 1999, a mix of native prairie legumes, forbs, and C4 grasses were established in a three-block randomized complete block design with two treatments: a high-diversity mix (25 species) and a low-diversity mix (6 species), for a total of six plots of restored prairie (Prairie) (Supplementary Information, Fig. 1)[42].

Soil sampling

In 1989, prior to the establishment of WICST, baseline soil samples were collected across the entire 24-ha field by points on a 27 × 27-m grid. At each sampling point, four cores were taken, divided and homogenized by depth (0–6, 6–12, 12–24, and 24–36 inches, or 0–15, 15–30, 30–60, and 60–90 cm, hereafter in cm). These increments were first chosen to align with standard agronomic soil tests based on surface soil (agronomic fertility, 0–15 cm) and deep soil sampling (soil NO_3–N, 0 to 90 cm). In addition to initial agronomic considerations, the glacial till (found at 80 to 120 cm) precluded consistent deeper sampling across the entire experiment. After initial analysis in 1989, the samples were dried, ground, and archived. In 2009, these dried homogenized samples were cleaned of visible plant material and analyzed for C content, which is expected to be stable in dried archival samples[43]. Full details on soil sampling and processing of the samples from 1989 can be found in Sanford et al.[20].

In June 1989, cores for ρ_b were collected at two sampling depths (0–15 and 15–30 cm) on the same 27 × 27-m grid. Given that detectible change in ρ_b below 30 cm between 1989 and 2009 was unlikely, ρ_b values from 2009 were used for 1989 below 30 cm (see Sanford et al.[20]). Comparison of the 2009 and 2019 ρ_b validated this assumption as no significant differences were found between the two most recent timepoints below 30 cm. Therefore, like Sanford et al.[20], we used ρ_b values from 2009 for the 30–60 and 60–90 cm depths in 1989.

In April through July 2009 and October through November 2019, samples for ρ_b and SOC analysis were collected at the center of each third of each plot (North, Center, South). Full details on soil sampling and processing of the samples from 2009 can be found in Sanford et al.[20]. In 2019, we collected cores for ρ_b in the autumn using a 5.4 cm diameter hydraulic core. Missing or damaged cores for ρ_b (3.5% of total cores) were recollected in October 2020. Cores were divided into 0–15, 15–30, 30–60, and 60–90 cm sections, as in 2009. Prior to weighing, we dried the sections in a 50-°C oven until weights stabilized. After weighing, we sieved the sections to 2 mm to remove rock fragments from glacial till. We subtracted the weight and the estimated volume of these fragments from the total section weight and volume prior to ρ_b calculation, so that ρ_b estimates represent the same soil as the SOC measurements (see von Haden et al.[5]). After this adjustment, we calculated ρ_b by dividing the weight of the dried section by the volume of its section of the soil core.

To align the original 1989 sampling grid with the 2009 and 2019 data, which were collected at locations within plots not yet established in 1989, we georeferenced a map of the original sampling grid and determined the location of the original sampling points relative to plot-level sampling points using ArcGIS. We then used ordinary kriging to spatially interpolate the 1989 data and digitally resample at the plot-level sampling points using R package gstat (v4.3.1). This differs from the approach of Sanford et al. (2012) who used an unweighted average of samplings that occurred within each plot[20].

Organic C determination

Because inorganic C in these soils is negligible (~0.005%)[44] we used total soil C interchangeably with SOC. To confirm this assumption and verify that routine applications of aglime ($CaCO_3$ or $CaMg(CO_3)_2$) had not significantly increased inorganic C in the surface 15 cm, we measured organic C of samples from all recently limed plots using standard methods provided by Thermo Finnignan for use with our Flash EA 1112 CN Automatic Elemental Analyzer[45]. We found no statistical evidence that SOC was different from total soil C, so we continue to assume total soil C is interchangeable with SOC.

Finely powdered subsamples of the dried soils from each depth (0 to 15, 15–30, 30–60, and 60–90 cm) at each point in the 1989 grid or in each location (N, Ct., S) in each plot were weighed into 5 × 9-mm tin capsules. While 8 to 10 mg of soil was used for all depths of the 1989 and 2009 soils (see Sanford et al.)[20], a soil mass of 15, 18, 30, and 50 mg was used for the 0–15, 15–30, 30–60, and 60–90 cm depths, respectively, in 2019 to accommodate declining C content with depth and enhance signal to noise ratio. Total C concentration for each sample was determined by dry combustion using a Flash EA 111d CN Automatic Elemental Analyzer (Thermo Finnigan, Milan, Italy)[45].

Estimating SOC stocks

To determine C stocks, rather than using depth from surface, we used cumulative mineral soil mass from surface as it is a reference system that remains stable over time (i.e., not impacted by changes in ρ_b or changes in organic matter)[5]. The ESM method accounts for compaction, expansion, and addition or loss of organic matter, ensuring the same section of the soil profile is considered each time. For the 20-year analysis, Sanford et al. (2012) used Excel software to convert depth-based measurements to ESM to calculate the SOC stock per unit area[20]. Here, for the 30-year analysis, these calculations were performed using R code provided by von Haden et al.[5].

Analysis of SOC change over time

General linear mixed effects models (PROC GLIMMIX, SAS v 9.4) were used to: (1) estimate change in SOC within each system between 1989, 2009, and 2019 ($\Delta SOC_{1989\text{-}2009}$, $\Delta SOC_{1989\text{-}2019}$, $\Delta SOC_{2009\text{-}2019}$), and (2) compare between systems the estimated change in SOC. The dataset was subset by depth (0–15, 15–30, 30–60, 60–90, and 0–90 cm) and year (2009 and 2019). For each subset, to address the potential influence of outliers, any $\Delta \pm 2$ SD

from the mean for each system were removed. Then, for each subset, a general linear mixed effects model was used to estimate ΔSOC as a function of cropping system. In this analysis, *system* (Maize, MS, org. MSW, MaAA, org. Mo/aA, MIRG, Prairie) was treated as a fixed effect, and *block* (1–4 for the core trial, 5–7 for the prairie) was treated as a random effect. Because of expected spatial and temporal correlations in the data, and to enable variance heterogeneity between cropping systems, we chose a variance-covariance matrix with a first-order heterogeneous autoregressive structure (subject = plot, group = system). Within SAS, LSMEANS was used to determine means, standard errors, and *p*-values for each cropping system. Because of the inherent spatial variability of SOC, we used an alpha level of 0.1 for all statistical comparisons.

Sensitivity analysis of ΔSOC methods

To examine the influence of SOC stock estimation methodology (space-for-time, depth-based, and shallow sampling) used in estimating $\Delta SOC_{1989\text{-}2019}$, we analyzed three datasets, each produced with each method. These were then compared to a dataset generated using a *comprehensive* SOC stock estimation method based on: longitudinal measurements, ESM correction, and the full 90-cm soil profile (Supplementary Information, Table S4). In the simulated space-for-time dataset, only data from 2019 were used. MaAA was chosen as the baseline scenario for calculating ESM conversions and change-from-baseline since it is most like the crop rotation present at the site prior to the establishment of WICST and would thus be assumed at SOC equilibrium in a traditional space-for-time analysis. Equivalent soil mass and change since 1989 were determined using an average of MaAA plots in each block in 2019 as the baseline. For the shallow-sampling dataset, data were converted to ESM to account for ρ_b changes, then SOC data below 30 cm were removed, simulating a scenario where we did not measure below 30 cm. For the depth-based dataset, the full 90-cm SOC stock was included, but not translated to ESM coordinates. Each simulated dataset was then analyzed for change over time using the same linear mixed effects model as the comprehensive dataset to determine estimates of $\Delta SOC_{1989\text{-}2019}$. To quantify the impact on SOC stock estimates of less comprehensive methods, $\Delta SOC_{1989\text{-}2019}$ obtained via each alternative method (space-for-time, depth-based, shallow sampling) was subtracted from $\Delta SOC_{1989\text{-}2019}$ obtained via the comprehensive method to calculate $\Delta(\Delta SOC_{1989\text{-}2019})$.

Reporting summary

Further information on research design is available in the Nature Portfolio Reporting Summary linked to this article.

Data availability

The soil data analyzed in this manuscript are available through Dryad https://doi.org/10.5061/dryad.b8gtht7mv.

Code availability

The SAS code used to generate the linear mixed effects model is available in the Supplementary Information (Supplementary Information, Supplementary Notes 1).

Alfalfa Stand Length and Subsequent Crop Patterns in the Upper Midwestern United States

Matt A. Yost,* Michael P. Russelle, Jeffrey A. Coulter, and Paul V. Bolstad

ABSTRACT

Alfalfa (*Medicago sativa* L.) can provide many economic and environmental benefits to crop rotations. Our objectives were to quantify alfalfa stand lengths, identify the two crops following alfalfa, and determine the soil and temporal factors affecting them. The USDA-National Agricultural Statistics Service (NASS) Cropland Data Layers (CDLs) for 2006 to 2012 and USDA-NRCS soil survey layers for North Dakota, South Dakota, Nebraska, Minnesota, Iowa, and Wisconsin were combined and used to meet these objectives. Location and soil textural class generally determined stand length, with alfalfa being kept in production longer outside the major Corn Belt area of this region. Soil textural class effects on stand length varied by state. Corn (*Zea mays* L.) was the most common crop planted during the first- and second-year following alfalfa (79 and 61%, respectively), except in North Dakota (35% both years). Soybean [*Glycine max* (L.) Merr.] was grown in 11 and 28% of cases, respectively. Small grains were planted as the first-year crop in 29% of cases in the Dakotas and 6% of cases in the other four states. As a second-year crop, small grains occurred in 26% of cases in North Dakota and 5% of cases in the other five states. Stand length, soil textural class, state, and year significantly influenced grower choice of both following crops. These geographic assessments will guide research and extension education designed to increase use of perennials for economic and environmental benefits. Similar methods can be applied to other crop rotations or U.S. regions.

Alfalfa is the fourth most widely grown and valuable crop in the United States (USDA-NASS, 2013a) after corn, soybean, and wheat (*Triticum aestivum* L.). For 2010 to 2012, USDA-NASS estimated that 7.6 million ha of alfalfa was grown annually in the United States and that this crop had a value of U.S. $7.5 billion. In addition to the economic benefits, alfalfa provides many environmental benefits to cropping systems (Olmstead and Brummer, 2008). Growing alfalfa often improves soil physical properties because tillage does not occur after the crop is established (Raimbault and Vyn, 1991; Russell et al., 2006; Coulter et al., 2013). Other soil quality benefits of alfalfa include: (i) reduced soil NO_3–N losses compared to corn and soybean (Randall et al., 1997; Huggins et al., 2001; Kanwar et al., 2005) primarily because alfalfa provides continuous soil cover, requires no fertilizer N, and can extract soil NO_3–N to depths of at least 2.7 m (Kelner et al., 1997; Entz et al., 2001); and (ii) reduced weed seedbanks and herbicide requirements (Cosgrove and Barrett, 1987).

Alfalfa also provides many benefits to subsequent crops. It often can reduce weed (Ominski et al., 1999; Porter et al., 2003), insect, and disease pressure (Bullock, 1992; Pikul et al., 2005) leading to increased yield for subsequent annual crops. For example, grain yield for first- and second-year corn following alfalfa often is at least 10% higher than adequately fertilized continuous corn (Crookston et al., 1991; Mallarino and Ortiz-Torres, 2006; Stanger and Lauer, 2008). Another well documented benefit of alfalfa is provision of organic or "free" N to subsequent crops. A summary of 471 site-years concluded that the fertilizer N requirement of first-year corn following alfalfa frequently was eliminated or reduced (Yost et al., 2014c). Another 67 site-year summary for second-year corn following alfalfa indicated that fertilizer N was required in only 55% of the cases (Yost et al., 2014b). Alfalfa-supplied N also can benefit the following crop of wheat, but wheat often responds to fertilizer N (Westermann and Crothers, 1993; Malhi et al., 2010) even though its total N requirements are lower than corn. Wheat following alfalfa also can be sensitive to excessive N, which can increase lodging and reduce harvestable grain yield (Kelling et al., 2002). Due to lower water requirements, wheat or other small grains following alfalfa may be preferable to corn for water-stressed environments (Pikul et al., 2005). Finally, the N benefits to subsequent crops may be severely underutilized if N-fixing crops such as soybean or dry bean (*Phaseolus vulgaris* L.) are grown following alfalfa (Robbins and Carter, 1980; Meek et al., 1994).

Crop rotation benefits of alfalfa depend on the length of time the crop is grown. For example, the frequency and level of fertilizer N response for first-year corn were greater following short (≤2 yr) alfalfa phases than longer (3–7 yr) phases (Yost et al., 2014c). Alfalfa stand length also affects net returns, with optimal phase lengths varying by region. In Wisconsin and western Canada, 2- to 3-yr-long stands (including the establishment year) maximized average annual net return during alfalfa production (Zentner et al., 1986; Barnett, 2006; Undersander and Barnett, 2008), whereas 4- to 5-yr-long stands were optimal in Manitoba (Jeffrey et al., 1993). Despite the stand age importance to alfalfa N contributions for succeeding crops and overall profitability, no geographic and only limited survey data exist quantifying alfalfa stand or phase lengths in the Upper Midwest (i.e., North Dakota, South Dakota, Nebraska, Minnesota, Iowa, and Wisconsin), where about one-third of the nation's alfalfa is produced (USDA-NASS, 2013a). Furthermore, no geographic data are available that describe crop rotation patterns following alfalfa termination. Several factors, including geographic location, soil texture, year, market prices, and weather, are hypothesized to be influencing the perceived role that alfalfa has in this region.

The USDA-NASS provides the most comprehensive estimates of crop area in the United States, with agricultural census data collected every 5 yr plus annual grower surveys. It also provides annual geographic estimates of crop area in CDLs by classifying satellite imagery into raster datasets with 30- or 56-m spatial resolution. With several years of CDLs now available for many states, crop rotation patterns can be examined. Cropland Data Layers have been used to evaluate potato (*Solanum tuberosum* L.) production systems in Maine during 2008 to 2010 (DeFauw et al., 2012), to monitor shifts from corn–soybean rotations towards increased monoculture cropping (four continuous years of either crop) in the central United States during 2003 to 2010 (Plourde et al., 2013), and to determine how increased corn price and production area have changed corn–soybean rotation patterns in Iowa during 2001 to 2010 (Stern et al., 2012). However, to our knowledge, CDLs have not been used to examine rotation patterns of perennial and annual crops.

The objectives of this research were to: (i) describe geographic trends in alfalfa phase length in the Upper Midwest; (ii) determine whether alfalfa phase length is related to soil textural class; and (iii) determine whether alfalfa phase length, soil textural class, or year are related to the two crops grown following alfalfa termination.

MATERIALS AND METHODS

Seven CDLs for North Dakota, South Dakota, Nebraska, Minnesota, Iowa, and Wisconsin (USDA-NASS CDL, 2006–2012) were combined. The CDLs were re-classified into five major crop categories for this region based on area (alfalfa, corn, soybean, small grains, and minor crops) and three other categories (noncropland, water, and a combination of perennial forages called "grass") using Spatial Analyst of ArcGIS (ArcGIS 10.1, ESRI, Redlands, CA). Within the re-classified CDLs, all types of corn were placed in a "corn" category, all major and minor small grains [i.e., wheat, barley (*Hordeum vulgare* L.), oat (*Avena sativa* L.), millet [primarily *Panicum miliaceum* L., *Pennisetum glaucum* (L.) R. Br., and *Setaria italica* (L.) P. Beauv.], rye (*Secale cereale* L.), triticale (× *Triticosecale* Wittm.), spelt (*Triticum spelta* L.), and "other small grains" were placed in a "small grains" category, and all other field, fruit, and vegetable crops were placed in a "minor crops" category. Categories with two crops in a year (i.e., double cropping) were re-classified as the first of the two crops. All subsequent raster and vector data processing, smoothing, merging, selecting attributes, and mapping were conducted using ArcGIS 10.1.

To combine the 7 yr of crop data, CDLs with spatial resolution of 56 m (i.e., 2006–2009) were split into 28-m resolution subsets and resampled at 30-m resolution with the nearest neighbor technique. The conversion from 56- to 30-m resolution, instead of the reverse, was chosen to better utilize the higher resolution data. All CDLs were generalized with two passes of an eight nearest-neighbor majority filter to remove single or small clusters of pixels inside broader agricultural fields or other large areas. After generalization, all seven CDLs within a state were combined into a single raster with the Raster Calculator tool using the equation: 2012 CDL + (2011 CDL × 10) + (2010 CDL × 100) + (2009 CDL × 1000) + (2008 CDL × 10,000) + (2007 CDL × 100,000) + (2006 CDL × 1,000,000). The combined 7-yr raster data were converted to vector data (polygons) for each state. Polygons with ≥1 yr of alfalfa and ≥0.5 ha were selected for further analyses of alfalfa phase length and following crop selection.

The area in hectares for each polygon was calculated by state using the North American (1983) (High Accuracy Reference Network–Transverse Mercator) projected coordinate system for Wisconsin and the World Geodetic System (1984) (Universal Transverse Mercator Zones 14–15 North) projected coordinate system for the other five states. After calculating the areas, the projected coordinate system of each state was converted to the North America Lambert Conformal Conic using the "North American Datum_1983 to High Accuracy Reference Network_Wisconsin" transformation for Wisconsin and "North American Datum_1983_to_World Geodetic System_84_1" transformation for the other five states. This manipulation enabled the data for all six states to be merged into one shapefile.

Soil textural class attributes from the USDA-NRCS soil survey geographic database (Soil Survey Staff, 2011) vector data layer were categorized into three classes and spatially joined to the CDL vectors. The coarse-textured category included sand and loamy sand soils. The fine-textured category included clay, clay loam, and silty clay loam soils. The medium-textured category included loam, silt loam, sandy loam, fine sandy loam, and sandy clay loam soils. Complex soils with multiple series were classified using the dominant series within the complex.

Selection Methods

Two selection methods were used to determine alfalfa phase length and crops grown during the 2 yr following alfalfa termination. The first method was to select all polygons with ≥2 consecutive years of alfalfa that began with and were followed by another crop category for any set of years between 2006 and 2012. The ≥6 and ≥7 yr alfalfa phase lengths ended with alfalfa in 2012 and the ≥7 yr phase length began with alfalfa in 2006. This method is hereafter referred to as the "generalized vectors."

14350645, 2014, 5, Downloaded from https://acsess.onlinelibrary.wiley.com/doi/10.2134/agronj14.0014 by Yale University, Wiley Online Library on [30/04/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

The second method, referred to as the "adjusted vectors," included all selections from the generalized vectors and followed the same set of rules for selecting an alfalfa phase length, except that the "grass" category was converted to "alfalfa" when the probability of alfalfa being misclassified as grass was 10% higher than the reverse. The comparisons of alfalfa and grass probabilities were based on user's accuracy and commission error rates from USDA-NASS analyses with ground reference data by state (USDA-NASS, 2013b). For example, the user's accuracy of alfalfa in 2009 in North Dakota was 74% and the corresponding commission rate to grass was 19%. The probability of alfalfa being misclassified as grass for this example was calculated as 19/(19 + 74) = 0.20. The product of probabilities for both types of misclassification was calculated for all combinations of two, three, or four consecutive years (2009–2012) with both alfalfa and grass. Probabilities could not be calculated for the 2006 and 2007 CDLs because full error matrices were not available from the USDA-NASS. The full error matrix was available for the 2008 CDLs, but probabilities were not used for this year because the USDA-NASS changed the definition of the "alfalfa" category beginning in 2009 to include two additional types of alfalfa from the USDA-Farm Service Agency reports (i.e., alfalfa–grass mixtures and alfalfa interseeded with small grains). Therefore, for the 2006 to 2008 CDLs, a single or double year of grass was converted to alfalfa when the majority of years for given alfalfa phase lengths were classified as alfalfa in generalized CDLs. For example, "grass" in the code "corn–grass–grass–alfalfa–alfalfa–alfalfa–corn–corn" for the 2006 to 2012 CDLs, respectively, was converted to "alfalfa".

The two crops following alfalfa also were selected using both the generalized and adjusted vectors. First-year crops following ≥2 yr of alfalfa were selected for 2008 to 2012, and the same criterion was used for second-year crops in 2009 to 2012. To test the effect of alfalfa stand length on the type of following crop, data were restricted to first-year crop in 2011 and second-year crop in 2012. Thus, crops following only 2- to ≥5-yr-old alfalfa could be determined for this analysis.

Statistical Analysis

Interactions between categorical variables were analyzed with chi-square statistics at $P \leq 0.05$ by state with $s \times r$ contingency tables (Stokes et al., 2012) using the FREQ procedure of SAS (SAS Institute, 2006). Data were analyzed with alfalfa phase length and year as ordinal variables, and with selection method, soil textural class, and following crop as nominal variables. Spatial clustering in alfalfa phase length across the six states was evaluated with the Getis–Ord Gi* statistic at $P \leq 0.05$ using hot spot analysis in ArcGIS 10.1. The hot spot analysis was conducted with Euclidean distance as the distance method and fixed distance band as the conceptualization of spatial relationships; the default neighborhood threshold was 34.3 km.

RESULTS AND DISCUSSION

Method Assessment

Alfalfa area in the original raster CDLs was severely underrepresented in most years and states, compared to the USDA-NASS census and survey data (Supplemental Table S1). Across the six states, only 38% of the alfalfa area in the census and survey was represented during 2006 to 2010. In 2011 to 2012, alfalfa area estimates increased and 65% of the crop in the census and survey data was accounted for. In contrast, 95 and 97% of corn and soybean area, respectively, was represented across years and states.

The user's accuracy was consistently high (91–99%) across years and states for corn and soybean, but was generally lower and more inconsistent (30–95%) for alfalfa (Supplemental Fig. S1). Nebraska and Wisconsin had the highest user's accuracy (82–95%) for alfalfa across years. Nebraska's accuracy was high likely because nearly one-third of alfalfa was irrigated compared to <4% in the other five states (USDA-NASS, 2013a), making it easier to distinguish spectrally from other crops or noncropland. The high accuracy for Wisconsin may have been due to improved ground reference data, because a higher percentage of total cropland (34%) was planted to alfalfa than in the other states (4–14%; USDA-NASS, 2013a). For the remaining states, the lower accuracy for alfalfa classification relative to annual crops is a concern, especially since alfalfa is the fourth most widely grown crop in both this region and the nation. Overall, the lower alfalfa accuracy is likely related to: (i) difficulty in distinguishing it from other hay types, grassland, and pastures using remote sensing; (ii) inadequate standards for determining how much alfalfa is necessary for a field to be classified as alfalfa vs. another hay type or grassland; and (iii) inadequate and inconsistent ground reference data from the USDA-NASS and the USDA-Farm Service Agency for alfalfa.

To remedy the low alfalfa classification accuracy, we generalized and converted the original raster files to vectors and removed all polygons <0.5 ha. On average, the generalized vector CDL had two-thirds of the original raster CDL area of alfalfa across years in Nebraska and North Dakota and had one-half the area in the remaining states (Supplemental Table S1). This decline likely occurred because: (i) some alfalfa fields in original raster CDLs had more grass pixels than alfalfa, so the alfalfa field was generalized to grass; and (ii) several alfalfa pixels in original raster CDLs were single or small clusters of pixels. Although generalized vector CDLs reduced alfalfa area, the estimates were highly correlated to original raster CDLs across years and states (generalized = 18.0 + 0.458 × original, $r^2 = 0.92$, $P < 0.001$, $n = 42$).

To further account for the original low classification accuracy for alfalfa, we adjusted generalized vector CDLs by converting some grass to alfalfa using classification error rates. This increased alfalfa area by 3 to 11% across years and states relative to generalized vector CDLs (Supplemental Table S1). Adjusted CDL alfalfa area also was highly correlated with the original raster CDLs across years and states (adjusted = 25.8 + 0.451 × original, $r^2 = 0.92$, $P < 0.001$, $n = 42$). For most cases, original raster, generalized vector, and adjusted vector CDLs were poorly correlated to the official census and survey area for alfalfa. We suggest this occurred because classifications of alfalfa during the establishment year and alfalfa–grass mixtures were inconsistent among years, states, and sources.

Selection method (generalized or adjusted vectors) significantly affected alfalfa phase length in all states, but it significantly affected first-year crop type only in Minnesota and Iowa and second-year crop type only in South Dakota (Supplemental Fig. S2). The added alfalfa area and subsequent changes in phase lengths from adjusted vectors differed by state because

14330645, 2014, 5, Downloaded from https://acsess.onlinelibrary.wiley.com/doi/10.2134/agronj14.0014 by Yale University, Wiley Online Library on [30/04/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

adjustments were dependent on state and year classification error rates (Supplemental Fig. S1). All phase lengths were increased in states with lower alfalfa classification accuracy (North Dakota, South Dakota, Minnesota, and Iowa), whereas only longer phases were affected in states with higher accuracy (e.g., 4 to ≥7 yr phases in Nebraska; ≥6 yr phases in Wisconsin). In general, the proportion of longer alfalfa phases increased in most production areas of this region with adjusted vectors (Supplemental Fig. S3). Both selection methods resulted in significant ($P < 0.001$) interactions for alfalfa phase length × soil textural class, alfalfa phase length × following crop, year × following crop, and soil textural class × following crop. Only the adjusted vector results are presented because of the consistency between methods and ability of adjusted vectors to partially remedy the relatively lower alfalfa classification accuracy in the original raster CDLs.

Alfalfa Phase Length

Geographic Location. Alfalfa stands were maintained for ≤4 yr in a higher proportion of polygons in the eastern states of Iowa (82%), Wisconsin (67%), and Minnesota (62%), than in the drier western states of Nebraska (45%), South Dakota (38%), and North Dakota (12%) (Supplemental Fig. S2), but phase length distributions differed within states (Fig. 1). Areas with spatial clustering of shorter alfalfa phases had 72% of phases ≤4-yr-long, whereas areas with longer phases had 76% of phases ≥5-yr-long; areas with no clustering had an equal number of both phase categories. Shorter phases were typical in Iowa (except for the southern part of the state), the southeastern part of South Dakota, the eastern quarter of Nebraska, and nearly everywhere south of U.S. Interstate 94 in Minnesota. Longer alfalfa phases were typical across the Dakotas (except near the Red River Valley in North Dakota and the southeast area of South Dakota), in western areas of Nebraska, and northern areas of Minnesota. Wisconsin had the greatest spatial complexity in alfalfa phase length, with three to four clusters of both shorter and longer phases.

A survey of 253 growers in Manitoba and Saskatchewan (Entz et al., 1995) found that forage (including alfalfa) phase length was dependent on annual precipitation; phases ranged from 3 to 5 yr in wetter areas and from 6 to 9 yr in the driest areas. Their survey results also revealed that most growers did not rotate according to planned schedules but rather terminated forage when yield declined. Another survey of 528 growers in Minnesota confirmed these results; 98% rotated alfalfa for reasons other than a planned schedule (Yost et al., 2014a). Therefore, the patterns we identified in alfalfa phase length likely were related to climatic zones, which affect alfalfa's productivity and over-wintering ability. Growers in the drier areas of this region (i.e., most areas north, west, and northwest of the major Corn Belt) may be able to maintain alfalfa stands longer because the likelihood of soil compaction and alfalfa disease pressure can be lower than in wetter areas. In contrast, low water availability in drier climates can reduce alfalfa yield and feed quality (Vough and Marten, 1971). Another possible reason for shorter alfalfa stands inside the major Corn Belt area of this region is the higher presence of dairy cattle and alfalfa end-use. Much of the Dairy Belt lies within the Corn Belt area and alfalfa feed quality is typically of higher importance for lactating dairy cow than other cattle rations. Therefore, growers in the Corn Belt may harvest and rotate alfalfa more frequently to maintain high feed quality and to avoid thin

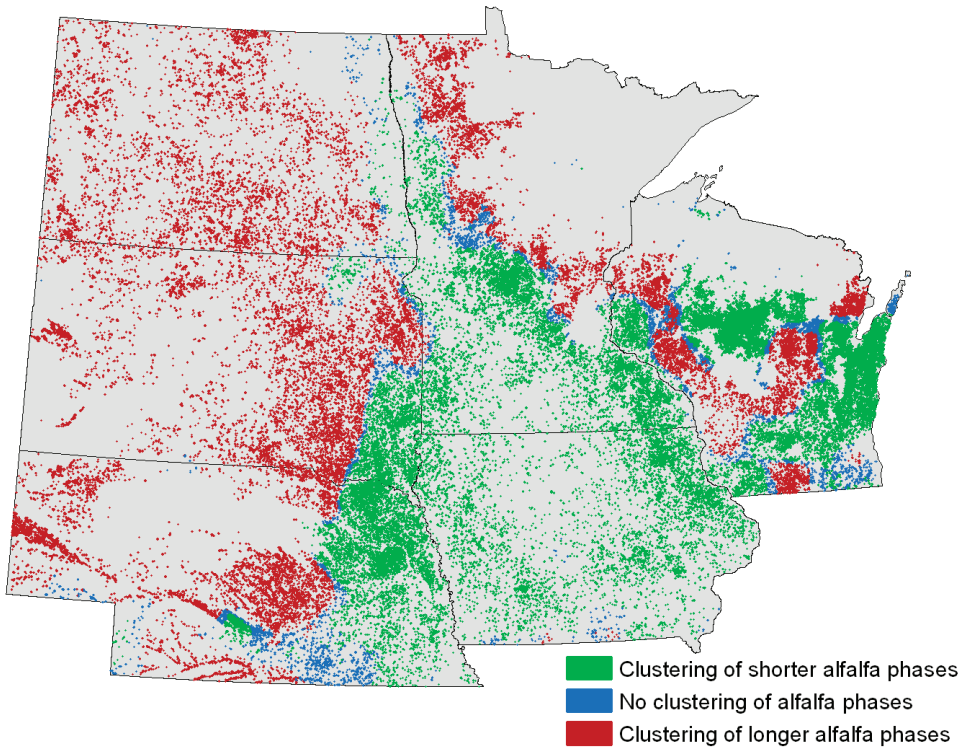

Fig. 1. Spatial clustering patterns of alfalfa phase length (2 to ≥7 yr) in the upper midwestern United States from the adjusted vector USDA-National Agricultural Statistics Service Cropland Data Layers (2006–2012) according to Getis-Ord Gi* statistic at $P \leq 0.05$. Areas with shorter phase clustering had 72% of phases ≤4-yr long, whereas areas with longer phase clustering had 76% of phases ≥5-yr long; areas with no clustering had an equal number of both phases. Polygon borders are enlarged to enhance visibility.

14350645, 2014, 5, Downloaded from https://acsess.onlinelibrary.wiley.com/doi/10.2134/agronj14.0014 by Yale University, Wiley Online Library on [30/04/2026]. or weedy stands. Such generalizations do not account for the complex weather variations within and among states that affect alfalfa phase length. Further analyses should determine these effects; dynamic empirical crop rotation models (MacEwan, 2012) may prove useful in that research.

Soil Textural Class. Alfalfa is grown on all three soil textural classes in this six state region. Medium-textured soils had the greatest area and spatial distribution, while coarse-textured soils had the least (Fig. 2; Supplemental Fig. S4). Soil texture affects aeration, water holding capacity, organic matter retention, and other factors that influence crop production. Alfalfa phase lengths in the Dakotas and Iowa were relatively consistent for coarse- and medium-textured soils, but fine-textured soils had a higher frequency of shorter phases (Fig. 3). A similar trend occurred in Nebraska, Minnesota, and Wisconsin, with the exception that phase length generally declined as soil textural class changed from coarse to fine. The trend for longer phases in some of the central sand plains of Wisconsin may be related partially to the lower risk for soil compaction and disease caused by excess water and poor drainage on these soils than on medium- and fine-textured soils. Shorter phases on fine-textured soils across these states, coupled with survey results indicating that most forage growers do not follow planned crop rotations (Entz et al., 1995; Yost et al., 2014a), suggests that fine-textured soils may not support alfalfa stands as long as soils with less clay. Machinery traffic required for multiple alfalfa harvests per year, together with the pressure for timely harvest on soils with greater water holding capacity (fine-textured soils; Hamza and Anderson, 2005) increases the likelihood for soil compaction, which often leads to decreased herbage yield and greater winter damage (Bélanger et al., 2006). Future research and education should focus on whether and how alfalfa management should differ by soil textural class.

Several other management factors including: (i) cultivar characteristics (winter-hardiness, disease resistance, yield potential); (ii) disease, nutrient, pest, and weed management; (iii) harvest timing and frequency; (iv) end-use (feed for on-farm use or hay sold as a cash crop); (v) market prices of alfalfa and other commodity crops; and (vi) sociological conditions (e.g., off-farm employment, dependence on custom harvesting, etc.) also affect how frequently growers terminate alfalfa in this region (Undersander et al., 2011). However, we do not have sufficient data to analyze how these complex factors interact with each other and with climate and/or soil conditions. Future research should seek to identify additional factors beyond geographic location and soil textural class that regulate trends in alfalfa–annual crop rotation patterns.

First-Year Crops following Alfalfa

Many of the complex interacting factors affecting alfalfa phase length also can affect a grower's selection of subsequent crops. We defer speculation regarding which of these factors influenced first- and second-year crop selection following alfalfa, but show geographic distributions of each and present statewide trends to examine generalized grower behavior. Our goal is to help guide future research that may be able to identify specific reasons for these behaviors and how they vary within and among states.

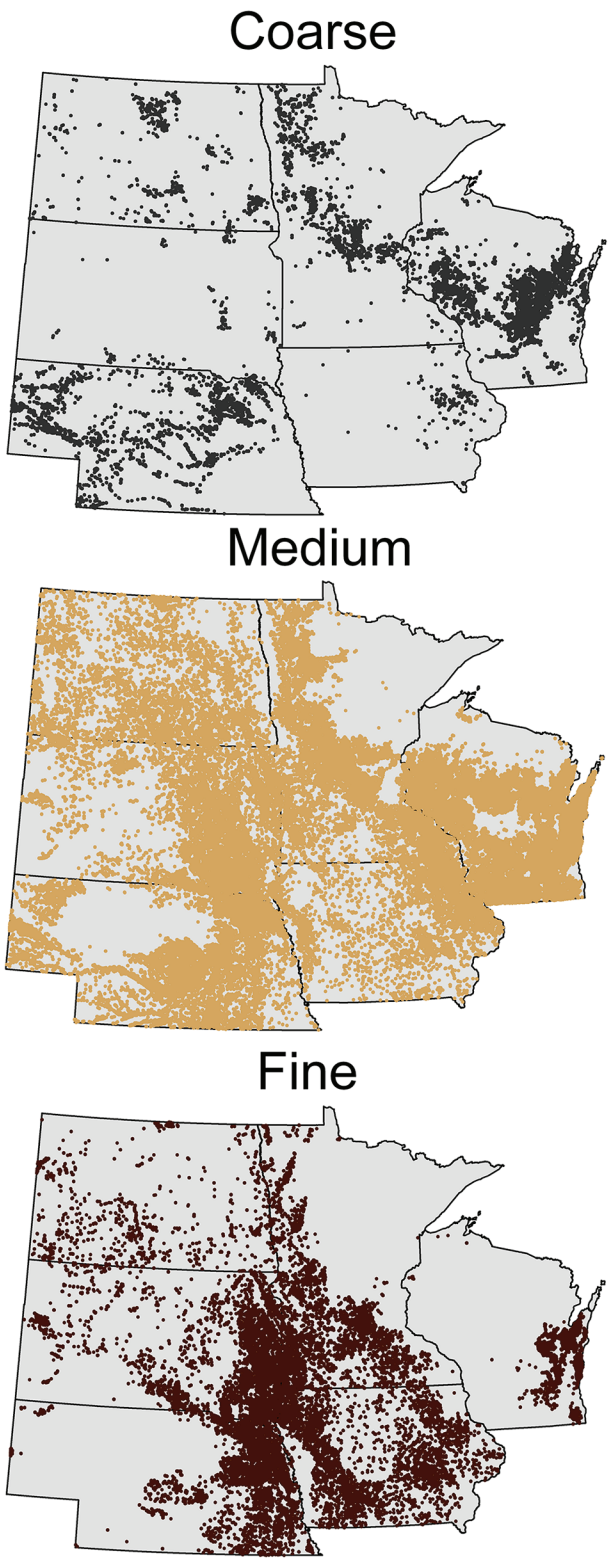

Fig. 2. Soil textural class (coarse, medium, or fine) for polygons where alfalfa phase length or following crops could be determined from the adjusted vector (described in text) USDA-National Agricultural Statistics Service Cropland Data Layers (2006–2012). Polygon borders are enlarged to enhance visibility.

Spatial distributions for corn and soybean as first-year crops were generally similar in all states except Nebraska, where only corn was produced in the western part of the state (Fig. 4; Supplemental Fig. S5). Corn was the most frequent first-year

14350645, 2014, 5, Downloaded from https://acsess.onlinelibrary.wiley.com/doi/10.2134/agronj14.0014 by Yale University, Wiley Online Library on [30/04/2025]. Fig. 3. The percent of total area where the phase length of alfalfa (shading represents years) could be determined from the adjusted vector (described in text) USDA-National Agricultural Statistics Service Cropland Data Layers (2006–2012) by state and soil textural class (coarse, medium, and fine). Differences in alfalfa phase length categorization among soil textural class within states according to chi-squared tests were denoted with *** for $P \leq 0.001$.

crop (61–92% of cases) in all states except North Dakota (40%) (Fig. 5). Soybean, which usually requires no fertilizer N (Salvagiotti et al., 2008), was the first-year crop in 15% of the cases in the Dakotas, Minnesota, and Iowa, 7% in Nebraska, and 3% in Wisconsin. These cases were spatially distributed across much of the region except for the western halves of the Dakotas and Nebraska, indicating that a substantial, widespread proportion of growers may be underutilizing the large first-year N supply following alfalfa. This analysis cannot determine why soybean was planted following alfalfa, but we suspect that it is related to soybean market price, timing of alfalfa termination (late-spring or early summer termination), growing season length, and water use requirement of soybean vs. other crop types (Copeland et al., 1993). Future research should identify the conditions where soybean following alfalfa is economically and environmentally viable.

Spatial distributions for small grains and minor crops tended to be similar in North Dakota and Minnesota, whereas the areas of production did not overlap consistently in Nebraska, South Dakota, and Wisconsin (Fig. 4). Small grains, but not minor crops, followed alfalfa in the eastern halves of South Dakota and Nebraska and southern third of Wisconsin. Small grains were the first-year crop grown most frequently in the Dakotas (29% of cases) and Minnesota and Nebraska (10%), and minor crops most frequently in North Dakota (8%; Fig. 5). Most minor crops in North Dakota likely were sunflower (*Helianthus annuus* L.), sugarbeet (*Beta vulgaris* L.), and potato, because these were the minor crops with the largest area in these states (USDA-NASS, 2013a). Southeastern South Dakota and eastern Wisconsin had the highest spatial densities of small grains, which indicates that these areas may benefit from future research and education on alfalfa N credits to small grains (Fig. 4).

Alfalfa Phase Length. Phase length (2 to ≥5 yr) was significantly related to the type of first-year crop following alfalfa in 2011 in each state (Fig. 5), with the largest differences in North Dakota and Minnesota. In North Dakota, the longest alfalfa phases were more frequently followed by soybean and corn, whereas shorter phases were more frequently followed by small grains or minor crops. In Minnesota, the frequency of small

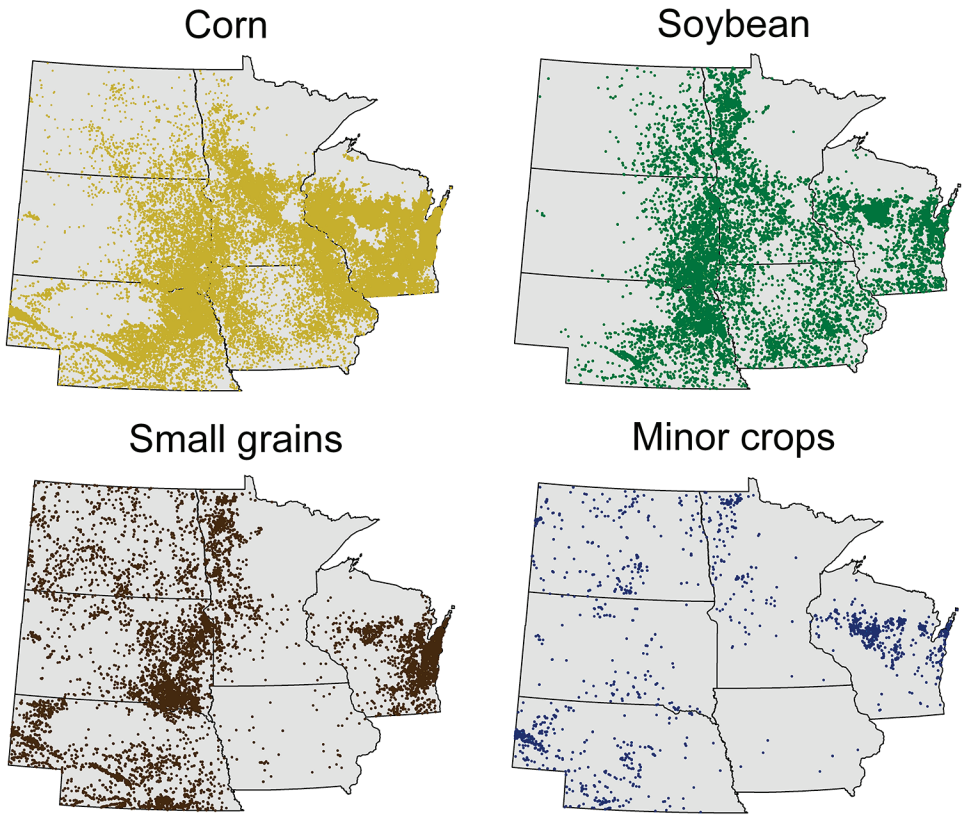

Fig. 4. Five-year (2008–2012) footprint of corn, soybean, small grains, and minor crops grown as the first crop after alfalfa termination, determined from the adjusted vector (described in text) USDA-National Agricultural Statistics Service Cropland Data Layers (2006–2012). Polygon borders are enlarged to enhance visibility.

14330645, 2014, 5, Downloaded from https://acsess.onlinelibrary.wiley.com/doi/10.2134/agronj14.0014 by Yale University, Wiley Online Library on [30/04/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

grains following 4-yr-long alfalfa phases was 31% compared to 7% frequency for the other phase lengths. There were smaller differences in the remaining four states, with small grains being slightly more frequent after longer alfalfa phases (i.e., 4 or ≥5 yr) in South Dakota, Nebraska, and Iowa, and soybean being more frequent after shorter phases in Nebraska. In Wisconsin, the frequency of minor crops as the first-year crop increased by 5% points when following 2-yr-long phases compared to all longer alfalfa phases, but there was high correspondence of areas with shorter phases followed by small grains and minor crops (Fig. 4). This pattern contrasts with that in the other states, where small grains and minor crops tended to follow longer alfalfa phases.

Soil Textural Class. The first-year crop type also changed with soil textural class (Fig. 5). In the Dakotas, corn frequency was highest for coarse-textured soils; small grains were more frequent for medium- and fine-textured soils. A higher frequency of corn on coarse-textured soils was unexpected because these soils typically have low water holding capacity and long-term trials in South Dakota indicate that when soil moisture is limited, the yield of first-year corn following alfalfa can be lower than corn in other rotations (Pikul et al., 2005). We speculate that the higher frequency of corn on coarse-textured soils was due to availability of irrigation. Field research for first-year corn following alfalfa on coarse-textured soils showed that it usually requires fertilizer N to maximize economic return (Yost et al., 2014c). This indicates that significant losses of mineralized N from alfalfa may be occurring even with a crop that has high N uptake potential. Crops with lower N uptake potential than corn, such as small grains and soybean, may further increase N loss under these conditions. In Nebraska, soybean frequency as the first-year crop increased and small grains decreased on medium- and fine-textured soils (Fig. 5). Crop type was less related to soil textural class in Minnesota, Iowa, and Wisconsin. Minnesota and Iowa had higher corn and lower soybean frequencies on medium-textured soils than other textures, and Minnesota also had slightly higher small grain and lower corn frequencies on coarse-textured soils than other textures. Wisconsin had slightly higher small grains and lower minor crop frequencies on medium- and fine-textured soils.

Year. First-year crop type was affected by the year in which it was produced in all states, although differences were small for Nebraska and Wisconsin (Fig. 5). Corn frequency decreased and minor crop increased in 2009 to 2011 in North Dakota. Corn frequency increased and small grains decreased from 2008 to 2012 in South Dakota; increasing corn frequency may be related to increasing corn grain prices during this time (Stern et al., 2012; USDA-NASS, 2013a). Corn was grown as the first-year crop less frequently in 2009 and 2010 in Minnesota and Iowa compared to other years; soybean replaced much of this corn area in Iowa and small grains replaced much in Minnesota. Market prices of the major and minor crops influence which crops are grown following alfalfa each year in this region, but this analysis does not include the temporal and spatial complexities in crop market prices and how they might influence grower decisions about which crops to grow. Hennessy (2006) investigated price-dependent and price-independent crop rotation structures for corn–soybean rotations in Iowa and found evidence for price dependencies

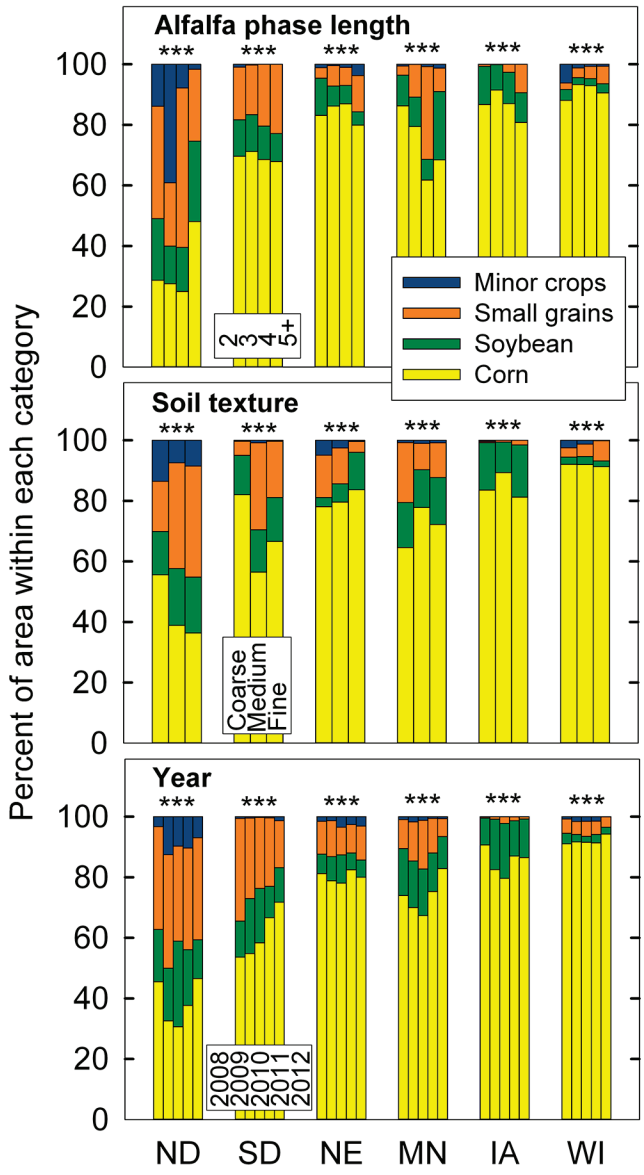

Fig. 5. The percent of the total area where the first-year crop following ≥2-yr-old alfalfa could be determined from the adjusted vector (described in text) USDA-National Agricultural Statistics Service Cropland Data Layers that was major and minor crops for each state by: (i) the length of the alfalfa phase in years (top); (ii) soil textural class (middle); and (iii) year when the indicated crops were grown (bottom). Differences in categorization among phase length, soil textural class, and year within states according to chi-squared tests were denoted with *** for $P \leq 0.001$.

(i.e., memories) of 1 yr for corn and 2 yr for soybean. Residual effects of soybean included a lower fertilizer N requirement and higher corn yield than continuous corn. This type of analysis could be expanded to include price structures for alfalfa–annual crop rotations.

Second-Year Crops following Alfalfa

Distributions of corn and soybean as second-year crops after alfalfa were similar to their first-year distributions, but fewer hectares were planted to corn and more to soybean (Fig. 6; Supplemental Fig. S6). Corn was the second-year crop grown in one-half to three-fourths of the cases in all states except North Dakota, where it was grown in about one-third of the cases (Fig. 7). Soybean was grown in one-fourth to one-third of the

14350645, 2014, 5, Downloaded from https://acsess.onlinelibrary.wiley.com/doi/10.2134/agronj14.0014 by Yale University, Wiley Online Library on [30/04/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cases in each state except Wisconsin, where soybean frequency was only 14%. The high frequency of soybean distributed across most states indicates that many growers may not be utilizing the "free" N supply from alfalfa to the second-year crop, but perhaps are taking advantage of the soybean yield increase due to the rotation effect with corn (Crookston et al., 1991). Evaluation of the relative effects of residual N availability vs. the non-N rotation effect for second-year crops may provide the basis for making better decisions to improve economic returns.

Small grains as second-year crops were less common than as first-year crops, but spatial distributions of small grains as both crops were similar. Small grains were the second-year crop in 5% of the cases in all states except North Dakota, where they comprised one-fourth of the cases (Fig. 6). North Dakota also had the highest frequency of minor crops (8%). Alfalfa was the second-year crop in 5% of the cases across all states (Fig. 7), but it was more common within some areas, such as central and eastern Wisconsin and south-central and east-central Nebraska (Fig. 6). Because it is slow to establish, alfalfa as the second-year crop could lead to high nitrate losses if the N supply from the previous alfalfa phase continues to be high (Huggins et al., 2001).

Alfalfa Phase Length. Second-year crop types in 2012 were affected by alfalfa phase length in each state (Fig. 7). Soybean frequency as the second-year crop in North Dakota was higher when following alfalfa phases of ≥5 yr, and alfalfa frequency increased for 4-yr phases relative to other phases. In South Dakota, corn frequency increased from 38 to 53% when following 3-, 4-, and ≥5-yr alfalfa phases relative to 2-yr phases. Nebraska had a higher frequency of minor crops and a lower frequency of soybean for the longest phase length compared to shorter phases. Corn frequency decreased following longer alfalfa phases (4 and ≥5 yr) relative to shorter phases in Minnesota, but this may reflect the different geographic locations of the fields (Fig. 1). In Iowa, soybean followed 2-yr alfalfa

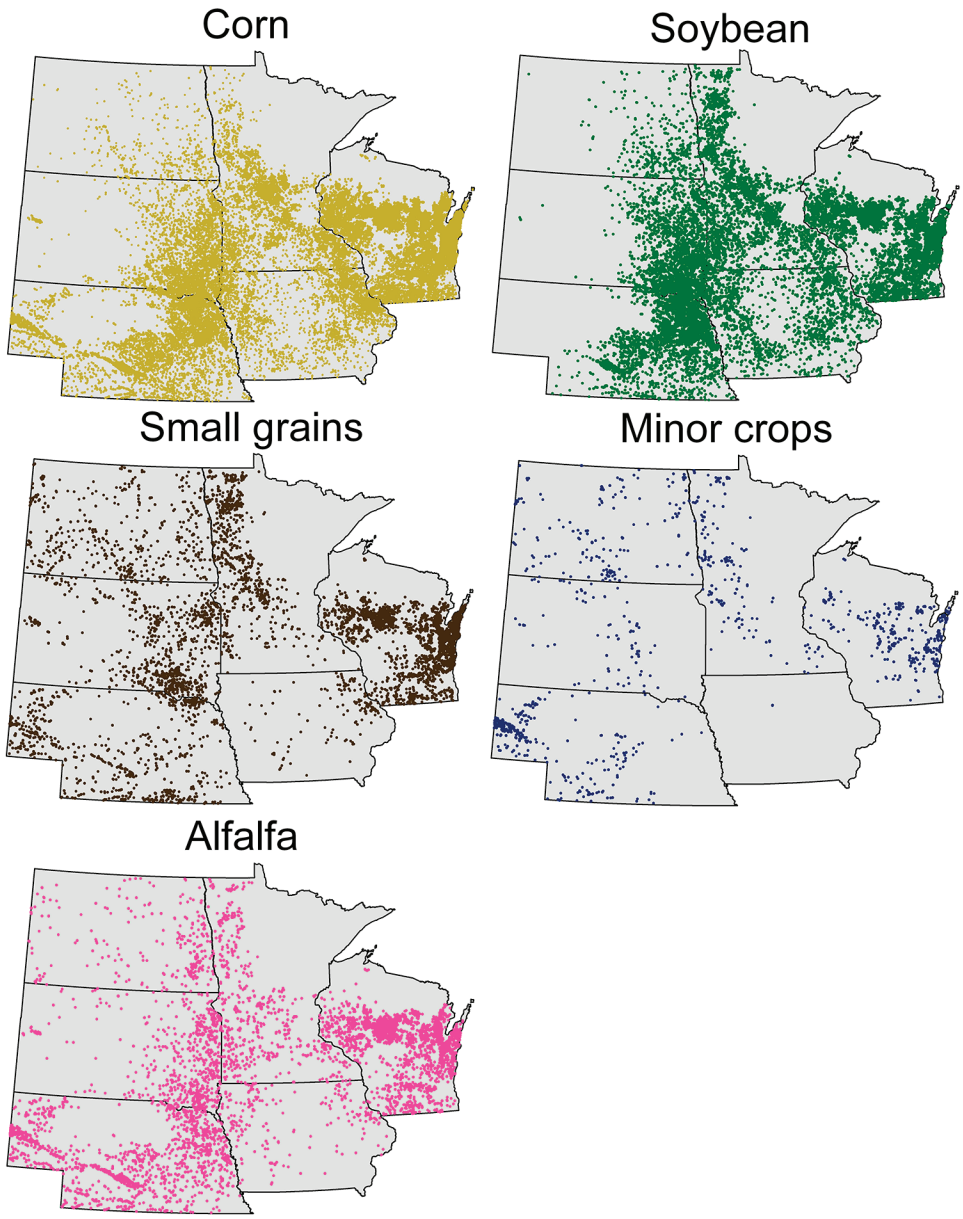

Fig. 6. Four-year (2009–2012) footprint of corn, soybean, small grains, minor crops, and alfalfa grown as the second crop after alfalfa termination, determined from the adjusted vector (described in text) USDA-National Agricultural Statistics Service Cropland Data Layers (2006–2012). Polygon borders are enlarged to enhance visibility.

14350645, 2014, 5, Downloaded from https://acsess.onlinelibrary.wiley.com/doi/10.2134/agronj14.0014 by Yale University, Wiley Online Library on [30/04/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

phases more frequently than longer phases, which were more frequently corn (Fig. 7). Increased soybean frequency following shorter alfalfa phases may be related to a perception by growers that the alfalfa N credit is higher after longer alfalfa phases. The frequency of alfalfa as the second-crop was higher following shorter alfalfa phases (2 and 3 yr) in Wisconsin, and there was a slightly lower frequency of corn for the shortest phase.

Soil Textural Class. As with the first-year crop, the second-year crop also was affected by soil textural class in each state (Fig. 7). In North Dakota, the frequency of minor crops increased and corn decreased as soil textural class changed from coarse to fine. In contrast, coarse-textured soils in South Dakota had higher corn and lower small grain frequencies than medium- and fine-textured soils. As described for first-year crops, the increased frequency of corn on coarse-textured soils may be related to increased availability of irrigation for these soils relative to other textural classes. As soils changed from coarse to fine in Nebraska, soybean frequency increased, whereas all remaining crop types decreased. The frequency of corn as the second-year crop increased relative to all remaining crop types on medium-textured soils in Minnesota and on coarse- or medium-textured soils in Iowa. Small grains frequency increased and minor crops decreased on fine-textured soil in Wisconsin.

Year. The type of second-year crop following alfalfa was affected by the year in which it was produced in each state (Fig. 7). In North Dakota, Nebraska, and Minnesota, corn was less frequently grown in 2010 and 2011 than other years. North Dakota had a large increase in alfalfa frequency in 2011 (13% points higher than other years) and soybean frequency decreased by 16% points from 2009 to 2012. In South Dakota, decreased frequency of small grains corresponded with increased soybean from 2009 to 2012. Higher minor crop and lower small grain frequencies occurred from 2009 to 2012 in Nebraska. Wisconsin had minor changes in all second-year crop types from year to year.

First- and Second-Year Crops following Alfalfa

The eight most common sequences of both the first- and second-year crop following alfalfa were various combinations of corn, soybean, small grains, and alfalfa; sequences other than these are referred to as "secondary crop sequences". These various sequences had both overlapping and distinct spatial distributions (Fig. 8). Corn–corn occurred in about one-fifth of the cases in the Dakotas, one-half of the cases in Nebraska, Minnesota, and Iowa, and about three-fourths of the cases in Wisconsin (Fig. 9). Corn–soybean was the second most frequent sequence following alfalfa in all states except North Dakota; this sequence occurred in about one-fourth of the cases (13–31%) across the five states.

The remaining six of eight common crop sequences occurred in 0 to 17% of the cases across states. Soybean–corn had a similar spatial distribution to corn–soybean, suggesting that selection of the first crop in these cases may depend on time of alfalfa termination (Fig. 8). The three common crop sequences with 1 or 2 yr of small grains were distributed mainly in central and eastern Wisconsin and the western half of the region. Most small grains and canning crops (included in minor crops) are short-season crops and may not utilize the alfalfa N supply as effectively as full-season crops like corn. Therefore, despite the agronomic and economic advantages of short-season crops, consideration should be given to the potential for nitrate leaching losses. Secondary crop sequences were most frequent in Minnesota (15% of the time) and North Dakota (34%).

The common and secondary sequences with alfalfa as the second-year crop represented 3 to 7% of the total area in this region. Of this area, the first-year crop was corn 14 to 31% of cases in the Dakotas, 76% of cases in Wisconsin, and 44 to 51% of cases in the remaining states. Soybean was the first-year crop 30 to 43% of cases in all states except Nebraska and Wisconsin (7–11% of cases), small grains were 33% of cases in the Dakotas and Nebraska, and minor crops were 1 to 9% of cases across states. Although sequences with alfalfa as the second-year crop comprise a low percentage of the total in this region, they represent opportunities for crop sequences that more fully utilize the ≥2 yr N contribution of terminated alfalfa.

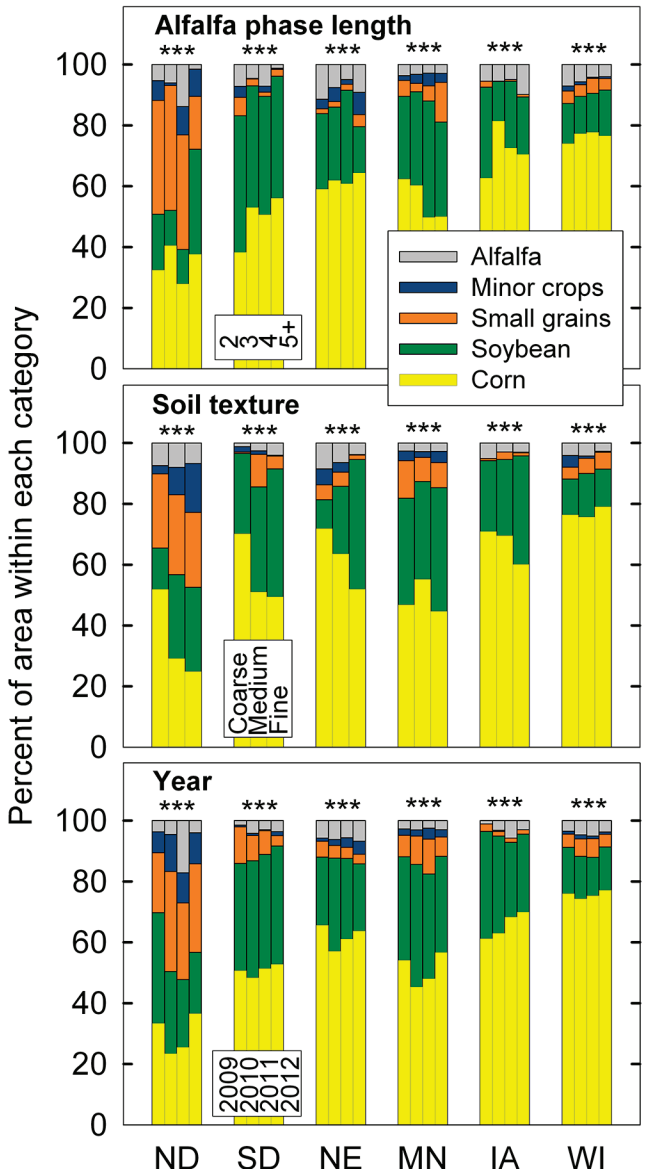

Fig. 7. The percent of the total area where the second-year crop following ≥2-yr-old alfalfa could be determined from the adjusted vector (described in text) USDA-National Agricultural Statistics Service Cropland Data Layers that was major and minor crops. For further description, see caption for Fig. 5.

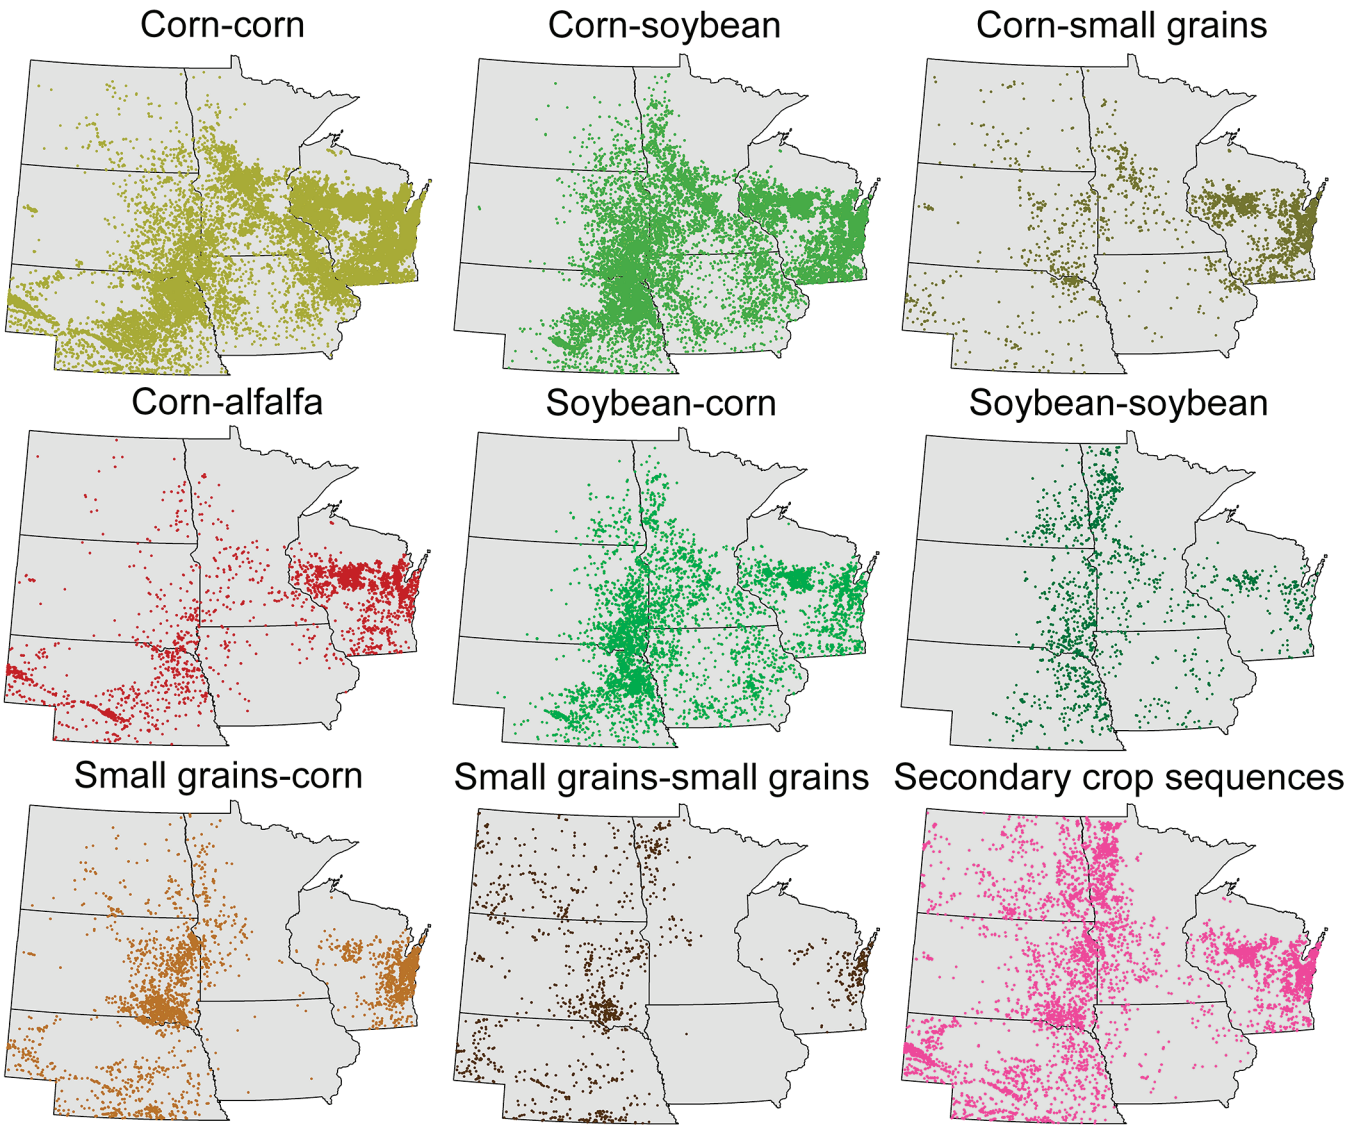

Fig. 8. Five-year (2008–2012) footprint of 2-yr crop sequences following alfalfa termination determined from the adjusted vector (described in text) USDA-National Agricultural Statistics Service Cropland Data Layers (2006–2012). Polygon borders are enlarged to enhance visibility.

Alfalfa Phase Length. Specific sequences of the first-year crop in 2011 and second-year crop in 2012 were affected by the preceding alfalfa phase length in each state (Fig. 9). In North Dakota, ≥5-yr-long alfalfa phases were followed less frequently by 2 yr of small grains and secondary crop sequences than shorter phases; this area was replaced mainly by corn–soybean and small grains–corn sequences. South Dakota had less corn–corn but no change in corn–soybean when following 2-yr-long alfalfa phases compared to longer phases; the opposite occurred in Nebraska. In Minnesota, corn–corn frequency increased by 16% points when following shorter alfalfa phases (2 and 3 yr) relative to longer phases (4 and ≥5 yr), and secondary crop sequence frequencies were variable among phases. Iowa had lower corn–corn and higher corn–soybean frequencies when following 2-yr phases than longer phases. In Wisconsin, corn–corn frequency increased following 3- and 4-yr alfalfa phases relative to other phase lengths, and secondary crop sequence frequency increased following 2-yr phases relative to other phases.

Soil Textural Class. In each state, soil textural class also affected the frequency of specific 2-yr crop sequences following alfalfa (Fig. 9). Corn–corn frequency was higher in the Dakotas on coarse-textured soils than on medium- and fine-textured soils. In Nebraska, corn–corn frequency decreased and corn–soybean increased as soil textural class changed from coarse to fine. Minnesota and Iowa had similar trends for corn–corn; its frequency was higher on medium-textured soils than other soil textural classes. In Wisconsin, secondary crop sequences were less and small grains–corn were more frequent as soil textural class changed from coarse to fine; otherwise crop sequences were relatively consistent across soil textural classes.

Year. The 2-yr crop sequences following alfalfa differed with year in each state, discussed here as the year of the second crop (Fig. 9). Corn–corn was less frequent in 2010 and 2011 than other years in North Dakota, Nebraska, Minnesota, and Iowa; much of the reduced corn–corn area in Minnesota and North Dakota was replaced by secondary crop sequences. In South Dakota, corn–soybean frequency increased and small grains–corn and small grains–small grains decreased from 2009 to 2012. In contrast, the frequency of secondary crop sequences increased from 2009 to 2012 in Nebraska. From 2009 to 2012 in Iowa, the frequency of corn–soybean decreased by 9% points and soybean–corn increased by 6% points. Wisconsin had a slightly

14350645, 2014, 5, Downloaded from https://acsess.onlinelibrary.wiley.com/doi/10.2134/agronj14.0014 by Yale University, Wiley Online Library on [30/04/2026]. Fig. 9. The percent of the total area where both the first- and second-year crop following ≥2-yr-old alfalfa could be determined from the adjusted vector (described in text) USDA-National Agricultural Statistics Service Cropland Data Layers that was combinations of corn (C), soybean (S), small grains (G), alfalfa (A), or secondary combinations of these and minor crops. Year in the bottom figure represents the year when the second-year crop was grown. For further description, see caption for Fig. 5.

higher frequency of corn–small grains in 2010 to 2011 than other years, but was otherwise relatively consistent across years.

IMPLICATIONS

These are the first geographically-specific estimates describing the broad-scale crop rotation patterns of alfalfa with annual crops practiced by growers in the upper midwestern United States. Such spatial descriptions of alfalfa stand length and the two subsequent crops should improve estimates of site-specific economic and environmental benefits of alfalfa in crop rotations, aid in planning of fertilizer need assessments for alfalfa and the crops that follow, and help focus the development of educational programming and future research on crop rotation practices that maximize net return to alfalfa production and utilize the large N supply following alfalfa. Furthermore, these data may help improve water quality and soil erosion modeling at regional and watershed scales, promote more in-depth investigation of N cycling and loss when alfalfa is followed by crops other than corn, and support calculation of locally relevant crop production costs. The methodology we developed also may prove useful for examining rotation patterns of other annual and perennial crops. Future work should seek to identify and understand the complex effects of environmental, economical, and sociological factors on crop rotation patterns over large production areas.

ACKNOWLEDGMENTS

This research was supported by the Minnesota Agricultural Fertilizer Research and Education Council and the Hueg-Harrison Fellowship. We appreciate the technical assistance of Andrew Jenks in processing data and the assistance of David Johnson and Patrick Willis with the USDA-National Agricultural Statistics Service in providing background information about Cropland Data Layers. Carbon-sink potential of continuous alfalfa agriculture lowered by short-term nitrous oxide emission events

Alfalfa is the most widely grown forage crop worldwide and is thought to be a significant carbon sink due to high productivity, extensive root systems, and nitrogen-fixation. However, these conditions may increase nitrous oxide (N_2O) emissions thus lowering the climate change mitigation potential. We used a suite of long-term automated instrumentation and satellite imagery to quantify patterns and drivers of greenhouse gas fluxes in a continuous alfalfa agroecosystem in California. We show that this continuous alfalfa system was a large N_2O source (624 ± 28 mg N_2O m^2 y^{-1}), offsetting the ecosystem carbon (carbon dioxide (CO_2) and methane (CH_4)) sink by up to 14% annually. Short-term N_2O emissions events (i.e., hot moments) accounted for ≤1% of measurements but up to 57% of annual emissions. Seasonal and daily trends in rainfall and irrigation were the primary drivers of hot moments of N_2O emissions. Significant coherence between satellite-derived photosynthetic activity and N_2O fluxes suggested plant activity was an important driver of background emissions. Combined data show annual N_2O emissions can significantly lower the carbon-sink potential of continuous alfalfa agriculture.

Alfalfa (*Medicago sativa*), a nitrogen (N) fixing species, is the most widely grown perennial forage crop worldwide and the largest crop by land area in the Western United States[1,2]. Alfalfa is traditionally used as cattle feed and growth in alfalfa land area is largely driven by increasing global feed demand for dairy and other livestock production[3]. Soil N inputs from symbiotic N fixation[4] help support plant growth but may also be a source of nitrous oxide (N_2O) emissions from both nitrification and denitrification[5]. From a carbon (C) accounting perspective, alfalfa has been referred to as a climate-friendly feedstock due to its soil C sequestration potential as a deep-rooting, perennial plant and reduced N fertilizer inputs[6]. However, few studies have combined carbon dioxide (CO_2), methane (CH_4), and N_2O fluxes in the total net annual CO_2-equivalent (CO_2e) budgets of alfalfa agroecosystems. Continuous measurements are needed to assess the greenhouse gas emissions and net C balance of continuous alfalfa ecosystems as these are likely to differ from other agriculture practices that incorporate alfalfa in short-term rotations[7–9].

The biogeochemical processes that drive N_2O production are notorious for being temporally dynamic and characterized by hot moments of emissions, defined as short periods in time with fluxes significantly larger than the mean[5,10,11]. Thus short-term or infrequent sampling is likely to underestimate the role of hot moments in annual N_2O fluxes[12]. Alfalfa typically has a high water demand and is often irrigated throughout the growing season to maintain productivity[13]. Short periods of anaerobiosis following irrigation or rainfall events combined with soil N inputs can create ideal conditions for hot moments of N_2O production. Acidic conditions may exacerbate the effect as N_2O reductase is inhibited at low pH[5,14]. Oxygen (O_2) availability is an important control on N_2O production via nitrification and anaerobic denitrification[5]. Nitrous oxide production can also be

[1]Ecosystem Science Division, Department of Environmental Science, Policy and Management, University of California at Berkeley, 130 Mulford Hall, Berkeley, CA 94720, USA. ✉e-mail: t.anthony@berkeley.edu

limited by temperature, substrate C, nitrate (NO_3^-), or ammonium (NH_4^+) availability[15]. In soils, these variables are likely regulated by nonlinear asynchronous processes across temporal scales[5,16], requiring high frequency measurements to effectively characterize the controls on N_2O hot moments, and determine drivers of background (i.e., non-hot moment) N_2O fluxes.

The global warming potential of alfalfa agriculture is also affected by carbon dioxide (CO_2) and methane (CH_4) fluxes. Both CO_2 and CH_4 fluxes may be characterized by hot moments of soil emissions. Increased CO_2 respiration often occurs following soil rewetting[17–20] and these pulses can contribute a significant fraction of the annual CO_2 release, particularly in water-limited systems[19,21]. Heterotrophic respiration is thought to be directly regulated by substrate availability, primarily plant photosynthate[22], which can also stimulate the production and emissions of N_2O and CH_4[23,24]. For example, root exudates are well-known labile soil C sources that can prime microbial activity and associated pulses in soil respiration[25]. Up to 20% of C fixed by photosynthesis is released by root exudation that may occur as pulsed inputs[26,27]. Changes in plant productivity within and across years may also regulate greenhouse gas fluxes through impacts on other photosynthetic inputs such as plant litter[28,29]. Alfalfa is generally a net CH_4 sink via microbial CH_4 oxidation under well-drained conditions[6,30,31], but high rainfall events and irrigation can produce anaerobic conditions that can stimulate hot moments of methanogenesis[32]. Even with the potential for periodic CH_4 emissions and CO_2 pulses, long-term eddy covariance measurements of CO_2 and CH_4 suggest that alfalfa cropping systems can be net C sinks at an ecosystem scale[6,31]. However, continuous N_2O measurements are needed to determine the total CO_2e of soils emissions from alfalfa.

With the increasing agricultural demand for alfalfa, continuous long-term measurements of greenhouse gas fluxes are needed to better quantify the net climate impacts of alfalfa agroecosystems. It is also critical to determine the drivers of greenhouse gas emissions to better manage alfalfa for emissions reduction. We used a combined suite of automated flux chambers, continuous environmental sensing, eddy covariance, and satellite imagery of photosynthetic activity to determine patterns and associated controls of CO_2, N_2O, and CH_4 fluxes over four complete years in irrigated alfalfa. We used continuous cavity ring-down spectroscopy (CRDS) and automated chambers to collect over 103,000 individual N_2O, CH_4, and CO_2 flux measurements which were coupled with soil O_2, moisture, and temperature sensors installed across the soil profile and a year-long intensive weekly sampling campaign for soil gas (CO_2, N_2O, and CH_4), mineral N, and soil pH. We tested the hypothesis that the combination of mineral N availability and low redox conditions are the primary drivers of hot moments of N_2O emissions and that hot moments offset a significant portion of the net CO_2e sink. We predicted that low redox conditions would occur during irrigation and high rainfall events, particularly during warm periods as the solubility of O_2 decreases with increasing temperature[33]. We also hypothesized that background patterns in N_2O emissions would follow patterns in plant activity indicative of the potential impact of plants on C or substrate availability.

Results and discussion

Annual soil N_2O budgets and ecosystem CO_2e balance

Annual mean N_2O fluxes were 624.4 ± 26.8 mg N_2O m^{-2} yr^{-1} (Table 1, range: 247.0 ± 5.7 to 901.9 ± 74.5 mg N_2O m^{-2} yr^{-1}) and were similar to or greater than other N_2O flux estimates from alfalfa systems[7,34–37]. However, few studies report flux measurements from irrigated, continuous alfalfa monocultures[36,37], which make up the majority of alfalfa ecosystems in the Western United States[2,7,13,38]. Annual soil N_2O emissions were highest in site years 2 and 3 (Table 1, $p < 0.001$) and lowest in site year 4 ($p < 0.001$). The use of N-fixing crops as a means to reduce N fertilizer inputs to agroecosystems is expected to decrease overall N_2O agricultural emissions[39]. However, the mean N_2O fluxes observed here (4.0 ± 0.2 kg N-N_2O ha^{-1} y^{-1}) were equal to or higher than rates from fertilized agricultural ecosystems[40,41]. This suggests net N_2O emissions from irrigated alfalfa may not always be reduced relative to other agricultural ecosystems receiving inorganic N inputs, particularly on relatively C-rich soils.

Soil N_2O fluxes reduced the annual net CO_2e sink (sum of eddy covariance NEE and chamber N_2O and CH_4; Table 1) by up to 14% (mean: 8 ± 0.4%). The ecosystem was a consistent net CO_2e sink (mean: −450.4 ± 121.9 g CO_2e m^{-2} y^{-1}) when estimated using eddy covariance NEE observations and chamber observations of N_2O and CH_4 (Table 1). Annual global warming potential (GWP) values were significantly greater in years 3 and 4 than years 1 and 2, driven by significant increases in net ecosystem exchange (NEE) and lower N_2O fluxes in year 4 (Table 1). Annual CH_4 fluxes were a consistent CO_2e sink (mean: −1.5 ± 0.1 g CO_2e m^{-2} y^{-1}) but were always less than 0.5% of the annual net GWP.

The importance of N_2O hot moments

Inter- and intra-annual variability in N_2O fluxes were largely driven by differences in the magnitude and frequency of hot moments of N_2O production. Hot moments represented only 0.2 to 1.1% of annual N_2O measurements but contributed up to 57% (mean: 44.4 ± 6.3%) of total N_2O emissions (Table 2), highlighting the importance of continuous measurements for capturing high emission events and that continuous background fluxes (i.e., lower than hot moments) still represent a significant portion of the annual budget. The magnitude of hot moments decreased with stand age, and the contribution of hot moments to the annual flux also decreased over time (Fig. 1c, Table 2, $p < 0.001$). The decrease in the magnitude of hot moments of N_2O emissions over time may be partially explained by increased alfalfa taproot development with stand age. Nitrous oxide fluxes are generally expected to increase with alfalfa stand age[36], driven by increasing organic matter and N inputs from more developed root systems. However, irrigation frequency is likely to decrease in more established stands or in systems supported by subsurface irrigation or a shallow water table[42–44], which could lower N_2O fluxes[45]. A well-developed taproot system can maintain access to a deep-water table to support plant water demands, reducing drought stress[46,47] and the need for irrigation events that stimulate hot moments of N_2O emissions. The decreased contribution and magnitude of N_2O hot moments did not consistently correspond to decreases in annual emissions (Table 2). This may be due to increases in N_2O emissions associated with the accumulation and mineralization of residual alfalfa-derived organic matter[36]. Here we found that reduced irrigation frequency drove the observed decreases in hot moment emissions with stand age. However, these emissions reductions were partially offset by background (i.e., lower than hot moment) increases in N_2O production, which could have been derived from greater soil C and N availability.

Drivers of soil N_2O emissions

Acidic soil conditions were maintained throughout the year (Fig. 2c), creating a favorable pH environment for incomplete denitrification following decreases in soil O_2 availability[48]. These soils were relatively C-rich (5% soil C from 0–30 cm)[49], which may have also contributed to the higher observed N_2O emissions here[50], but newly mineralized alfalfa roots and shoots were likely an important soil NO_3^- source[51] and substrate for denitrification. We found that hot moments of N_2O production occurred following rapid increases in moisture and decreases in soil O_2 in warm surface soils; lower soil temperatures in winter appeared to limit hot moments of N_2O emission following rain events (Fig. 2). Summer hourly mean N_2O fluxes peaked in late afternoon (Fig. 3c, $p = 0.06$), within hours after the onset of irrigation events. However, short periods of irrigation did not always correspond to increased soil moisture at depths below 10 cm (Fig. 2). This could

Mean (± standard error) annual nitrous oxide (N_2O) fluxes by site year, number of measurements, number of outlier measurements, outlier mean (± standard error) N_2O fluxes, mean N_2O fluxes (± standard error) without hot moments included, and contribution of hot moments to total mean flux. Hot moments were calculated separately for each year and in aggregate for the total dataset (All years).

indicate that the majority of N_2O production during hot moments occurred near the soil surface.

Soil N_2O fluxes were significantly greater in the summer and lowest in the fall (Fig. 3c, $p < 0.001$). Seasonal and diel trends in soil N_2O fluxes further emphasized the importance of soil moisture changes from irrigation and rainfall events. Mean hourly N_2O fluxes during summer periods, when most irrigation events occurred, were consistently greater than any other period (Fig. 3c, $p < 0.001$). Overall, daily mean N_2O fluxes were positively correlated with weekly soil atmosphere N_2O concentrations across depths, suggesting N_2O production across the soil profile contributed to background soil N_2O emissions (Supplementary Information, Fig. S1, 10 cm $R^2 = 0.60$, $p < 0.001$, 30 cm $R^2 = 0.53$, $p < 0.001$, 50 cm $R^2 = 0.45$, $p < 0.001$). Temporal patterns in soil moisture, soil temperature, and bulk soil O_2 concentrations covaried across all depths and were significantly related to patterns in net N_2O fluxes on a daily timescale (Fig. S2, $p < 0.05$). Primary interactions between N_2O and moisture, temperature, and O_2 suggested that changes in N_2O fluxes were generally in phase but lagged changes in these variables at daily and weekly timescales (Supplementary Information, Fig. S2, $p < 0.05$). At weekly and monthly timescales, N_2O fluxes were predominantly associated with soil temperature and moisture at 10 and 30 cm depths (Supplementary Information, Fig. S2, $p < 0.05$). Wavelet coherence analyses suggested that short-term, hot moments of N_2O emissions were stimulated by changes in moisture and O_2 concentrations in surface soils, as well as sustained acidic soil conditions. Acidic soil pH (Fig. 3) and lagged responses of temperature and moisture were the predominant controls at longer timescales (Supplementary Information, Fig. S2, $p < 0.05$).

Continuous low-magnitude N_2O production was an increasing fraction of total N_2O emissions over time (Table 2). In contrast to hot moments, consistent low magnitude N_2O fluxes were regulated by plant activity, soil moisture, and soil temperature throughout the soil profile. Increases in background (low magnitude) N_2O emissions were positively correlated with periods of high gross primary productivity (GPP), measured with satellite observations of near-infrared reflectance of vegetation (NIRv, Supplementary Information, Fig. S3, $p < 0.05$)[28]. Alfalfa releases a small proportion of its symbiotically-fixed N as NH_4^+ to the soil[52–54], and decreases in photosynthate supply to root nodules and exudates following shoot harvest may also limit C substrate availability to nitrifiers and denitrifiers[55]. While no relationships were observed between soil NO_3^- or NH_4^+ and N_2O emissions during our weekly sampling campaign (Fig. 2b, Supplementary Information), observed coherence at a daily timescale between NIRv and N_2O suggested plant-derived C or NH_4^+ availability may regulate low magnitude N_2O emissions. Plants likely shifted C and N allocation to new plant growth immediately after cutting, leading to lower soil N_2O emissions. Emissions increased over the growing season, possibly due to greater root exudation as aboveground plant biomass re-established.

Soil CH_4 emissions

Soils were a small consistent net sink of CH_4, accounting for only 0.06% of the total net C based-CO_2e uptake over the four year period. Annual mean soil CH_4 fluxes were −53.5 ± 2.5 mg CH_4 m^{-2} y^{-1} (Table 1, range: −78.2 ± 8.8 to −31.6 ± 2.5 mg CH_4 m^{-2} yr^{-1}). The net CH_4 sink was significantly greater in site year 4 than all other years (Table 1, $p < 0.001$). Sinks measured here were larger than others alfalfa ecosystem estimates[10,31,56], likely from the lower detection limit of the CRDS and automated chambers. In contrast to expectations, decreases in bulk soil O_2 concentrations did not appear to drive significant increases in net CH_4 production or decreases in the CH_4 sink (Fig. 1). Extended periods of soil anaerobiosis may be required to stimulate net CH_4 production[12,57], and this was not observed during the four year measurement period. We did observe a substantial increase in soil CH_4 concentrations (but not surface fluxes) shortly following the largest decrease in soil O_2 concentrations in March and April 2019 (Fig. 1, Supplementary Information, Fig. S8). Elevated soil moisture may have limited gas diffusion. Slower diffusion together with methanotrophic consumption near the soil surface likely regulated net soil CH_4 efflux during this period[58,59]. We also observed significant variability in hourly mean diel CH_4 fluxes (Fig. 3d), but this

variability was not significantly correlated with any measured soil characteristics.

Methane fluxes varied in response to temperature across depths and timescales and temperature was the strongest control on net CH_4 consumption (Supplementary Information, Fig. S4, $p < 0.05$). Decreases in soil moisture stimulated net CH_4 consumption (Supplementary Information, Fig. S4, $p < 0.05$), likely due to increased diffusivity[60,61] and O_2 availability. Periods of CH_4 uptake were highest in the late summer, occurring when soils were the driest throughout the soil profile (Fig. 1a, c). Lower soil moisture across the soil profile also generally corresponded to higher rates of CH_4 uptake and lower overall soil moisture increased CH_4 uptake with stand age, except for site year 2 (Table 1). Sustained CH_4 consumption combined with observed trends in N cycling suggest that CH_4 oxidation by nitrifiers or nitrification by methanotrophs[62–65] could be regulating non-CO_2 greenhouse gas production and consumption under oxic conditions.

Agroecosystem CO_2 balance

Soil CO_2 emissions were greater than other alfalfa ecosystems[6], likely driven by a combination of high plant productivity, relatively high soil C content[49], and warm temperatures throughout the growing season. Chamber CO_2 fluxes, which here represent combined soil and root respiration, averaged 4925.9 ± 13.5 g CO_2 m^{-2} yr^{-1} and were lower than ecosystem respiration (R_{eco}) estimates (6451 ± 12 g CO_2 m^{-2} yr^{-1}) from the nearby eddy covariance observations (Table 1). Soil CO_2 fluxes closely followed seasonal patterns in soil temperature, with similar trends in soil temperature observed across depths (Fig. 1a, b). Surprisingly, soil CO_2 fluxes did not vary significantly with NIRv on

a daily scale (Supplementary Information, Fig. S3, $p < 0.05$). Soil CO_2 fluxes and NIRv covaried on weekly, monthly, and annual timescales highlighting the importance of plant harvesting and phenology in regulating soil respiration[28].

To quantify for C removed from the field, we used mean annual yields of 595 ± 137 g C m^{-2} y^{-1} or 2,072 ± 502 g CO_2 m^{-2} y^{-1} [31]. This is equivalent to 89% of NEE, with the remaining C (258.3 g CO_2 m^{-2} y^{-1} or 70.4 CO_2 m^{-2} y^{-1}) assumed to be stored as belowground biomass or soil C. With this number, the CO_2e of N_2O emissions would then offset 70% of the net CO_2 sink. The fate of harvested C was not considered in this study, which examined only ecosystem-scale fluxes. However, it should be noted that if conducting a life cycle analysis, harvested alfalfa is typically used as dairy or cattle feed, where alfalfa C is converted to a combination of both CO_2 and CH_4[66].

We observed significant differences in NIRv following alfalfa cutting events (Fig. 1c) and mean annual NIRv decreased significantly across the measurement period (Table 3, $p < 0.01$). Lags observed between NIRv and soil CO_2 fluxes may represent a delayed response to photosynthate availability as plants likely reallocate new photosynthate to aboveground biomass production following harvest events[67]. Alfalfa in this region can be harvested up to seven times per year, where the majority of aboveground plant biomass is removed[28,31]. Cuttings corresponded to significant reductions in mean daily soil respiration values, although soil respiration values typically recovered

Table 3 | Moisture, rainfall, and NIRv

Year	Mean 0-50 cm Soil Moisture (%)	Rainfall (mm y^{-1})	NIRv
1 (2017-2018)	–	444 a	–
2 (2018-2019)	47.8 ± 7.8 b*	356 ab	0.23 ± 0.01 a
3 (2019-2020)	35.3 ± 17.1 a	447 a	0.21 ± 0.01 b

All	31.5 ± 14	331 ± 64	0.21 ± 0.01

Annual mean (± standard error) 0–50 cm soil moisture ($n = 96$ measurements per day for 763 total days), annual rainfall (mm y^{-1}), and mean (± standard error) annual near-infrared reflectance of vegetation (NIRv) by site year (e.g., January 27 to January 26, $n = 365$ per year).
*Site year 2 soil moisture values include 5 out of 12 months. Letters denote significant differences between annual values ($p < 0.01$) with statistical results reported from one-way repeated measures ANOVAs.

within 5 to 7 days (Fig. 1a). Periods of increased plant growth rates following harvests likely resulted in a shift in C allocation from below- to aboveground[68] and highlights the importance of substrate limitation on NEE[29]. If aboveground regrowth increases plant nutrient demands, it could induce a lagged response in belowground respiration driven by subsequent reallocation of photosynthate belowground followed by enhanced soil nutrient mining by microbial communities[69]. The observed lagged relationships between NIRv and ecosystem greenhouse gas fluxes may also represent delays between photosynthetic CO_2 uptake and root C exudation processes. Short-term increases in soil moisture content and associated decreases in O_2 availability throughout the year were also important controls on soil respiration (Supplementary Information, Fig. S5, $p < 0.05$). Soil temperature across depths was significantly associated with respiration rates across timescales.

This combination of automated chambers, eddy covariance, soil sensing, and satellite imagery used here provided a comprehensive dataset of multi-year, annual, ecosystem-scale fluxes from a continuous alfalfa agroecosystem. We were able to determine the importance of both short-term hot moments and background emissions on total greenhouse gas budgets and explore scale-emergent drivers of N_2O emissions. We found that N_2O emissions reduced the net CO_2e sink at the ecosystem-scale by up to 14% annually and offset 70% of the ecosystem C sink after accounting for harvest biomass removal (post-harvest fate of harvested alfalfa was not included in this calculation). As hypothesized, this was predominantly driven by rare hot moments of soil N_2O emissions supplied by elevated soil NO_3^- pools and acidic soil conditions and stimulated by irrigation and rainfall events. Hot moments were ≤1% of measurements but averaged 44.4 ± 6.3% of annual N_2O fluxes. Additionally, background fluxes were likely driven by sustained substrate availability that varied with moisture, temperature, and NIRv, a possible index of plant inputs to soil. Lagged relationships between NIRv, CO_2, and N_2O fluxes suggested that plant inputs were likely an important driver of soil CO_2 fluxes and background N_2O emissions. Our results show that N_2O emissions likely significantly lower the field-scale C sink potential of this globally important crop. Hot moments of N_2O emissions, typically underestimated with traditional measurement approaches, played an outsized role in annual ecosystem-scale greenhouse gas budgets, highlighting the importance of continuous measurement for accurate ecosystem-scale greenhouse gas accounting.

Methods

Site info

The study was conducted in the Sacramento-San Joaquin Delta region of California, USA (38.11°N, 121.5°W). The site was in conventional perennial alfalfa (>5 years) that was periodically flood-irrigated during the growing season. The site was located on highly degraded

peatland soils that have lost a significant proportion of their initial organic matter[49]. Alfalfa and corn are the dominant agricultural land uses in the region, with alfalfa representing 20% of agricultural land area (32,000 ha) in the Sacramento-San Joaquin Delta[70] and the largest crop by area in California (405,000 ha)[71]. Nearly 100% of alfalfa in California is irrigated, with flood irrigation being the most common practice[71]. The site had a Mediterranean climate with hot dry summers and cool wet winters. The region's historical mean annual temperature was 15.1 ± 6.3 °C and a mean annual rainfall averaging 326 ± 4 mm[23]. Site year (January 27 - January 26) rainfall data was collected from a nearby (<1 km) Ameriflux site[72]. Near-infrared reflectance of vegetation (NIRv), a metric for canopy photosynthetic activity[28], was calculated from daily 3 m resolution normalized difference vegetation index (NDVI) and near-infrared radiation (NIR) was collected from Planet Labs satellite imagery[73–75]. Near-infrared reflectance of vegetation was also used as a proxy for plant inputs to soils given that up to 20% of C fixed by photosynthesis is released by root exudation[26,27].

Ryde is the major soil series found under alfalfa in the region, and is widespread across the Sacramento San Joaquin-Delta and along the central coast of California[76]. Ryde soils belong to the fine-loamy, mixed, superactive, thermic Cumulic Endoaquolls taxonomic class and are very deep, poorly drained soils formed in alluvium from mixed rock sources and decomposed vegetative matter[76]. Total soil C concentrations (mean ± standard error) were 5.26 ± 0.02% at 0–15 cm, 5.00 ± 0.15% at 15–30 cm, and 1.99 ± 0.09% at 30–60 cm[49]. Total soil *N* concentrations were 0.38 ± 0.003% at 0–15 cm, 0.35 ± 0.01% at 15–30 cm, and 0.16 ± 0.01% at 30–60 cm[49].

Automated chamber measurements

Surface fluxes of N_2O, CH_4, and CO_2 were measured continuously from January 2017 to February 2021 using an automated chamber system. The system consisted of nine opaque, automated gas flux chambers (eosAC, Eosense, Nova Scotia, Canada) connected to a multiplexer (eosMX, Eosense, Nova Scotia, Canada). The multiplexer allowed for dynamically signaled chamber deployment and routed gases to a cavity ring-down spectrometer (Picarro G2508, Santa Clara, CA, USA). Chambers were measured sequentially over a 10-min sampling period with a 1.5-min flushing period before and after each measurement.

Chambers were deployed in a 10 × 10 m grid design, with each chamber approximately 5 m from other chambers. Extended 15 cm soil collars were utilized to maintain measurement collection and ensure chambers were not inundated during irrigation or high rainfall events. Chambers were randomly assigned to either plant rows ($n = 5$) or inter-plant areas of bare soil ($n = 4$). Chambers remained in their original positions throughout the field campaign, except for short periods (<3 days) during field management activities (e.g., harvest, winter grazing). Foliage near chambers were minimally trimmed as needed between harvests if it inhibited chamber closure.

To determine chamber volume, chamber collar heights were measured approximately weekly and interpolated between measurements to account for changes in chamber height over time. Chamber volumes were also used to calculate the minimum detectable flux of 0.002 nmol N_2O m^{-2} s^{-1}, 0.06 nmol CO_2 m^{-2} s^{-1}, and 0.002 nmol CH_4 m^{-2} s^{-1} [77]. The minimum detectable fluxes reported here are conservative estimates, as the actual chamber volume was always smaller than the maximum theoretical volume used to calculate these values.

Flux calculations and analyses were first performed using Eosense eosAnalyze-AC v. 3.7.7 software, then data quality assessment and control were subsequently performed in R (RStudio, v.1.1.4633)[78]. Fluxes were removed from the final dataset if they were associated with erroneous spectrometer cavity temperature or pressure readings or if any gas concentrations were negative, corresponding to instrument malfunction. Fluxes were also removed if the chamber deployment period was less than 9 min or greater than 11 min, indicative of chamber malfunction. Calculated linear and exponential fluxes were compared using estimate uncertainty to estimate ratios, and in cases where both the linear and exponential models produced high uncertainty, the individual flux was eliminated from the dataset. Data filtering removed 2.1% of flux measurement periods, generating a final dataset of 108,638, 103,013, and 102,997 simultaneous flux measurements of CO_2, N_2O, and CH_4, respectively. Following data filtering, all statistical analyses were performed using JMP Pro 15 (SAS Institute Inc., Cary, NC). Differences in site year, hourly, and seasonal mean flux values were analyzed with one-way ANOVAs followed by post-hoc Tukey tests. Values reported in the text are means ± standard errors unless otherwise noted.

To quantify site-level CO_2 uptake[49] and calculate site-level global warming potential (GWP) we utilized annual net ecosystem exchange (NEE) estimates from a nearby (<1 km) Ameriflux tower[72] in alfalfa grown with identical management practices and soil type. Here we used the eddy covariance technique[79] to capture continuous, long-term exchange of CO_2, CH_4, H_2O, and energy fluxes between the landscape and the atmosphere, along with measurements of environmental drivers[80]. Fluxes were measured at a frequency of 20 Hz using open-path infrared gas analyzers (LI-7500 for CO_2 and H_2O, LI-7700 for CH_4, LiCOR Inc., Lincoln, NE, USA) that were calibrated at least every 6 months. Sonic anemometers measured sonic temperature and three-dimensional wind speed at 20 Hz (WindMaster Pro 1590, Gill Instruments Ltd, Lymington, Hampshire, England). To convert N_2O and CH_4 flux measurements to CO_2e, we used the IPCC AR5 100-year GWP values of 28 CO_2e for CH_4 and 298 CO_2e for N_2O[81].

Quantifying hot moments of greenhouse gas emissions

This large, continuous dataset allowed us to quantify N_2O hot moments and their impact on total N_2O emissions. Following data filtering, the quantity and magnitude of hot moment measurements and their impact on annual flux estimates were determined. We defined hot moments as flux measurements with values greater than four standard deviations from the mean[12], as statistically 99.9% of the population should fall within four standard deviations of the mean. Yearly mean flux values were then calculated for only hot moment fluxes, the entire flux dataset, and the flux dataset with hot moment observations removed to determine the impact of outlier fluxes on annual greenhouse gas emissions. Given our large and continuous dataset, we could also compare mean fluxes with and without high flux events[12,82] to better quantify the importance of hot moments.

Weekly soil measurements

Weekly soil samples (0–15 cm depth, $n = 10$ $week^{-1}$) were randomly collected with a 6 cm diameter soil auger within 30 m of the chamber array from April 2018 to May 2019. Soil samples were analyzed for gravimetric soil moisture, soil pH, and 2 M potassium chloride (KCl) extractable nitrate (NO_3^-) plus nitrite (NO_2^-) and ammonium (NH_4^+). For KCl extracts, we utilized a 5:1 ratio of 2 M KCl volume to oven dry equivalent (ODE) soil that were shaken for 1 h and subsequently filtered with Whatman Grade 1 filter paper[83]. The KCl extracts were then analyzed colorimetrically for NH_4^+ and NO_3^- using an AQ300 analyzer (Seal Instruments, Mequon, WI). Soil moisture was determined gravimetrically by drying 10 g of field-fresh soil to a constant weight at 105 °C. Soil pH was measured in a slurry of 10 g of field-fresh soil in 10 mL of distilled deionized water[84].

Soil sensor measurements

Two sets of soil sensors were installed from September 2018-February 2021 at depths of 10 cm, 30 cm, and 50 cm. This included SO-110 oxygen (O_2) and soil temperature sensors (Apogee Instruments,

Logan, UT) and CS616 moisture sensors (Campbell Scientific, Logan, UT) connected to a CR1000 datalogger (Campbell Scientific, Logan, UT) storing data at 15 min intervals. Sensors remained installed throughout the year. Erroneous data corresponding to sensor malfunction were removed from the dataset, which included 1.7% of soil moisture measurements and 3.4% of soil O_2 measurements. In total, there were 73 of 839 days missing during the soil sensor measurement period.

Weekly soil depth gas samples

Two replicate soil gas samples were taken for CO_2, CH_4, and N_2O at 10 cm, 30 cm, and 50 cm depths weekly from September 2018 to December 2019. Instrument grade stainless steel 1/8" tubing (Restek, Bellefonte, PA) was installed in parallel to the soil sensors above, with approximately 15 cm of tubing installed with multiple sampling holes parallel to the soil surface. Sampling septa (Restek, Bellefonte, PA) were installed in 1/8" Swagelok union (Swagelok, Solon, OH) permanently connected to the stainless-steel tubing. Septa were changed monthly. Gas samples were collected weekly with 30 ml BD syringes after first clearing the tubing dead volume. Short periods of soil inundation following extensive rainfall (March-April 2019) made it impossible to collect gas samples from some depths. Samples were stored in over-pressurized 20 ml glass vials with thick septa (Geomicrobial Technologies, Oechelata, OK) until manual sample injection analysis on a Shimadzu GC-34 (Shimadzu Corp., Tokyo, Japan). Generalized pairwise regression analyses were used to explore the relationships between measured soil atmosphere CO_2, CH_4, and N_2O concentrations and surface soil CO_2, CH_4, and N_2O fluxes.

Wavelet coherence analysis

Wavelet coherence analysis was used to identify interactions between soil greenhouse gas fluxes, NIRv, and the soil variables (O_2, moisture, and temperature at 10, 30, and 50 cm) measured[12,85,86]. Wavelet coherence is a tool for comparing time series and is used to determine significance, causality and scale-emergent interactions between variables[16,80,87]. Wavelet coherence measures the cross-correlation between time series and allowed us to explore relationships between greenhouse gas fluxes and potential controls of NIRv, O_2, moisture, and temperature at daily, monthly, and annual timescales. Wavelet coherence is derived from two time series as a function of decomposed frequency (Wave.xy) and the wavelet power spectrum (Power.x, Power.y) of each individual time series:

$$\text{Coherence} = \frac{|\text{Wave}.xy|^2}{\text{Power}.x \cdot \text{Power}.y} \quad (1)$$

This approach allows for continuous wavelet-based analysis of univariate and bivariate time series, facilitating comparisons of time series data across scales, leads, and lags[86,88]. Missing data were replaced with zeroes to compute an unbiased estimator of the wavelet variance for time series with missing observations[86,89]. Statistical significance (p-value) was computed using 1000 Monte Carlo simulations. All wavelet decomposition and coherence calculations were conducted using the WaveletComp 1.1 R package[88].

Reporting summary

Further information on research design is available in the Nature Portfolio Reporting Summary linked to this article.

Data availability

The daily mean greenhouse gas fluxes (chamber CO_2, CH_4, N_2O, and eddy covariance CO_2), satellite-derived vegetation indices (NIRv), soil gas concentrations, and soil O_2, temperature, and moisture sensor data generated in this study and used to create the figures have been deposited the Dryad database: https://doi.org/10.6078/D1ZQ53.

Code availability

The corresponding R code used in this study have been deposited in the Dryad database: https://doi.org/10.6078/D1ZQ53.

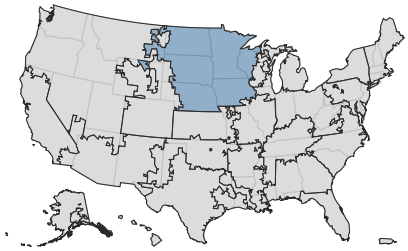
Power Profiler

Updated with 2023 eGRID data!

Español

How clean is the electricity you use?

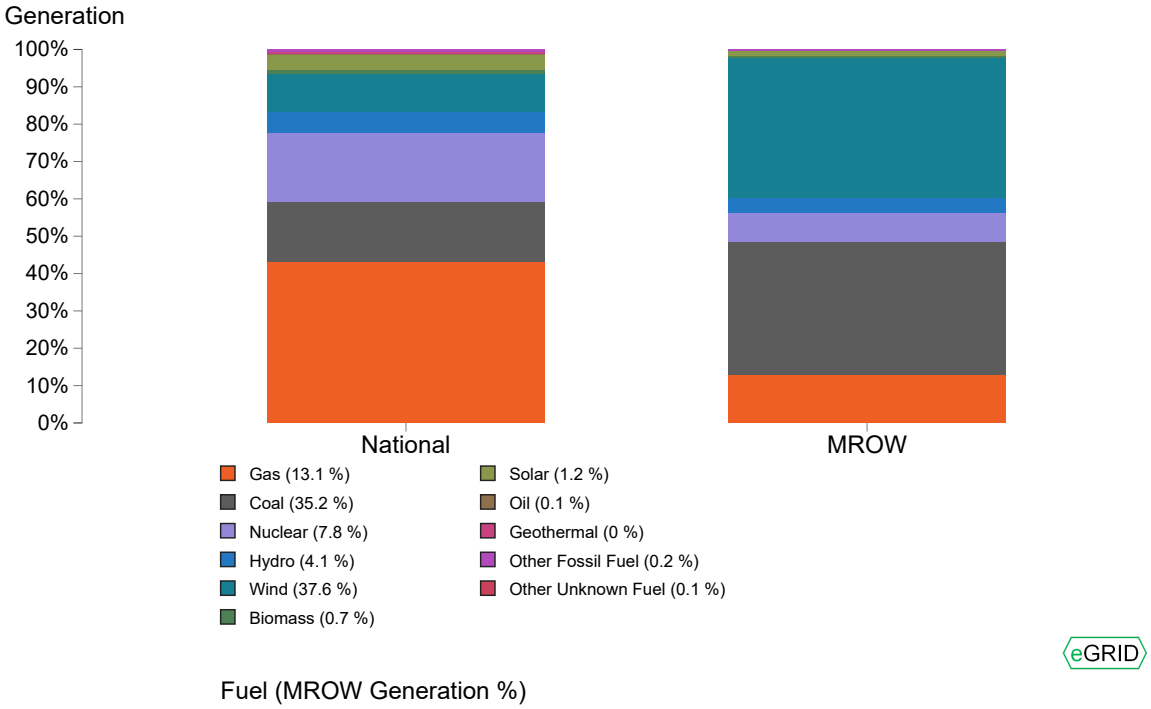
In the United States, electricity is generated in many different ways, with a wide variation in environmental impact. Electricity generation from the combustion of fossil fuels contributes toward unhealthy air quality, acid rain, and global climate change.



Many electricity customers can choose their provider of electricity or can purchase green power from their utility. In fact, you might now have the option of choosing cleaner, more environmentally-friendly sources of energy.

To compare the fuel mix (i.e., resource mix) and air emission rates of the electricity in your region to the national average and to determine the air emissions that result from electricity use in your home or business, either select the appropriate eGRID subregion or enter your ZIP code to determine the appropriate eGRID subregion.

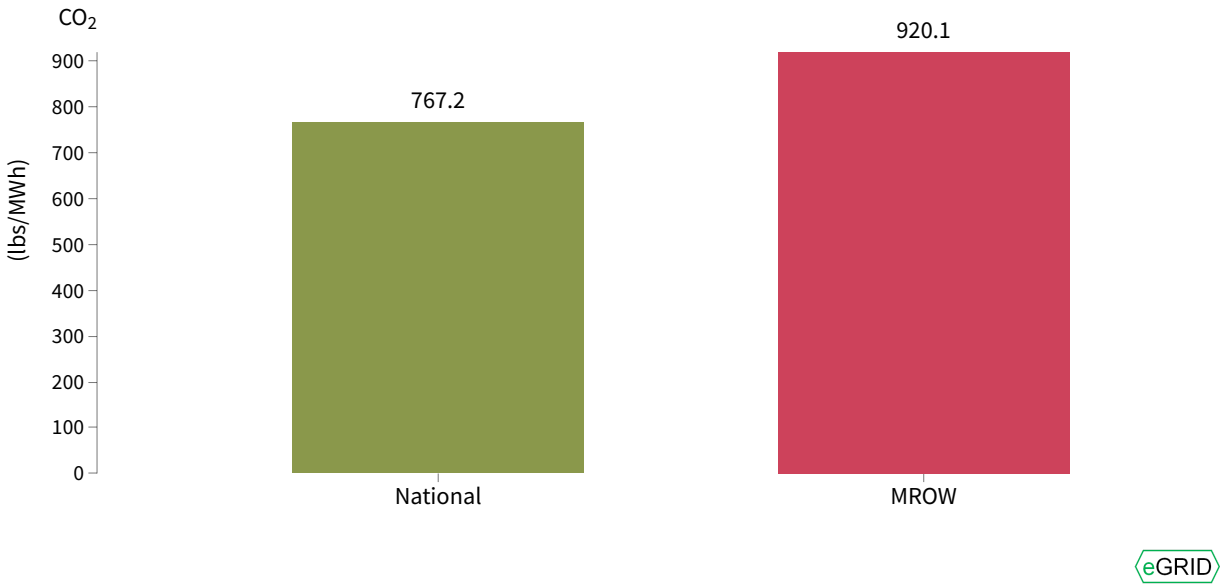
Power Profiler does not provide information about the environmental attributes of electric power generated by individual companies. For company-specific information, access EPA's eGRID database <https://epa.gov/egrid>.



MROW Emission Rates

CO2: 920.1 lbs/MWh SO2: 0.896 lbs/MWh NOx: 0.711 lbs/MWh

Fuel Mix



This chart compares fuel mix (%) of sources used to generate electricity in the selected eGRID subregion <https://www.epa.gov/system/files/images/2024-05/egrid-subregion-map.png> to the national fuel mix (%).

Acknowledgments

We would like to thank the members of the Ammonia Stakeholder Working Group for their valuable feedback and contributions to this report. Contributors include Agricultural Utilization Research Institute, Ammobia, AmmPower, Power-to-X Analytics LLC, Talus Renewables, and Minnesota Department of Commerce.

We also thank Natalie Janzow, Kyle Clark-Sutton, Patrick Molloy, Oleksiy Tatarenko, and other collaborators for providing valuable contributions and feedback throughout the project.

This research was conducted with support from Breakthrough Energy. Results reflect the views of the authors and not necessarily those of the supporting organization.

About RMI

RMI is an independent nonprofit, founded in 1982 as Rocky Mountain Institute, that transforms global energy systems through market-driven solutions to align with a 1.5°C future and secure a clean, prosperous, zero-carbon future for all. We work in the world's most critical geographies and engage businesses, policymakers, communities, and NGOs to identify and scale energy system interventions that will cut climate pollution at least 50 percent by 2030. RMI has offices in Basalt and Boulder, Colorado; New York City; Oakland, California; Washington, D.C.; Abuja, Nigeria; and Beijing.

Introduction

Ammonia (NH_3) accounts for over 1% of global greenhouse gas (GHG) emissions, and with a production scale of around 185 million tons per annum (tpa), it is an essential commodity in fertilizer production and contributor to climate change.[1] Ammonia production is currently concentrated in low-cost natural gas and coal regions such as the US Gulf, China, and Russia. Present-day ammonia supply chains involve complex, multistep processes spanning thousands of miles, as production is often far removed from consumption. During periods of low fossil fuel prices and efficient transportation by ship, pipeline, and truck, the existing supply chain structure adequately ensures fertilizer production, purchase, and application in the quantities needed. However, the stability of such supply chains and low pricing are not guaranteed. Geopolitical factors and extreme weather events have exposed the vulnerabilities of the current centralized system and fossil fuel dependence of existing supply chains, all of which directly affect fertilizer consumers.

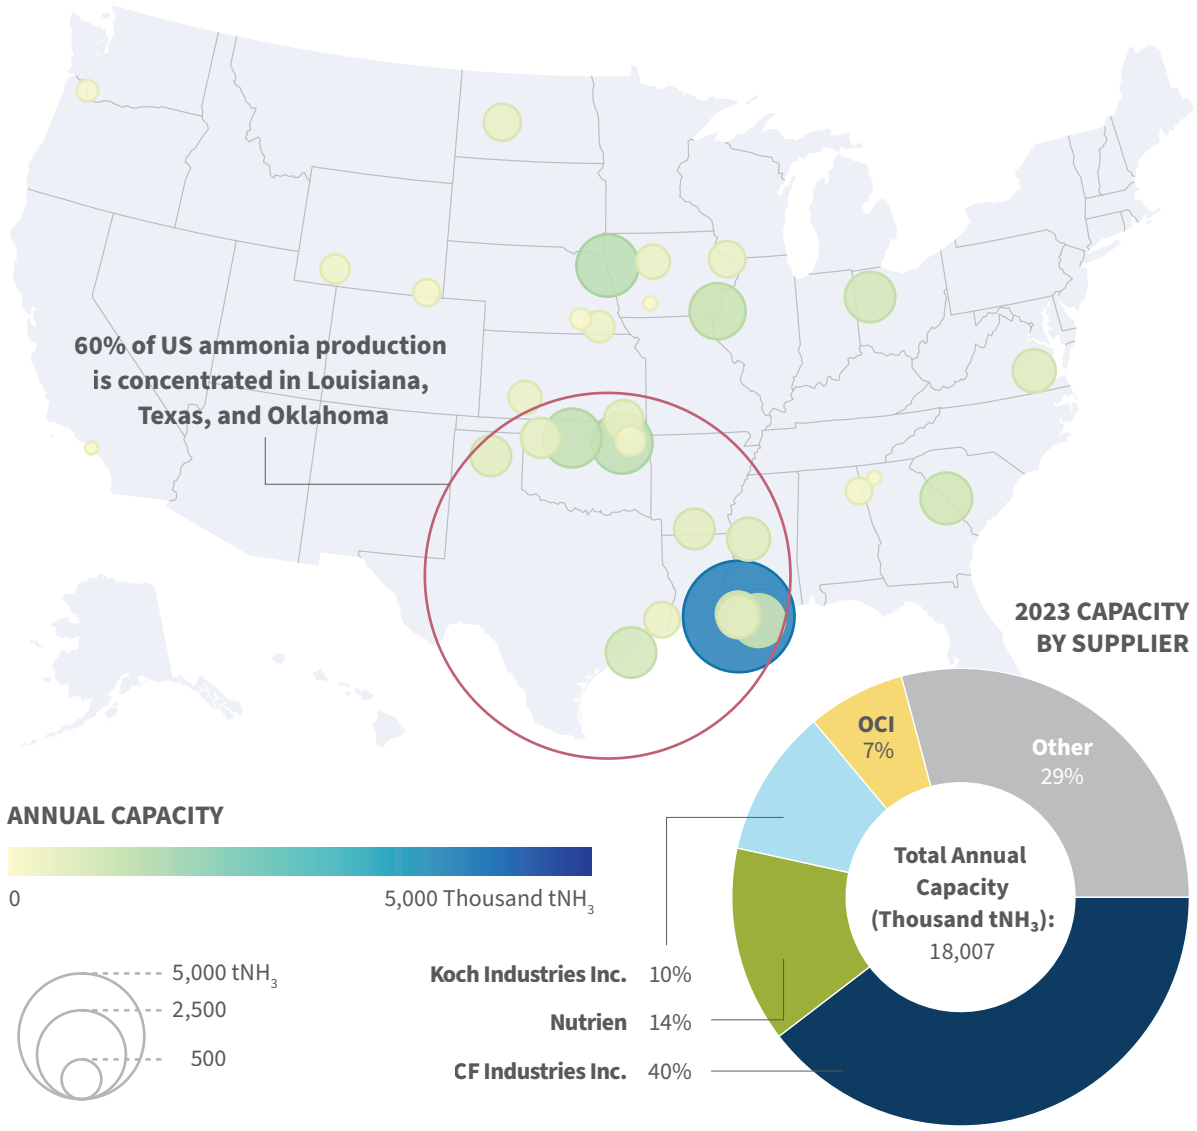
Russia's invasion of Ukraine highlighted several weaknesses of highly centralized fertilizer supply chains and natural gas–based production processes. The war disrupted both ammonia and natural gas production, resulting in limited supply and elevated prices. Reduced supply of natural gas from Russia led to high-priced domestic natural gas feedstocks in Europe and the United States. Because natural gas is a primary feedstock for ammonia production, high natural gas prices drove ammonia to cost points producers could not justify, reducing ammonia supply by 70% in Europe and more than tripling prices in the immediate aftermath of the Russian invasion to over \$1,600/tNH_3 from the historic market average of \$516/tNH_3 in the United States.[2]

The compounding challenges of high carbon intensity, centralized production, and feedstock price variability suggest the need for a complementary ammonia production system that is founded on a low-carbon, decentralized processes — that is, distributed green ammonia (DGA) deployed near consumption centers.

In the United States, Minnesota is a prime candidate for initiating the inaugural wave of distributed ammonia projects. The state is a major consumer of fertilizer, yet Minnesota's agricultural sector faces higher fertilizer costs compared with the national average due to higher transportation costs. This underscores the urgency and potential positive impact of localized ammonia production. Minnesota has also demonstrated robust policy backing with dedicated grants for localized fertilizer production, setting the stage for innovative ventures in the ammonia sector. With these factors in alignment, Minnesota stands poised to spearhead the advancement of distributed ammonia projects, heralding a paradigm shift in the Midwest and, potentially, in other regions of the United States.

This roadmap for advancing DGA in Minnesota focuses on the decarbonization of ammonia production and the direct application of ammonia as a fertilizer in the state. There are significant emissions associated with the use of fertilizers, but that issue is beyond the scope of this report. This roadmap includes an evaluation of business models, techno-economic dynamics, and necessary policy frameworks essential for translating these aspirations into actionable projects in Minnesota, a state that well understands the benefits of local, carbon-free fertilizer production. Key analytical elements include:

- Assessment of the enabling environment of Minnesota, including a high-level market analysis, demand profile, emissions intensity, renewable energy capacity and potential, techno-economic analysis, and available policy support



- Engagement with key stakeholders in Minnesota's low-carbon fertilizer space, including state agencies, financial institutions, nonprofit organizations, project developers, and original equipment manufacturers (OEMs), through bilateral conversations and focus-group discussions

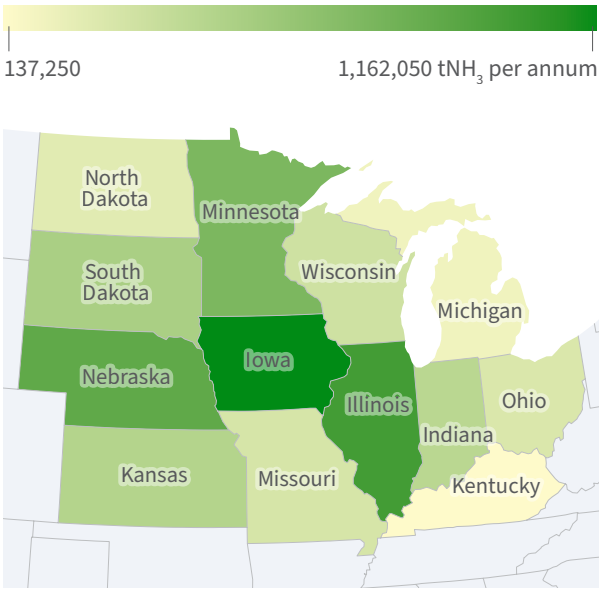
- Formulation of targets and a suggested implementation strategy for DGA through emissions reduction goals, business model proposals, and policy recommendations

The US Fertilizer Market

In the United States, domestic production of ammonia is dominated by 17 manufacturers and is geographically centralized within the Gulf Coast region due to the strategic access to natural gas reserves and well-established pipeline infrastructure. Three major ammonia producers, CF Industries, Nutrien, and Koch Industries, provide 64% of the entire domestic ammonia supply, with the majority of their ammonia manufacturing plants concentrated in Louisiana, Oklahoma, and Texas (see Exhibit 1).[3]

Exhibit 1 Ammonia Production Capacity Profile by Location and Company

RMI Graphic. Source: RMI analysis; Nutrien, **https://nutrien-prod-asset.s3.us-east-2.amazonaws.com/s3fs-public/uploads/2024-01/Nutrien_2023Fact%20Book_Update_12624.pdf**



With approximately 80% of US ammonia consumption going to agricultural fertilizers, farms in the Midwest represent the primary consumption hub, with corn driving roughly 50% of all US agricultural ammonia demand. Minnesota is the fourth highest-consuming state of ammonia fertilizer, driving over 10% of market demand, yet no ammonia production facilities are located in the state (see Exhibit 2).

Minnesota, along with many other Midwestern states, relies on ammonia transported from the Gulf through a complex network encompassing pipelines, barges, railways, and trucks, facilitated by market intermediaries ranging from logistics and distribution entities to wholesalers, agricultural retailers, integrated distributors, and cooperatives (see Exhibit 3).

The existing market structure, while serving as the backbone of fertilizer distribution in Minnesota and the broader Midwest region, falls short in ensuring consistent stability regarding both fertilizer prices and volumes of fertilizer.

Distributed Green Ammonia Opportunity

DGA can address the challenges of the current fertilizer market. DGA shortens supply chains so that production is located more closely to ammonia consumption and shifts feedstocks away from natural gas–based feedstocks toward renewable electricity, increasing certainty of supply and price stability for consumers.

Technology Profile of Distributed Green Ammonia

A new wave of technology that efficiently and economically produces ammonia at scales far smaller than traditional ammonia plants creates an opportunity to shift fertilizer production toward a distributed business model. Conventional ammonia synthesis processes have seen significant cost reductions in scaling up production volumes. Consequently, most units are sized to produce 100,000 to more than 1 million tpa.

New production processes, deriving from the Haber-Bosch (HB) process,[i] employ technology with different operational and design advantages that forgo the need to upsize plants to reduce production costs. Regional-scale systems slightly modify the traditional integrated ammonia synthesis plant to optimize for production up to 100,000 tpa, whereas single-farm systems rely on novel, modular containerized style units for easily replicable construction and standardizable mass production, best for production scales up to 3,500 tpa (see Exhibit 4, next page). These new ammonia production technologies can be specifically tailored to meet the needs of off-takers. They are well suited for the demand of a single, large US farm, which needs at most 3,500 tpa,[ii] and up to the scale of an agricultural cooperative, which needs between 3,500 and 100,000 tpa.

Commercial maturity for these newer ammonia production systems is low, but technological maturity is generally high, depending on the specific process considered. Although there are alternative ammonia production methods that have yet to achieve full technology readiness levels (TRLs), this report focuses primarily on TRL 9 technologies that are derived from the Haber-Bosch process.

Deployment of DGA projects is necessary to take full advantage of learning curves, especially for modular systems, as cost-effectiveness is achieved with increased technology installation. Developing DGA projects will only reinforce cost reduction and technological de-risking, creating a positive feedback loop of falling costs. Projects must overcome the challenges associated with first-of-a-kind project development, but once projects get off the ground, DGA can offer broad benefits to consumers, local communities, developers, and financiers over incumbent ammonia production technology and business models.

---

i Haber-Bosch refers to the conventional, industrial ammonia synthesis process where hydrogen and nitrogen are combined at a high pressure and high temperature.

ii The 3,500 tpa amount is based on stakeholder engagement and average use volume.

Exhibit 4 Different Scales of Ammonia Production, with Examples of Current Green Ammonia Projects

H2F

Iberdrola and Fertiberia in Puertollano, Spain

- 100 MW solar PV, 5 MW battery storage, 20 MW PEM electrolysis, and 11 high-pressure hydrogen storage tanks
- In operation since 2022, H2F produces **17,000 mtpa of green ammonia** at its neighboring plant

NEOM Green Hydrogen Complex

NEOM, ACWA Power and Air Products in Saudi Arabia

- 4 GW of solar power, 650 mtpd of hydrogen, saving over 3 million tpa of CO_2
- In construction and scheduled to come online in 2025, producing **1.2 million tpa of green ammonia**

Active players in the green ammonia landscape

For small-scale systems, the Haber-Bosch technology is modified and improved so that it can be better integrated with renewable energy systems and operate at a single-farm level through containerized and low-maintenance devices. TRL levels vary across OEMs (between 3 and 9), but these systems can be differentiated into three categories:

1. Miniaturized Haber-Bosch, a process that optimizes the synthesis loop for small-scale production
2. Enhanced Haber-Bosch synthesis, a process that involves improved and more efficient synthesis at lower pressure and lower capital expenditures (capex) than traditional Haber-Bosch through reactor and catalyst modifications
3. Novel and alternative ammonia synthesis methods, which include less proven methods such as electrochemical and nonthermal plasma ammonia production

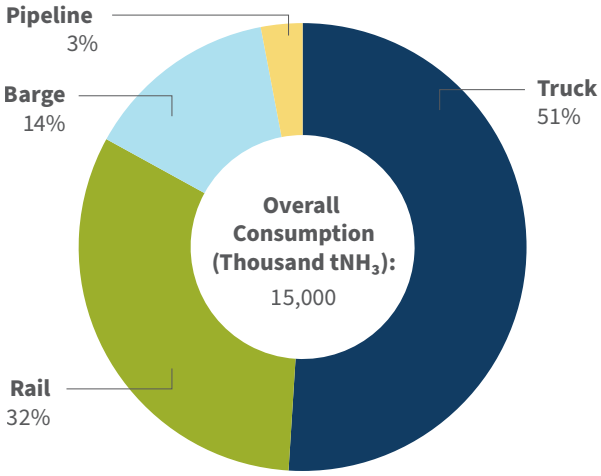
In the miniaturized Haber-Bosch space, Talus Renewables is demonstrating proof of concept with its recent commercial 15-year offtake agreement with the Kenya Nut Company, an agribusiness based in Nairobi, Kenya.[4]

Regional-scale systems feature minimal modifications to the Haber-Bosch process to allow for low capital expenditures and/or low-pressure synthesis at a smaller scale than conventional industrial-scale plants. These modifications are often in the form of design improvements, increased flexibility, catalyst innovation, or solid oxide electrolyzer integration into the Haber-Bosch synthesis. The TRL levels are usually higher, ranging from 6 to 9, with some projects expected to reach final investment decision this year. An initial effort in that direction is represented by ReMo Energy, a DGA OEM, which signed a memorandum of understanding for offtake with the logistics company Trammo for a 20,000 tpa facility to be built in Illinois.[5] In the ammonia technology space, incumbent Topsoe is designing regional-scale solid oxide–based modular plants of 100 megawatts (MW), the equivalent of 100,000 tpa, in collaboration with First Ammonia.[6]

Although not exactly DGA, larger-scale green ammonia projects, with production profiles similar to those of conventional centralized plants, are also underway. In Africa, Stamicarbon is developing a 300,000 tpa green ammonium nitrate plant in Angola and a 200,000 tpa renewable power-to-fertilizer plant in Kenya.[7] In the United States, Atlas Agro, a leading green ammonia project developer, has announced the Pacific Fertilizer Plant in Richland, Washington, with a production capacity of 700,000 tpa of nitrogen fertilizers.[8] This project relies on green ammonia synthesis technology from KBR, another incumbent OEM.

Fertilizer Market Dynamics and Distributed Green Ammonia Advantages

Cyclical downturns in commodity markets for ammonia-based fertilizers are exacerbated by the significant influence of supply and demand shocks on market participants. This phenomenon is particularly pronounced due to the high level of global integration in these markets. These challenges primarily manifest in price volatility and disruptions in supply chains, leading to adverse effects on farmers. DGA can act as a direct hedge to these challenges while providing a series of additional co-benefits in local investment and renewable energy integration.



From supply chain disruption to simplification

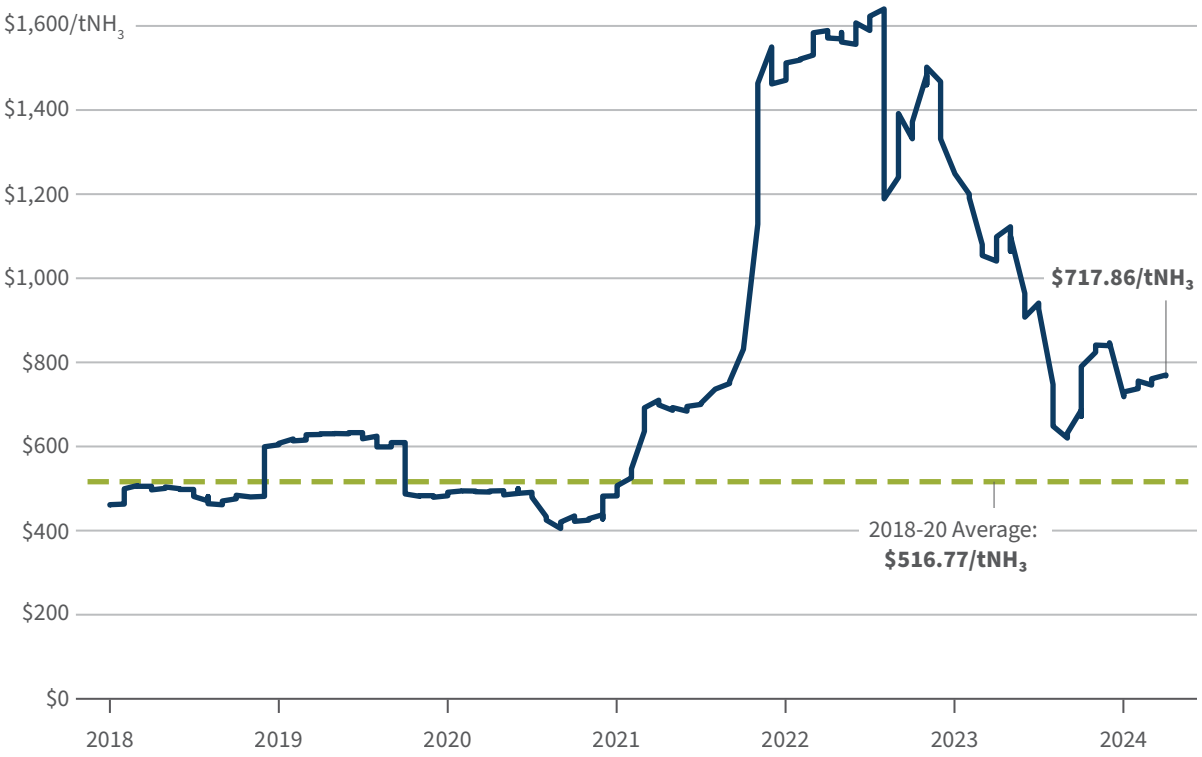
Multistep transport processes to deliver traditionally produced ammonia to users expose supply chains to weather or labor disruptions and increase pass-through costs. In the United States, ammonia is primarily transported by pipelines, trucks, railways, and barges (see Exhibit 5 for volume shares, next page), yet these modes of transportation are not always reliable. Railway strikes in 2022 threatened to halt the transport of ammonia via rail, which is the mode of transport for over 32% of ammonia.[9] Droughts in the Mississippi River, a core connector between fertilizer producers in the Gulf and consumers in the Midwest, hindered the transport of ammonia to farms in fall 2023 via barge, which accounts for 14% of overall ammonia transportation.[10] During the past decade, unintended stoppages and malfunctions among barges have increased by 700%.[11] Historically, weather patterns such as prolonged cold spells have resulted in production shutdowns due to high natural gas costs from increased home heating demands.

Logistics costs vary depending on factors such as such as the point of origin, the chosen mode of transportation, and the frequency of loading and unloading. Collectively, extended transportation routes, pass-through costs associated with multistep supply chains, and the utilization of high-cost transportation methods such as trucking can contribute to substantial expenses in the distribution of ammonia from the Gulf to the Midwest, often escalating logistics costs to well over $300/tNH$_3$.[12]

With distributed ammonia production, fertilizer supply chains shift from spanning thousands of miles with multimodal transport to being "within the backyard" of farming communities, leading to more reliable supply and significant cost reductions. Simplifying supply chain logistics can shield consumers from the geopolitical instability and unpredictable transportation that can impact fertilizer supply.

Exhibit 5 **Ammonia Transportation Modes and Volumes**

RMI Graphic. Source: RMI analysis; Fertilizer Institute, **https://www.tfi.org/wp-content/uploads/2024/03/TFI-fertilizer-logistics-and-transportation.pdf**; US Geological Survey, **https://pubs.usgs.gov/periodicals/mcs2024/mcs2024-nitrogen.pdf**



With the logistical challenges of fertilizer procurement lessened, the uncertainty of predicting how much ammonia will be available and of long lead times is also reduced. Localizing production also helps limit supply chain pass-through costs by streamlining distribution. This not only maximizes cost reduction but also minimizes the opportunity for supply chain disruptions to add unexpected costs and for intermediaries to inflate costs along the way.

From price volatility to stability

Imports and international pricing dynamics of ammonia significantly influence the pricing of ammonia in the US market. The United States produces most of the ammonia it consumes but still imports about 10% of its ammonia, mainly from Trinidad and Tobago or Canada. Domestic ammonia production prices rose only slightly with recent natural gas price volatility related to the Russian invasion of Ukraine, but in 2022 market prices rose three times over the market average from 2018 to 2020, reaching upward of $1,600/tNH$_3$ from $516/tNH$_3$. As of April 2024, despite the low natural gas prices, ammonia market prices were still 1.49 times higher (equivalent to $767/tNH$_3$) than the market average from 2018 to 2020 (see Exhibit 6, next page).

Because ammonia imports, especially lately, have been significantly higher priced than domestic ammonia, imports have had a price-setting effect on the US market. Typically, wholesale ammonia prices are not capped or predictable because contracts hinge on the fluctuating price of natural gas, with benchmarks such as the Cost and Freight (CFR) Tampa reflecting the average cost of ammonia production in the Gulf region (inclusive of transportation to its destination).

Exhibit 6 **Delivered Ammonia Market Prices in Iowa, US Midwest**

RMI Graphic. Source: RMI analysis; USDA, **https://mymarketnews.ams.usda.gov/viewReport/2863**

Minnesota farmers, like those in the rest of the Midwest, face considerable cost burdens due to ammonia's intricate supply chain dynamics and reliance on fossil fuels. Farmers' ability to procure fertilizer at the required volumes and prices is limited because they rely heavily on intermediaries to ensure timely availability during critical application seasons. However, the centralized nature of the supply chain necessitates farmers placing orders months in advance, demanding meticulous understanding of both local farming patterns and global production trends to ensure adequate supply.

This financial burden is reflected in the substantial decrease in net income for US farms when the price of ammonia increased after Russia's invasion of Ukraine, leading to widespread losses averaging $191 per acre through 2022.[13] Facing escalating expenses, some farmers may turn to synthetic fertilizer alternatives like manure, despite its labor-intensive application process and diminished nitrogen availability. This shift could impact crop yields, potentially driving up demand and market prices for agricultural products, thereby amplifying the broader economic repercussions stemming from fertilizer price volatility.

Producing ammonia with renewable energy will help stabilize fertilizer prices by decoupling ammonia production from natural gas price fluctuations and linking it with the set yearly cost of renewable electricity. This will reduce the current strain on farmers from constantly fluctuating and rising ammonia prices by ensuring that they can purchase fertilizer at more stable and affordable costs. Even with the shift to renewable-based ammonia, a future fertilizer market would not be isolated from price volatility given the seasonality of fertilizer demand, but green production can limit the severity of price volatility compared with production that relies on natural gas.

Distributed green ammonia co-benefits

Local investment

Moving fertilizer production to the Midwest could further benefit local economies by accelerating growth of renewable energy generation and creating green jobs in farming communities. Investments would spur a series of benefits, including the creation of a new specialized workforce of agronomists and technicians to operate distributed ammonia plants. This would provide the additional benefit of increasing investment in cooperative systems and ultimately increase the retention of dollars spent in local areas. Farmers and farming cooperatives (co-ops) will be the main beneficiaries of this transition, unlike in the current system where centralized producers define market dynamics.

Operational advantages for renewable electricity integration

New distributed ammonia production technologies will better enable integration with renewable electricity feedstocks. Conventional ammonia production technology must consistently maintain and operate high temperatures and pressures for the reaction of converting hydrogen and nitrogen into ammonia to occur. When these processes move away from the consistently supplied fossil feedstocks toward intermittently available renewable electricity, they require additional buffer in electricity supply through batteries or oversized renewables that increase costs and complexity. Newer, smaller-scale ammonia production processes are typically far more flexible in operation and can more readily adjust production to changes in renewable energy availability, providing opportunities for cost reduction and system simplification.

Project simplification and standardization

Once technological maturity is reached for distributed ammonia production, projects will have a lower financing risk and be more attractive to investors. Several distributed projects have been announced in recent years in the United States, involving companies such as ReMo Energy, Talus Renewables, First Ammonia, and Atlas Agro. Talus, in partnership with Landus Cooperative, opened the first plant in June 2024.

Deployment of DGA projects is necessary to prove the concept and the viability of the DGA pathway. Project developers and investors alike will appreciate the shorter construction periods; lower engineering, procurement, and construction (EPC) costs; and smaller amounts of capital required, making access to debt and equity financing a potentially easier ask. Once plants are operational, these systems may see less costly operation and maintenance costs alongside improved production resiliency given their more simplistic system design and technical improvements, which allow for lower pressure and lower temperature synthesis compared with conventional technology.

In addition, small-scale, containerized ammonia production facilities can be manufactured and installed much faster than large-scale ammonia plants (i.e., 1–3 years versus 3–10 years). The ability to go online sooner enables a faster return on investment, and the stackability of modular systems provides further benefits. Modular ammonia production systems can be installed in phases, allowing the farm or co-op to generate revenue as they gradually scale with a better understanding of offtake demand.

Many of these advantages give DGA business models a long-term economic edge compared with large-scale ammonia production processes. Nonetheless, key risks need to be addressed to effectively scale DGA.

Risks Related to Distributed Green Ammonia

Reshaping the fertilizer industry with a transition to DGA production requires the first wave of projects to access financing and establish early offtake contracts. This is particularly challenging for new players given the hesitancy of consumers to disrupt the status quo. Lack of product differentiation for green fertilizers and general perceptions of risk, cost premiums, and low commercial maturity create a challenge in getting these initial projects off the ground.

Heightened investment risk perception

First-of-a-kind distributed fertilizer projects involve a heightened perception of risk, a potential cost premium, and at times a lower TRL. This creates reluctance among capital providers and hesitation across off-takers to pivot to DGA production pathways. Both agricultural co-ops and lending institutions view the distributed pathway as high-risk because one has not yet been operated on a commercial scale. New ammonia reactors are only recently starting to being fully optimized and integrated into a unit with electrolyzers and powered by renewable electricity. Whole-system testing is important to validate OEMs' claims on a unit's ability to efficiently follow and operate at varying electricity loads in projects not connected to the grid.

Cost competitiveness

DGA's cost competitiveness is relative to changing fertilizer market prices, creating uncertainty about their economic advantage for off-takers. Fertilizer purchasers — notably agricultural co-ops and other market intermediaries — will benchmark DGA prices against ammonia market prices, and costs are a significant driver of buyer interest. Although DGA production costs in context of current fertilizer price spikes may appear competitive, buyers' expectations of price cyclicality may create hesitancy to commit to new fertilizer purchasing agreements. In other words, buyers may fear being locked into a price that appears competitive when market prices are high but that may not be the lowest price when market prices fall. Their concern stems from the ammonia market's typical cycle of price volatility and stability. Essentially, buyers are hedging against the risk of overpaying in the future as they anticipate prices of ammonia may become more stable as volatility factors are mitigated. By contrast, DGA producers expect their production cost to decrease in the long term. As production costs fall, DGA producers can increase their returns and see greater margins — even if market costs are higher or lower than the price contracted with off-takers.

Lack of targeted policy support

There is a critical need for policy that supports DGA deployment. The Inflation Reduction Act (IRA) has been instrumental in improving DGA economics, but other support programs that incentivize innovation, de-risk financing and investing, and provide supplementary financing to reduce burden on developers are still required. Leveraging existing tax credit structures where possible and engaging with existing support for co-ops, farmers, and stakeholders will be critical to enable early projects to secure offtake and illustrate the viability of the technology pathway. To help get early DGA projects with fertilizer applications off the ground, project developers should prioritize business models centered on economically strong agricultural co-ops in Midwestern states with robust policy support, such as Minnesota. Additionally, expanding buyer and investor education will provide greater clarity about the advantages of DGA, its costs, and its technological readiness. State and federal policy support should also be strengthened and expanded.

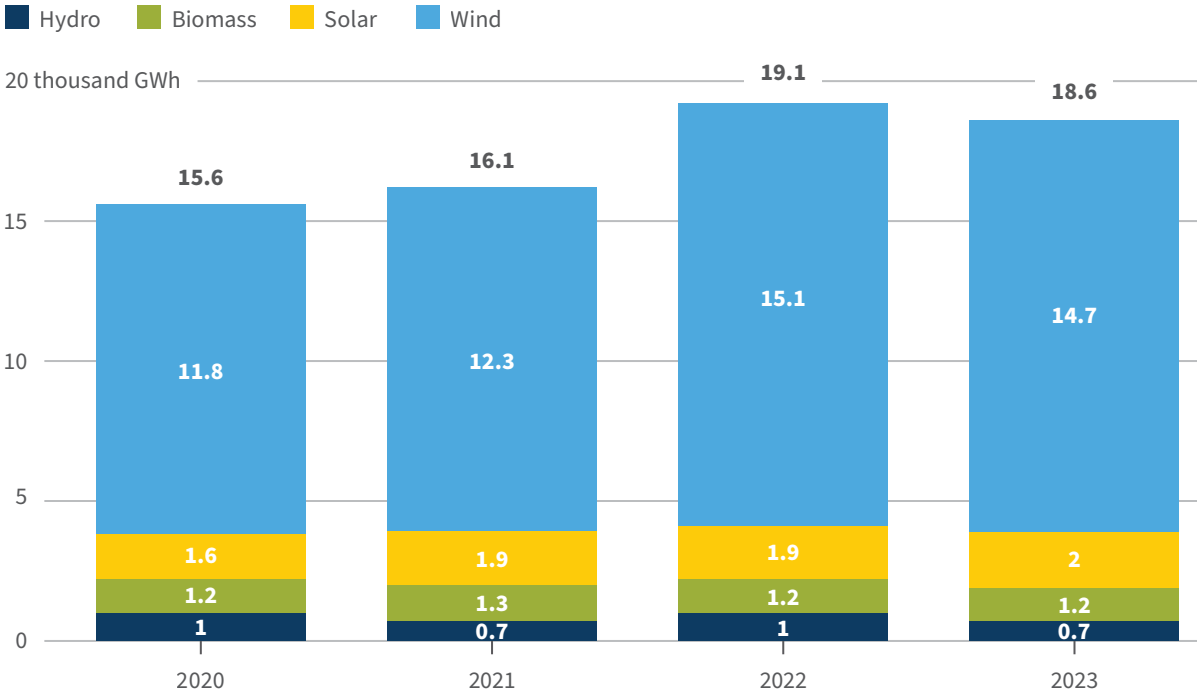
Developing Distributed Green Ammonia in Minnesota

Minnesota provides an ideal enabling environment for the first wave of DGA projects, owing to its supportive policy environment, strong renewable energy profile, and sizable demand for fertilizer demand. Minnesota is the fourth largest consumer of ammonia for agricultural use in the United States, with a current demand reaching 747,000 tpa for nitrogen fertilizers.[14,iii] Similar to other states in the Corn Belt such as North Dakota, Minnesota grapples with the intertwined challenges of price fluctuations and increased transportation expenses stemming from limited connectivity to the central ammonia pipeline distribution network. Moreover, Minnesota boasts abundant wind energy potential. These factors are further strengthened by the existence of grants incentivizing local production of green fertilizers by co-ops.

Current Landscape in Minnesota

Efforts to produce locally

Green ammonia projects are ramping up in the Midwest, and Minnesota is already positioning itself to tap into the opportunity to produce fertilizers closer to consumption. The state's dependence on external fertilizer sources has prompted a push for local production and decoupling ammonia synthesis from natural gas price fluctuations. In 2013, the University of Minnesota launched a first-of-its-kind green ammonia pilot program in Morris, in western Minnesota, to show the opportunity for distributed production.[15] This effort has gained momentum since the Russian invasion of Ukraine, which prompted other market actors to find opportunities in local low-carbon fertilizer production.



The Heartland Hydrogen Hub, a project funded by the US Department of Energy (DOE) that spans Minnesota, North Dakota, and South Dakota, is a more recent example of local production. As part of the hub, Xcel Energy is planning a large-scale urea plant that uses CO_2 offtake from ethanol refineries combined with green ammonia.[16] This project leverages Minnesota's ample sources of biogenic CO_2 from its ethanol refineries, as well as from several pulp and paper mills.

Similar projects have also been announced in North Dakota, which may look to Minnesota for customers given its large demand for nitrogen fertilizer. For example, NextEra plans to build a wind-powered $1.3 billion ammonia facility in Spiritwood.[17]

Minnesota provides an ideal enabling environment for the first wave of DGA projects, owing to its supportive policy environment, strong renewable energy profile, and sizable demand for fertilizer demand.

iii Requiring 911,000 tons of ammonia for production.

Exhibit 7 Cumulative Renewable Energy Generation in Minnesota, 2020–23

RMI Graphic. Source: US Energy Information Administration, **https://www.eia.gov/electricity/data/browser/#/topic/0?agg=2,1,0&fuel=9cdd&geo=g00004&sec=g&linechart=ELEC.GEN.WND-US-99.A~~~~~~~~~~~~~~~~&columnchart=ELEC.GEN.COW-US-99.A&map=ELEC.GEN.COW-US-99.A&freq=A&start=2018&end=2023&ctype=linechart&ltype=pin&rtype=s&pin=&rse=0&maptype=0**

Abundant renewable energy resources

Minnesota's efforts to produce green ammonia locally would not be possible without its excellent renewable energy profile (see Exhibit 7). In 2023, renewable energy accounted for 33% of Minnesota's electricity generation, with 54% of the state's total energy capacity coming from carbon-free sources including renewables, nuclear, and hydropower.[18]

Wind energy alone accounts for more than three-fourths of Minnesota's renewable generation. Most of Minnesota's utility-scale (1 MW or larger) wind farms are located in the southwestern part of the state where flat land is abundant.[19] This locality coincides with the majority of the state's farmland where direct-application ammonia fertilizer is typically utilized over urea.

In 2023, solar energy also provided almost 4% of Minnesota's total electricity generation, and hydropower accounted for more than 1% of the state's total electricity generation.[20] About 90% of the state's solar power came from utility-scale installations. Although there are nearly 30 utility-scale hydroelectric power plants in the state, most of the plants are small: The largest has a capacity of 76 MW.[21]

The state's utilization of multiple forms of alternative energy resources is ahead of many other states, and, largely thanks to the availability of high winds throughout Minnesota, there are still opportunities for further development to support additional endeavors such as clean fertilizer production.

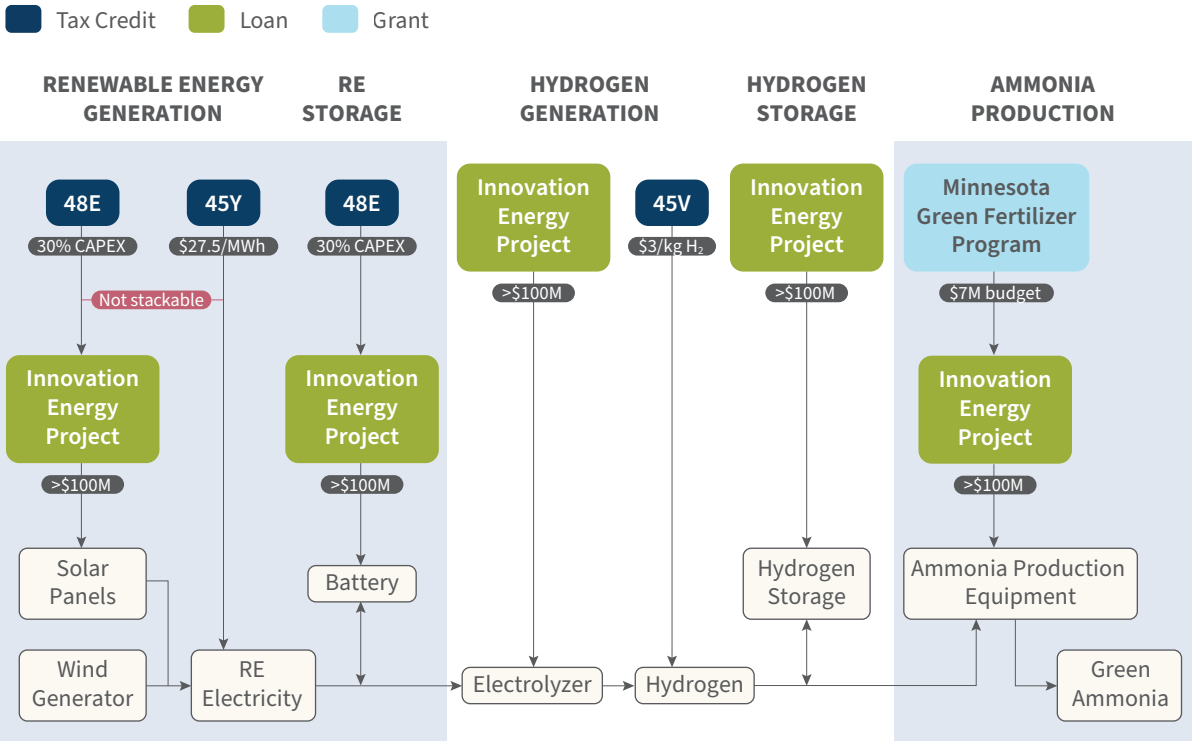
Existing Policy Landscape

To understand how Minnesota can best support the deployment of DGA systems, it is essential first to understand the existing policy landscape at the federal and state levels.

Federal policy

In recent years, the federal government, through the US Department of Agriculture (USDA), has prioritized and financially supported domestic fertilizer production and deployment of renewable energy projects for farmers.[22] The DOE has made the development of clean hydrogen a priority in its strategy, and the IRA represented a key milestone in supporting electrolytic hydrogen and incentivizing green ammonia.[23]

The Biden administration set a target of reaching 100% carbon–free electricity by 2035 and net-zero GHG emissions by 2050.[24] The DOE's Industrial Decarbonization Roadmap establishes that decarbonizing fertilizer is connected to the generation of hydrogen from low-carbon energy, highlighting ammonia as a key use of clean hydrogen.[25] Besides the federal government's recognition of green ammonia as key to decarbonize fertilizer emissions to reach its national decarbonization goals, there is federal support for innovative fertilizer production pathways. The IRA includes clean electricity tax credits and a clean hydrogen production tax credit, described below.



The Bipartisan Infrastructure Law created the DOE Regional Clean Hydrogen Hub program and allocated $7 billion to support the creation of hydrogen hubs.[26] The Heartland Hydrogen Hub, which includes Minnesota, was one of the seven hydrogen hubs selected,[27] with green fertilizer production mentioned as one of the main uses of hydrogen. In addition, DOE announced a $1 billion hydrogen demand program to design and implement demand-side incentives.[28]

The DOE's Loan Program Office (LPO) is another federal funding mechanism, with guaranteed loans through its Title 17 for innovative energy projects.[29] IRA provided an important boost to the LPO by appropriating $11.7 billion to issue new loans and increasing its existing loan program authority by $100 billion.[30] Although there is no minimum loan size, guarantees are usually $100 million and cannot exceed 80% of the anticipated project costs. Projects eligible under Title 17 must include a new or significantly improved technology not widely adopted in the United States.[31] They must demonstrate that the technology is used in three or fewer facilities and can catalyze the market by being employed in other commercial projects.

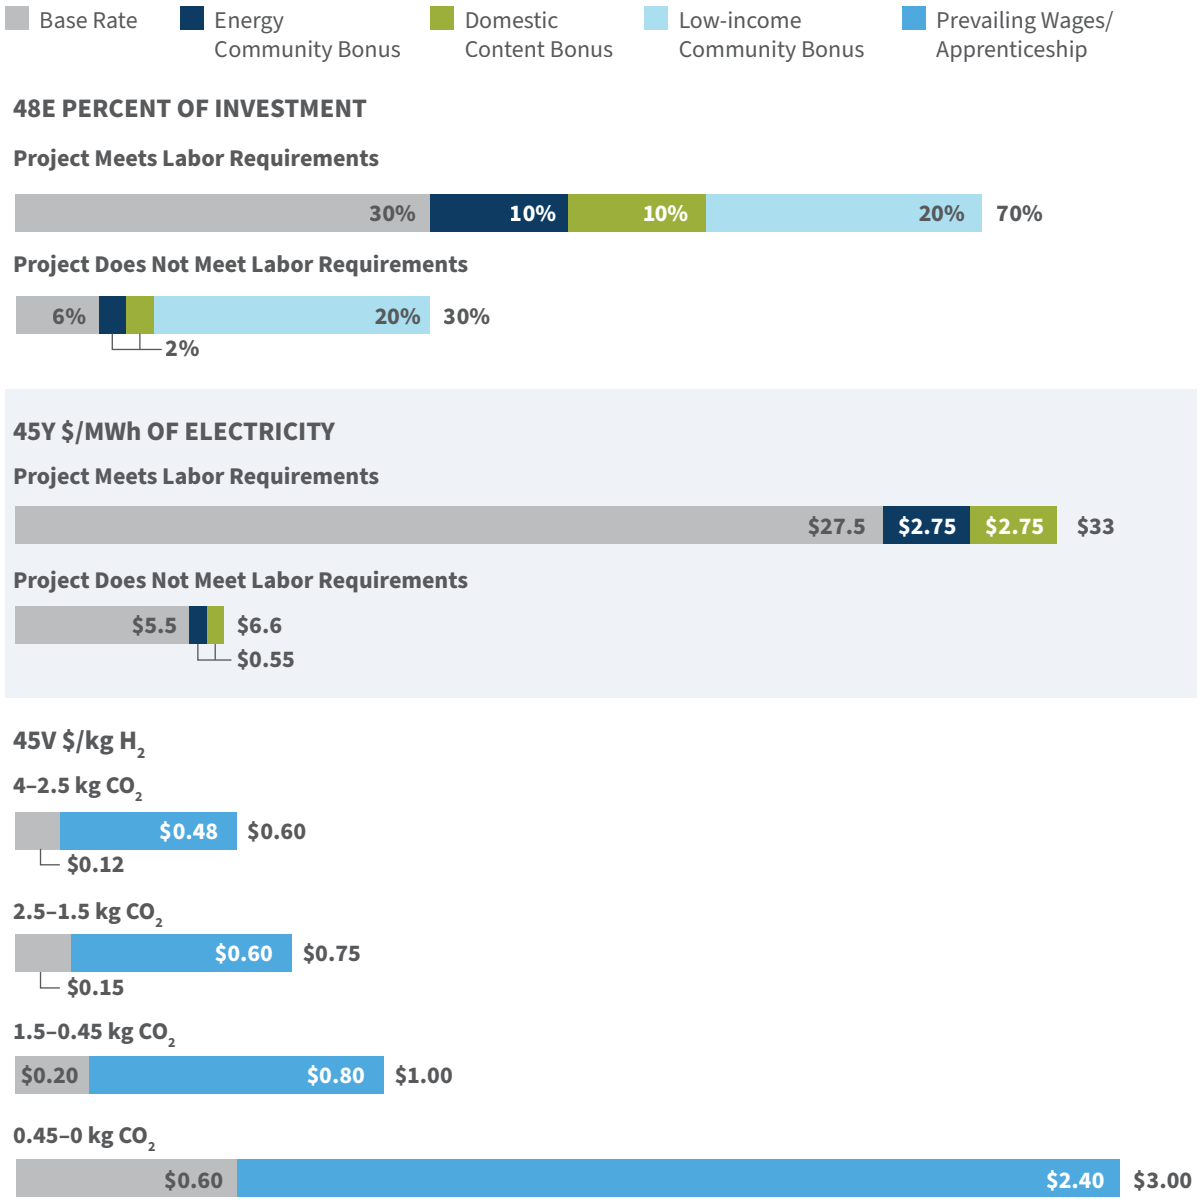
Exhibit 8 (next page) presents the main federal tax credits and LPO loan program across the value chain for green ammonia production, including renewable energy and electrolytic hydrogen generation and storage.

In recent years, the federal government has prioritized and financially supported domestic fertilizer production and deployment of renewable energy projects for farmers. The DOE has made the development of clean hydrogen a priority in its strategy, and the IRA represented a key milestone in supporting electrolytic hydrogen and incentivizing green ammonia.

Exhibit 8 Federal Tax Credits and LPO Loans for Which Green Ammonia Production Is Eligible

RMI Graphic. Source: RMI analysis; IRA Guidebook, **https://www.whitehouse.gov/wp-content/uploads/2022/12/Inflation-Reduction-Act-Guidebook.pdf**

Primary federal tax credits and financial support mechanisms that apply to green ammonia projects include:[32]



- **48E:** The 48E tax credit for clean electricity subsidizes 30% of the project's capital expenditure when prevailing and apprenticeship requirements are met. It can reach up to 70% with the domestic content, energy community, and low-community bonuses, as shown in Exhibit 9 (next page). The IRA also added stand-alone battery technologies under the scope of the tax credit.

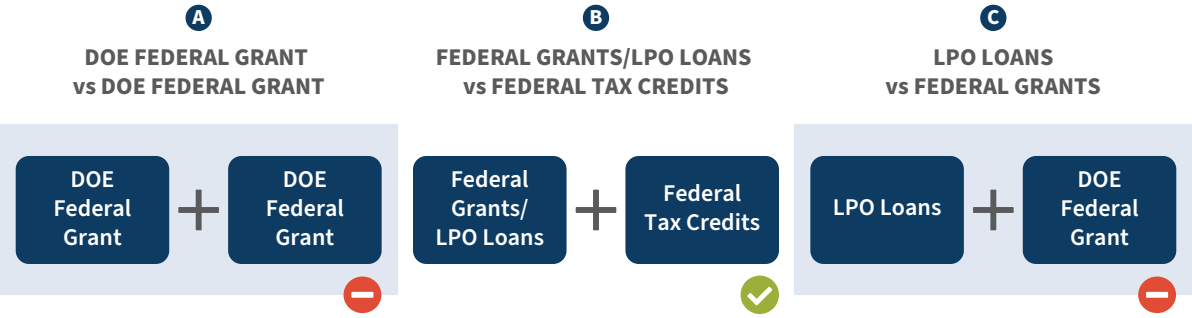
- **45Y:** The production tax credit 45Y provides a base rate of $27.5/MW hour (MWh) when prevailing and apprenticeship requirements are met. Bonuses similar to those in the 48E tax credit are applicable to 45Y.

- **45V:** The 45V clean hydrogen production tax credit offers up to $3/kg of hydrogen produced with less than 0.45kg of carbon dioxide equivalent (CO_2e) per kilogram of hydrogen produced. Dedicated renewable projects producing hydrogen will be able to take advantage of this tax credit and stack it with either 45Y or 48E. The US Internal Revenue Service (IRS) published the 45V tax credit guidance in December 2023, opening a comment period that closed in March 2024. However, there is no official timeline for when the IRS will publish the final guidance, and it could be released as late as the end of 2024.

- **LPO innovative energy projects:** Technologies across the entire value chain for green ammonia production are eligible for the DOE LPO program, including renewable energy and green hydrogen generation and storage. The Haber-Bosch process is eligible as a technology to reduce GHG emissions from industrial applications such as ammonia production.

Exhibit 9 **Federal Tax Credits**

RMI Graphic. Source: RMI analysis; IRA Guidebook, **https://www.whitehouse.gov/wp-content/uploads/2022/12/Inflation-Reduction-Act-Guidebook.pdf**



Several federal funding mechanisms are stackable, but there are some limitations based on the project's scope (see Exhibit 10, next page):

(a) Two federal grants cannot support the same project, scope of project, or budget.

(b) Federal tax credits are stackable with DOE federal grants and LPO loans.

(c) LPO loans are not stackable for projects that are expected to benefit directly or indirectly from another federal support program, such as grants.

Exhibit 10 Stackability Rules for Federal Fundings Mechanisms

RMI Graphic. Source: RMI analyses based on LPO's Title 17 Program, **https://www.energy.gov/lpo/title-17-clean-energy-financing; IRA Guidebook, https://www.whitehouse.gov/wp-content/uploads/2022/12/Inflation-Reduction-Act-Guidebook.pdf**

State policy

Minnesota has developed robust climate goals and targets. It set a goal of 100% carbon-free electricity by 2040. Its Climate Action Framework, published in 2022, aims to reduce the state's GHG emissions by 50% from 2005 levels in 2030 and achieve net-zero emissions by 2050.[33] Thanks to these efforts, GHG emissions from Minnesota's power sector have dropped by 40% over from 2012 to 2022.[34]

To reach the goal of achieving 100% clean electricity by 2040, Minnesota's Public Utilities Commission undertook a permitting reform for renewable energy projects. In December 2023, a working group proposed 12 reforms that could reduce permitting to nine months. The report was used to design a package that the Minnesota Legislature passed under the Energy Infrastructure Permitting Act in May 2024, which was waiting to be signed by the governor as of the publication of this report.[35]

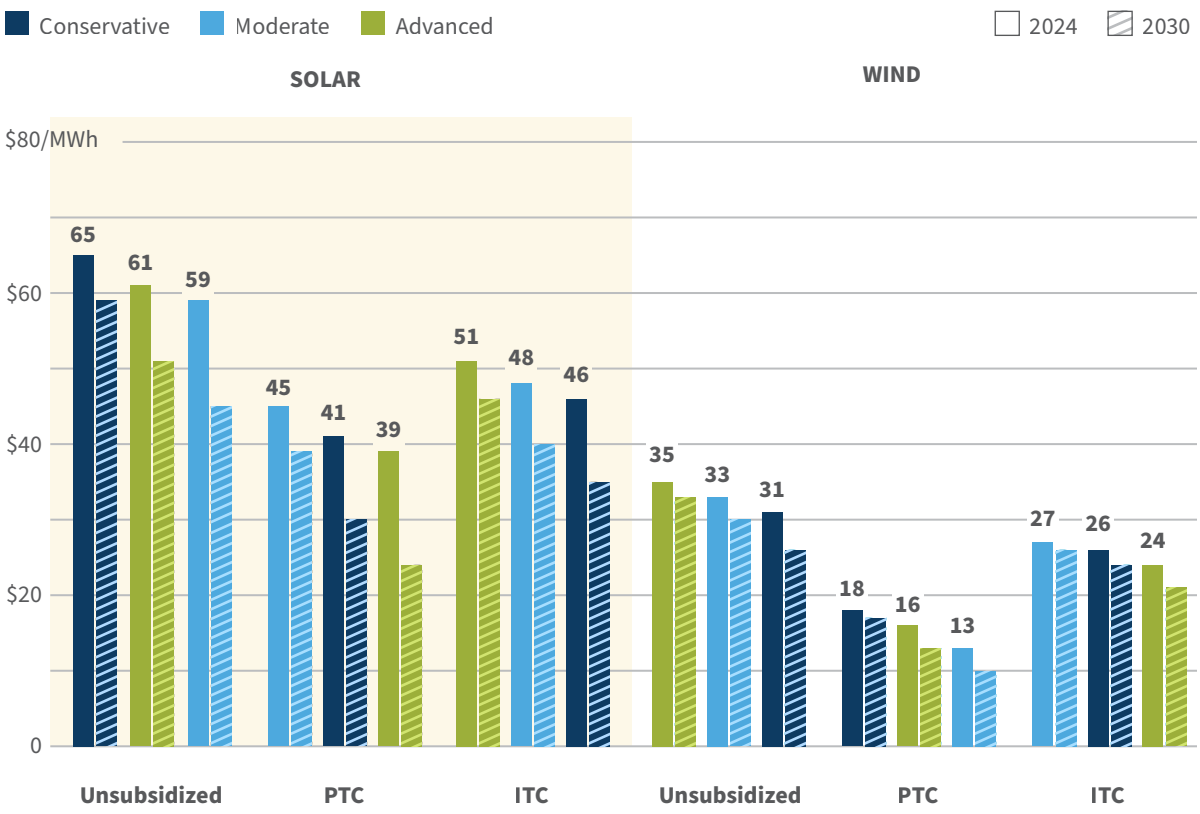
Minnesota is also the only Corn Belt state with specific incentives for in-state green fertilizer production. Minnesota's Department of Agriculture is designing a $7 million green fertilizer grant program to reduce fertilizer emissions.[36] The grant's objective is to provide financial support to co-ops that invest in a green fertilizer production facility in Minnesota. Co-ops must have long-term offtake agreements to purchase the green fertilizer and obtain training in nutrient management best practices, in alignment with the state nitrogen fertilizer management plan.[37]

Momentum in Minnesota with a First Wave of Commercial Projects

DGA production is already competitive with large-scale green ammonia production and can be competitive with grey and blue ammonia production pathways under specific assumptions, especially concerning natural gas pricing. Minnesota has good renewable energy generation, which makes DGA projects there economically feasible. The development of technologies and standardization of production solutions will strengthen DGA's market position. Modeled scenarios relating to cost factors, learning rates, and system configurations provide insights into when and how much cost reductions should be expected. In the coming years, a reduction in the levelized cost of ammonia (LCOA) of 30% will be achieved, as the cost of electrolyzers and modular ammonia synthesis systems continue to decline.

Distributed Green Ammonia Cost Analysis

Cost factors



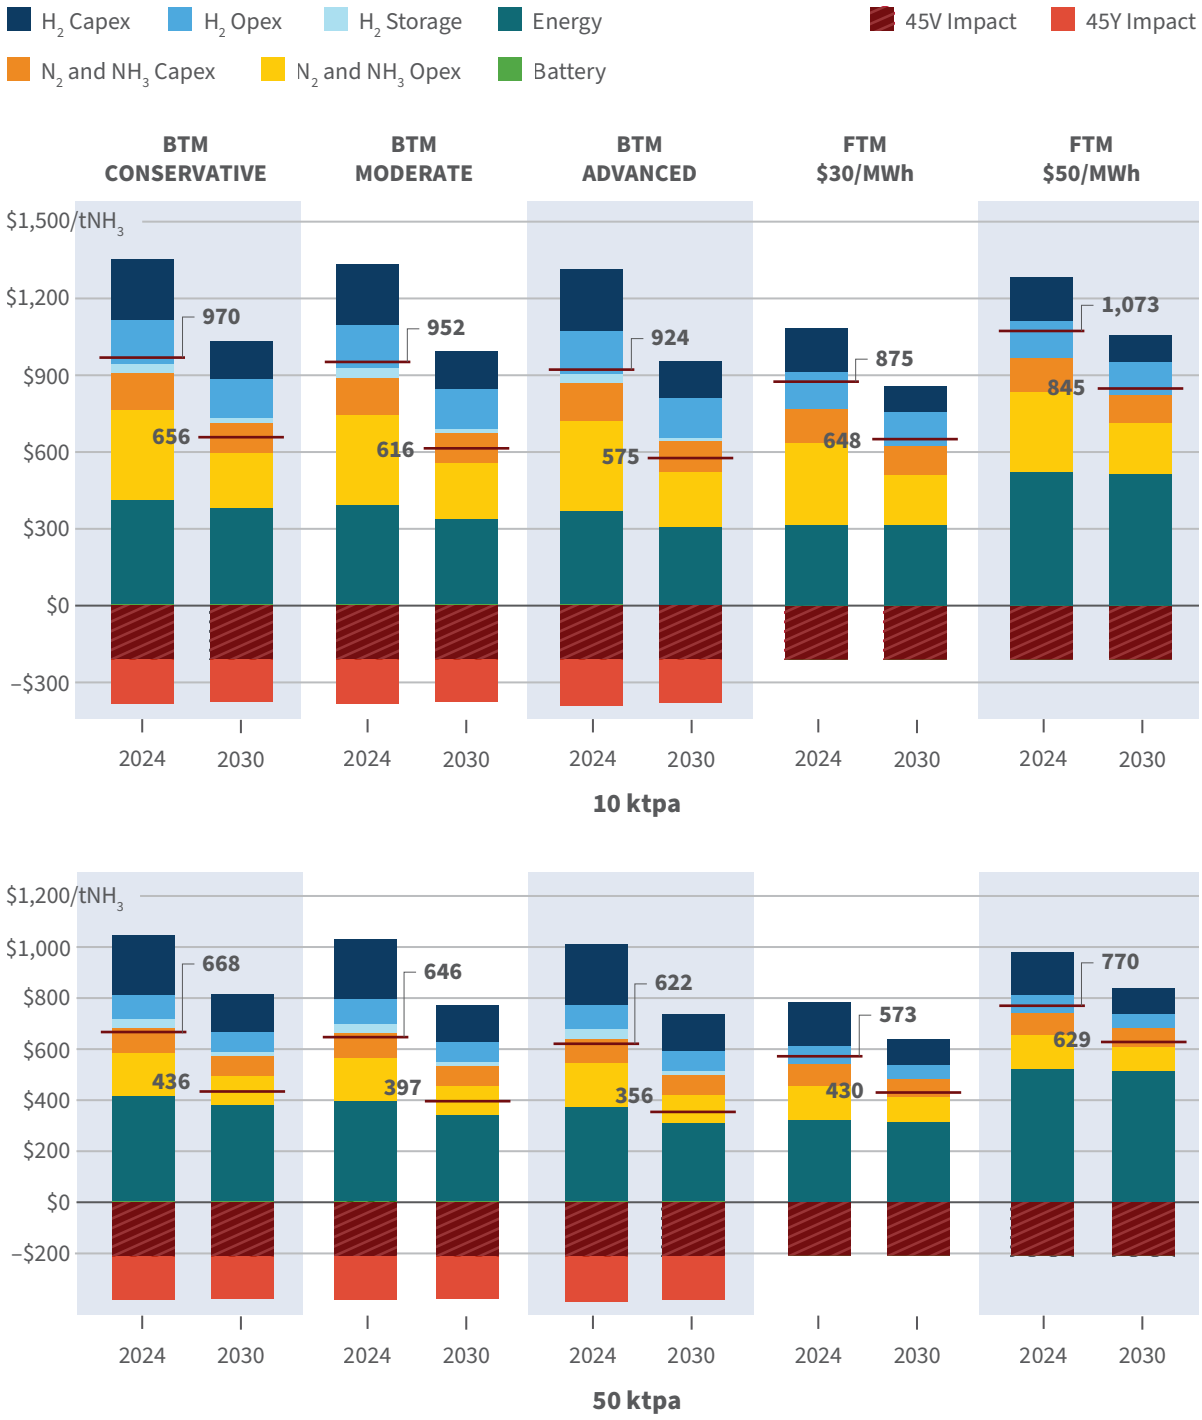
To calculate LCOA, the authors used a system optimization model they developed. This model designs an ammonia production system using various technical assumptions and market development scenarios. Such an approach makes it possible to determine the sensitivity of LCOA to changes in the main cost components — the cost of energy, the cost of hydrogen production, and the cost of nitrogen and ammonia production.

For a DGA project, energy is one of the primary cost factors, and it can vary within a wide range of 30%–80% of total LCOA, depending on the scenario. Whereas the cost of grey ammonia constantly fluctuates in response to natural gas price changes, the price of green ammonia is proportional to the cost of renewable energy (RE) available on-site.

Two power supply configurations were used in the analysis: behind the meter (BTM) and in front of the meter (FTM). In a BTM configuration, local RE generating and storing capacities are constructed to supply the ammonia plant. Energy supply and thus production rates depend on the wind and solar energy availability profiles in the plant location. By contrast, with an FTM configuration, energy is always available from the local energy grid. This decreases upfront project capital expenditures compared with a BTM alternative, because required feedstock production and storage capacities are lower.

A comparison between FTM and BTM energy supply configurations shows that FTM can provide a lower LCOA if energy cost is below $40/MWh, though this cost is below average market prices. It is important to highlight that Minnesota has favorable conditions for RE generation, especially for wind; see for levelized cost of energy (LCOE) modeling results. By 2030, the cost of solar energy will drop significantly, and therefore the consumption profile will shift toward higher solar energy utilization (see Exhibit 11, next page). Total cost reduction in this share of LCOA is expected to be 15% by 2030. Moreover, modeling results for a 10 ktpa and 50 ktpa (see Exhibit 12, page 24) production scales, demonstrate that flexible DGA systems allow for lower cost of energy compared with large-scale ammonia production (see Exhibit 13, page 25).

Exhibit 11 LCOE for Solar and Wind Energy Generation in Minnesota Considering Scenarios with an Investment Tax Credit (ITC), Production Tax Credit (PTC), and Unsubsidized Energy Generation

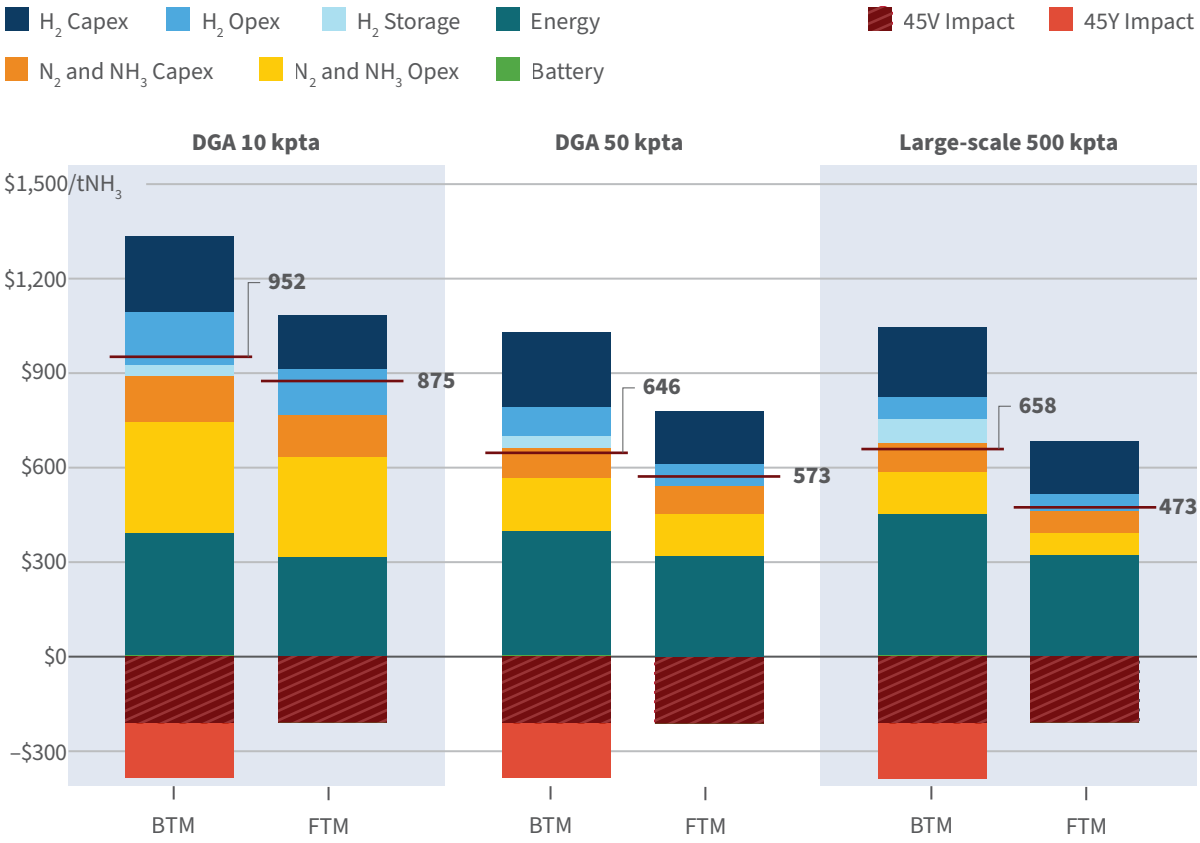


Note: LCOE calculation results. Three options of tax credit application were considered — unsubsidized energy generation, production tax credit (PTC), and investment tax credit (ITC). For each case three RE scenarios — conservative, moderate, and advanced (from left to right in each section of the exhibit) — from the Annual Technology Baseline (ATB) analysis by National Renewable Energy Laboratory (NREL) were used. Calculation was made for the most favorable locations in Minnesota. Bars are presented in pairs: The first bar represents 2024 results, and the second bar represents 2030 results. The DOE's Land-Based Wind Market Report: 2023 Edition states that an average unsubsidized LCOE of wind energy in the Midwest has reached the level of $32/MWh, based on data from already operational wind farms. As can be seen in the exhibit, this cost level nearly matches RMI's modeling result for 2024 using a moderate RE scenario from NREL ATB 2023.

RMI Graphic. Source: RMI analysis

Hydrogen costs can make up to 20% of a subsidized LCOA for a BTM configuration and are estimated to be around 3% for FTM projects, where energy is the major cost factor. Considering learning curves of electrolyzers and market dynamics, a 40% cost reduction in hydrogen is expected by 2030. Hydrogen expenses include capital expenditures and operating expenditures (opex) related to hydrogen production, operation, and maintenance, excluding energy costs. The dynamics of capital and operating expenditures associated with hydrogen show that the role of operating expenditures is most significant with small-scale production facilities, and that they decrease as ammonia production scales up. Hydrogen storage expenditures are relatively small across all analyzed scenarios. Analysis included deployment of pressurized canisters for DGA production and pipeline storage for large-scale systems, which is a cheaper option.

Exhibit 12 LCOA Modeling Results for Two DGA Production Scales



Note: The 10 kpta DGA comparison considers a BTM configuration with three RE scenarios from NREL ATB 2023, and a FTM configuration with two energy cost levels. Cost levels for 2024 and 2030 can be compared for each provided scenario. LCOA values are provided on top of the plot bars.

For the 50 ktpa DGA production scale, three RE scenarios for a BTM configuration and two energy cost levels for a FTM configuration are considered. Compared with a 10 kpta DGA, an increased ammonia production volume lowers the total LCOA by minimizing (1) opex related to hydrogen production, (2) capex related to nitrogen and ammonia production, and (3) opex related to nitrogen and ammonia production. Change of hydrogen-related capex and energy-related capex and opex is insignificant relative to the 10 ktpa production case.

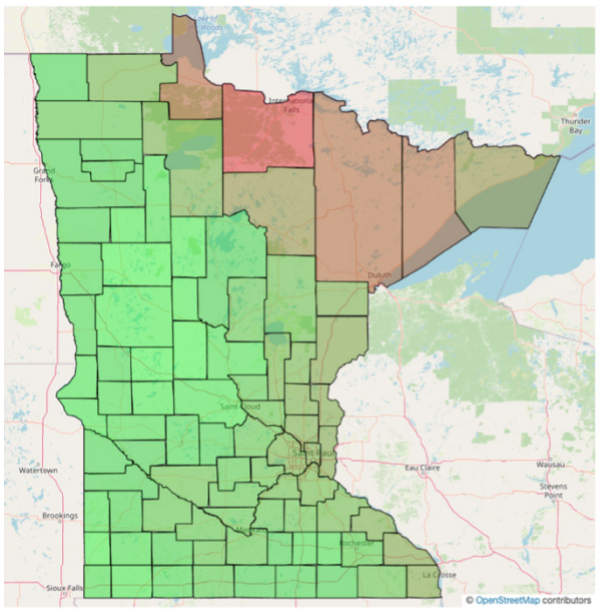
RMI Graphic. Source: RMI analysis

Exhibit 13 Comparative Analysis of DGA and Large-scale Ammonia Production Pathways

Note: Green ammonia production is modeled using a moderate RE scenarios by NREL ATB 2023 and a $3/MWh FTM energy price for comparison. As can be seen, flexible DGA ammonia synthesis systems can allow a competitive LCOA level, compared with a large-scale electrified conventional Haber-Bosch system. With low energy costs, DGA systems become competitive with grey and blue production pathways. The analysis considered air separation units (ASU) to be deployed for DGA and pressure swing absorption units (PSA) to be used for industrial-scale production. DGA can benefit from flexibility and scalability of PSA systems because they are well matched with RE sources. Both ASU and Haber-Bosch reactors, by contrast, benefit from economy of scale.

RMI Graphic. Source: RMI analysis

Costs associated with nitrogen and ammonia production account for 50% of a subsidized LCOA. Share of these costs is lower for an FTM configuration than for a BTM configuration, and it further declines for large-scale systems. As the DGA market matures, a 30% cost reduction can be achieved in this cost factor by 2030. EPC costs can comprise a significant share of the project budget, especially in developing sectors like hydrogen production and novel ammonia synthesis systems. Considering EPC costs, modular and stackable DGA systems can benefit from standardized feedstock production solutions as technologies evolve.



The last cost factor of LCOA is tax credits. Analysis considered 45V and 45Y tax credits, which were applied to hydrogen production and energy generation (for a BTM configuration) subparts of the ammonia production system. The 45Y incentives for RE generation include two available subsidy mechanisms: an investment tax credit (ITC) and a production tax credit (PTC). The financial calculation used the 45Y mechanism, which provides the lowest LCOE. As LCOA is calculated considering the whole service life of the ammonia plant, the total impact of the 45V hydrogen credit is lower relative to a credit value calculated over a single year.

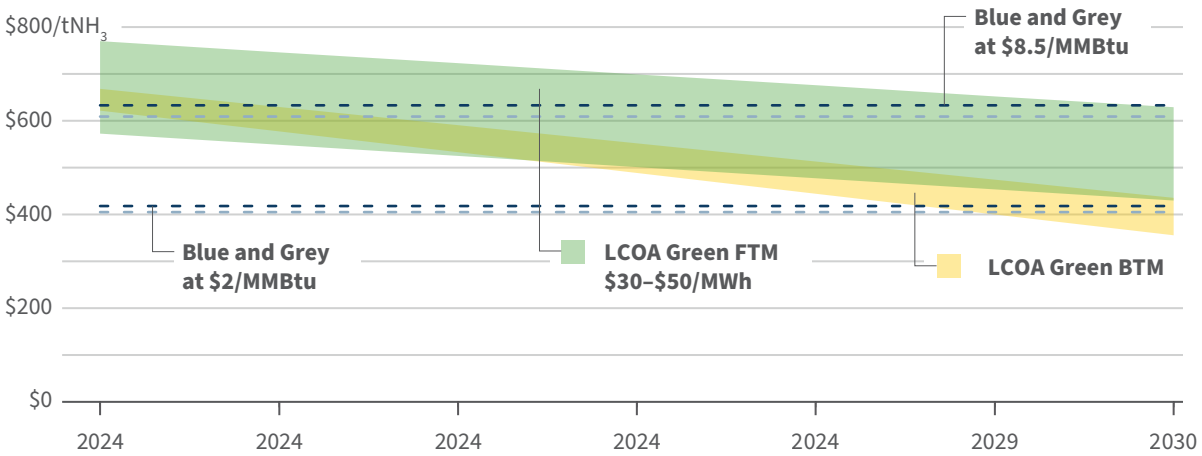
Exhibit 14 shows LCOA distribution across Minnesota counties, reflecting the areas most favorable for DGA production. Locations with the cheapest energy allow for the lowest LCOA. The data used for the map doesn't include transportation costs, assuming that a DGA production facility is placed near end users.

Cost Dynamics and Competitive Position

Regular fluctuations in natural gas prices and geopolitical factors abruptly inflating ammonia market prices (to $1,600/tNH$_3$) indicate that DGA ammonia production is already a viable solution. Assuming highly favorable wind conditions, the western and central parts of Minnesota are the most feasible locations for BTM DGA projects. Today, with high natural gas prices, DGA production of 50 kilotons per annum (ktpa) can already be competitive with blue and grey pathways. By 2030, DGA production of 50 ktpa can reach cost parity with grey and blue ammonia pathways even considering moderate RE market forecasts and low natural gas prices (see Exhibit 15, next page).

Exhibit 14 A Map of LCOA for a BTM DGA Production Across Minnesota Counties

Note: Because a BTM DGA system in Minnesota would primarily use wind energy, DGA projects in central and western parts of the state, which have the most favorable wind conditions, would have the lowest production costs. A more accurate estimation of a particular production location would require consideration of other factors, such as permitting to construct required RE capacity and the suitability of ammonia for local soil.



RMI Graphic. Source: RMI analysis

A 10 ktpa–scale system will be cost-competitive in a scenario with moderate and high natural gas prices. LCOA levels for centralized grey and blue production pathways are presented in Exhibit 16 (next page). Recognizing that levelized production costs and market costs are different, this comparison allows for the estimation of feasible ammonia price ranges and the value of a green premium. Importantly, the share of transportation expenses in these LCOA calculations was estimated to be around $180/tNH$_3$ (assuming ammonia delivery to Traverse County), while in unfavorable market conditions it can increase up to $300/tNH$_3$. A DGA production pathway implies ammonia production close to end-users, therefore transportation expenses were excluded.

Compared with DGA systems, large-scale blue and grey ammonia facilities can be profitable in high-cost environments. Even if the feedstock price increases from $2/million British thermal units (MMBtu) to $5/MMBtu (an increase of 2.5 times, see Exhibit 16), the feedstock cost for the hydrogen production increases by less than two times. This shows that grey and blue ammonia plants have a reduced sensitivity to feedstock pricing. As DGA will have to compete with these production pathways, lowering production cost, especially by targeting improved system efficiencies and securing low electricity prices, will be essential to remain competitive.

From 2024 to 2030, there will be a steady decline in the LCOA for both FTM and BTM DGA systems, as shown in Exhibit 15. Both become increasingly competitive with blue and gray ammonia over time. In fact, market development and commissioning of new projects will lead to a significant decrease of equipment costs in DGA.

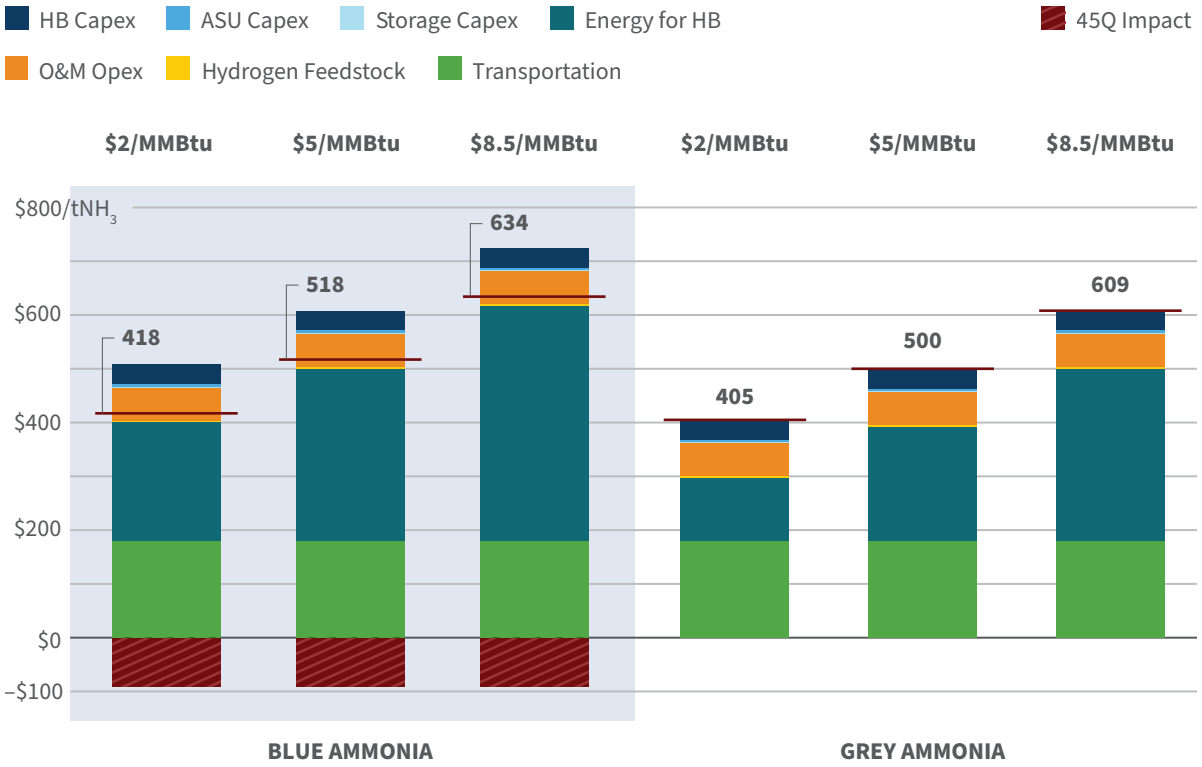


Exhibit 15 LCOA for FTM and BTM Green Ammonia Projects

Note: Projections of LCOA from 2024 to 2030 for BTM and FTM DGA systems at 50 ktpa in Minnesota compared with blue and grey ammonia production costs in the US Gulf. LCOA ranges for centralized blue and grey ammonia production are calculated with a natural gas price range of $2–$8.5/MMBtu.

RMI Graphic. Source: RMI analysis

Exhibit 16 LCOA for Blue and Grey Ammonia Production Considering Different Natural Gas Prices

Note: Delivered LCOA calculation results considering blue and grey centralized ammonia production in the Gulf using different market prices for natural gas prices from recent years: minimum ($2/MMBtu), average ($5/MMBtu), and maximum ($8.5/MMBtu). The capture rate for blue SMR is assumed at 85%. The application of 45Q incentive minimizes the cost difference between blue and grey ammonia. 45Q refers to the production tax credit based on the quantity of CO_2 captured and stored during the hydrogen synthesis process. The transportation cost assumes pipeline distribution from Louisiana to Iowa and distribution to demand centers in Minnesota by trucks.

RMI Graphic. Source: RMI analysis

This will result in an estimated 30% LCOA reduction for DGA ammonia pathways by 2030. With an estimated 20% learning curve effect for water electrolyzers and 10% for balance of plant equipment, there will be a 50% reduction in capital expenditures for both categories by 2030 due to a rapid growth of cumulative installed capacity in the coming years. For nitrogen synthesis equipment, a 10% total capital expenditure reduction by 2030 is expected. Novel small-scale ammonia synthesis systems cost will reduce 20% by 2030.

The importance of FTM systems accessing lower-cost electricity is evident in the projected decline in the LCOA for green ammonia. Access to cheaper electricity from diverse and large-scale power sources allows FTM systems to lower their operational costs over time, making DGA production increasingly competitive compared with blue and grey ammonia. As a result, the ability to tap into lower-cost grid electricity is crucial for driving down production costs and enhancing the economic viability of DGA.

Target Setting

The design of a coordinated plan for Minnesota to produce low-carbon fertilizers requires alignment between policymakers, investors, lenders, and developers to successfully deploy the first wave of DGA projects. Setting an ambitious target will help to anchor and measure the state's success in adopting green fertilizer, and new business models will help to scale successful frameworks.

Minnesota targets

To align DGA roadmap targets with existing statewide efforts, the overall 50% emissions reduction target from the **Minnesota Climate Action Framework** was used as an anchoring objective.[38] Drawing from 2020 production emissions, RMI established that total production emissions associated with annual Minnesota purchases of fertilizer is 2,267,991 tons CO_2e. Of those production emissions, 87% are attributable to nitrogen fertilizers. To meet annual Minnesota's nitrogen demand, approximately 900,000 tons of ammonia is needed. To reach a 50% reduction of emissions from ammonia production by 2030, the state would need to produce or import 450,000 tons of green ammonia per year. Achieving this target with production alone would necessitate a capacity of approximately 1 GW of electrolyzers and 2.5 GW of renewable energy. For context, no electrolyzer has been deployed in Minnesota, and the state will need to install new wind and solar that amounts to 40% of its current capacity of 6.3 GW to meet production requirements. To reach net-zero emissions by 2050, 2 GW of electrolyzer and 5 GW of renewable energy capacity dedicated to green ammonia production would be required, according to projections (see Exhibit 17).

Exhibit 17 Minnesota Ammonia Targets

Targets

Year	CO_2 Reduction	Ammonia Production Capacity	Required Electrolyzer Capacity	Required Renewable Energy Capacity
2030	50%	450 kt per year	1 GW	2.5 GW
2050	Net-Zero	900 kt per year	2 GW	5 GW

RMI Graphic. Source: RMI analysis

Business Models and Project Finance Risk Mitigation

Getting the first wave of projects off the ground will help de-risk DGA, spurring deployment of new systems in the future, which will ultimately help Minnesota reach its 2050 emissions reduction target. Effective business models play a crucial role in risk mitigation when structured appropriately. In the context of DGA projects, the initial focus is on minimizing risks associated with technology and offtake. Technology risks stem from DGA's novelty and its relatively low commercial maturation. Offtake risks center on securing a long-term offtake agreement from a creditworthy off-taker. It is paramount to address both.

Mitigating these risks commences with meticulously structuring project finance and contracts. This entails crafting offtake agreements tailored to the specifics of the project, considering factors such as the type and duration of the agreement. Establishing a suitable legal and business entity, often through a special purpose vehicle (SPV), offers insulation from liability. For smaller-scale ventures, joint ventures can be considered. Key tools for minimizing risk in project financing include assessing offtake contracts, prioritizing the creditworthiness of off-takers, and opting for SPV structures to shield parent companies from direct exposure. Evaluating the efficacy of these business models necessitates a comprehensive examination of their ability to address the unique risks inherent in DGA projects while also fostering profitability.

Beyond these tools, factors that determine the efficacy of a green ammonia business model include the type of offtake contract (i.e., length and price arrangements) and the ownership structure. The risk tolerance of investors, off-takers, and project developers informs both of these arrangements.

In considering pricing structures for ammonia offtake agreements, options include: (1) fully flexible price model; (2) floor-to-ceiling price model; and (3) fixed-price model. The fully flexible price model mirrors the current system in fertilizers, offering familiarity for off-takers but potentially making it more challenging for project developers to secure financing from lenders because the product price is unpredictable. The floor-to-ceiling price model offers the advantage of prearranged floor and ceiling prices, providing a semi-floating price for off-takers, yet it carries inherent risk because it relies on price estimations. Lastly, the fixed-price model offers a steady income stream and increases the likelihood of securing financing from lenders, although it may pose difficulties for agricultural co-ops seeking to enter into such offtake agreements.

In terms of length, short-term agreements are commonplace in the fertilizer market, whereas long-term agreements, though less common in this sector, can be instrumental in securing financing for ammonia projects. In general, conventional ammonia contracts are short term, with prices anchored to CFR Tampa spot prices — the benchmark for ammonia prices that fluctuate according to natural gas price variability. However, longer-term contracts, similar to power purchase agreements for clean electricity, might be generally preferred given the nascency of green ammonia projects.

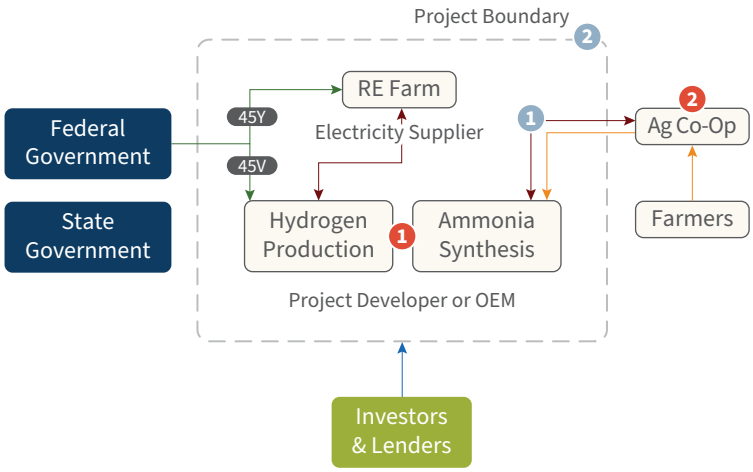
As for ownership structures for these projects, a variety of actors within the ammonia ecosystem can be involved. During initial deployment of DGA projects, OEMs will likely play a role in demonstrating commercial proof of concept. However, traditionally, we would see initial ownership from project developers, often following a build-operate-transfer model. Co-ops, whether electric or agricultural, could also take ownership of DGA projects. Although co-ops might lack expertise in operating DGA systems, co-op ownership would directly reduce reliance on external suppliers for ammonia required for electricity or agricultural applications. Another ownership model could involve ethanol producers, where ethanol facilities would own a DGA facility to combine ammonia with captured biogenic CO_2 to produce low-carbon urea.

Standard Business Model

As an example, consider a standard business model where an agricultural co-op represents the primary revenue source (see Exhibit 18, next page). In such a scenario, risks related to technology and off-taker creditworthiness must be mitigated. The agricultural co-op's involvement introduces revenue stability but also necessitates careful management of technological risks associated with this novel ammonia production process. Technology risk can be mitigated through the involvement of credible project developers and technology providers. Additionally, ensuring the creditworthiness of the off-takers becomes crucial to guarantee consistent revenue streams and overall project viability. Both of these factors determine the willingness of investors and lenders to provide capital and the overall economic sustainability of the project, which can be addressed through long-term offtake agreements and credible players involved in the project development.

Co-op Owned Business Model

An alternative business model involves direct ownership from agricultural co-ops. Although this model presents similar challenges as the standard business model, it relies on farmers for the only revenue stream, so the project's feasibility hinges primarily on revenue stability. Without a direct offtake agreement in place, ensuring the economic viability of the project becomes uncertain. However, agricultural co-ops would gain full control over their supply chain, thereby avoiding additional costs incurred through intermediaries.



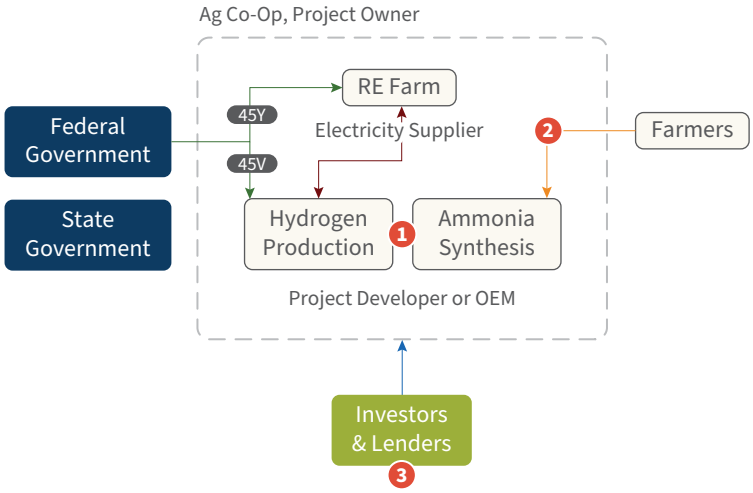
Moving Forward

These are just a few of the high-level risk considerations and mitigation tools project developers will encounter when assessing business models. Additional mitigation tools will vary depending on each project's specifics. Apart from economic tools, those developing a DGA project should also explore how policy can reduce overall investment risks.

Exhibit 18 Standard and Co-Op-Owned Business Models

Capital/Investments · Incentives · Revenue · Bilateral Offtake Agreement

STANDARD



KEY RISKS

1. **New Technology** — DGA projects are still in their first commercial wave.
2. **Creditworthiness** — Suppliers should ensure ag co-ops are at least medium-sized and financially sound.

DYNAMICS

1. **Contract** — Length and type of contract will mainly determine the economic viability.
2. **Ownership**— Different types and players could be involved in the ownership, from ag co-ops to OEMS.

CO-OP-OWNED

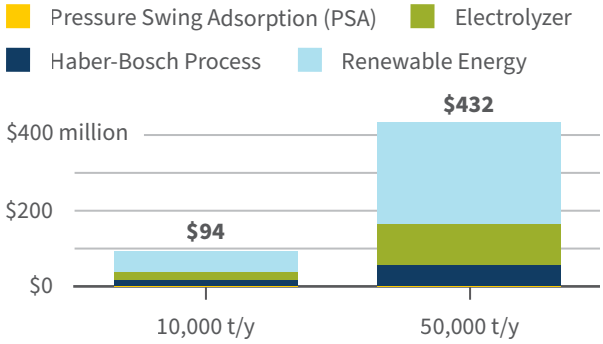
KEY RISKS

1. **New Technology** — DGA projects are still in their first commercial wave.
2. **Revenue Stability** — Farmers, unless locked into an offtake agreement, do not represent a stable income source.
3. **Securing Financing** —Without having secured a large, credit-worthy offtaker, it might be more difficult to convince lenders.

RMI Graphics. Source: RMI analysis

Key Recommendations

Future Policy Considerations



Policy Recommendation 1: Allocate Minnesota's green fertilizer grant for maximum impact

The Minnesota Department of Agriculture (MDA) is currently reviewing feedback received from stakeholders in its request for information on how to design the fertilizer grant program.[39] MDA can consider different alternatives to leverage the $7 million in current funding, along with potential additional funding, for maximum impact to help accelerate the first wave of DGA projects in the state.

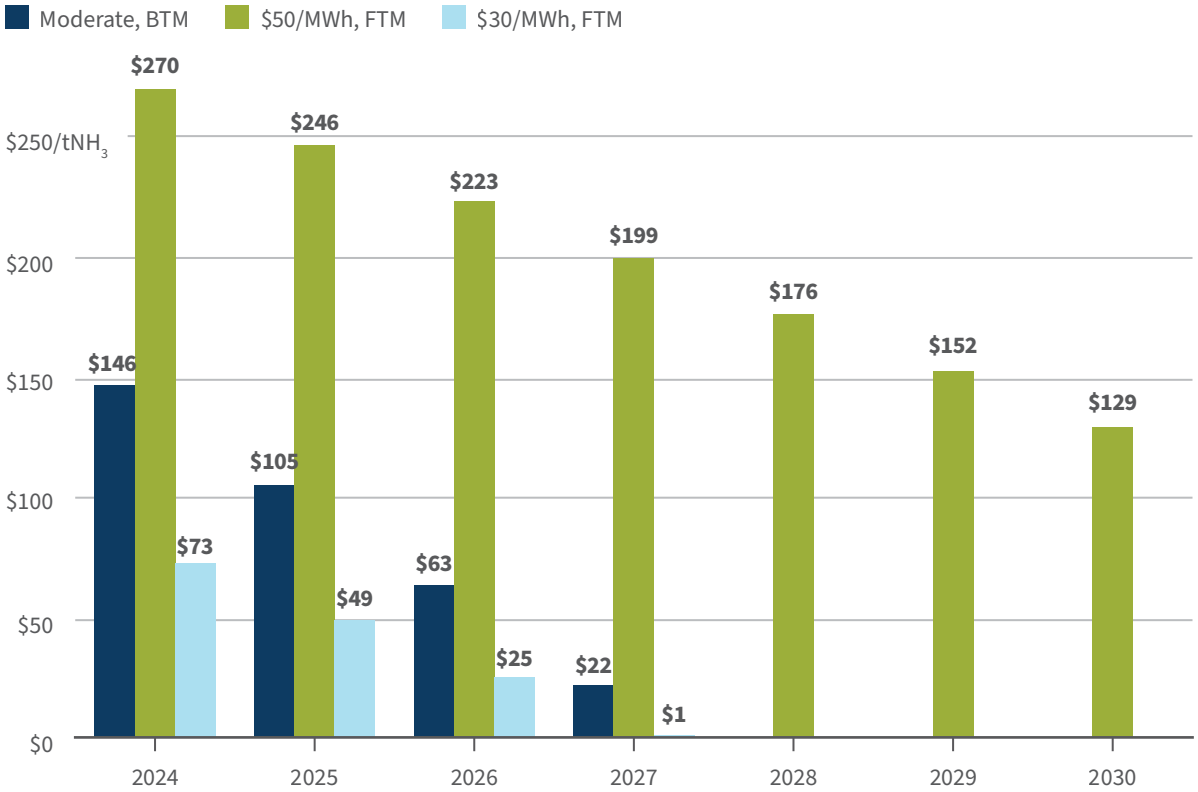
Green ammonia plants, even relatively small-scale distributed ones, are capital intensive. Estimated capital expenditures for 10 ktpa and 50 ktpa systems range from $94 million to $432 million, including capital expenditures for RE generating capacity (see Exhibit 19). The broad goals of the grant are to support deployment of the first wave of projects and move the state toward reaching the proposed production targets. In addition, these initial projects can serve as case studies to help future projects raise capital and reach final investment decision.

Exhibit 19

Total Capital Expenditure of Main Equipment for Distributed Green Ammonia Production Systems

RMI Graphic. Source: RMI analysis

This list is not meant to be exhaustive, and some options might not be permitted under the current grant guidance, but it is presented here to encourage more radical thinking:



- Provide direct capital expenditure support for one project. For a single, 10 ktpa system this could offset more than 7%, whereas supporting a 50 ktpa system would offset only 2% of project costs.
- Fund pre-feasibility and feasibility studies for DGA systems to support developers and ensure that the grant facilitates practical, data-driven decisions for implementing decentralized ammonia production facilities in Minnesota.
- Provide funding as cost share if projects unlock federal funds such as LPO loans, up to a specified amount per project (or limited based on estimated production).
- Fund a supply-side competitive auction for green ammonia production. This would help close the gap with conventional ammonia by awarding contracts to producers that can offer the most competitive production volume with offtake agreements at the lowest subsidy required (see Policy Recommendation 2).

Policy Recommendation 2: Design a competitive mechanism to provide subsidies to make DGA projects bankable

DGA projects need offtake agreements to be bankable and reach final investment decision. Also, as shown in Exhibit 20, green ammonia projects are more expensive than conventional ammonia in the short term, making it difficult to close these offtake agreements. Based on the available budget and the deployment targets, Minnesota could fund a competitive auction to incentivize green ammonia for fertilizer production, in a structure similar to the one used by the European Hydrogen Bank.[iv]

Exhibit 20 provides a sense of the range of the premium needed to design an auction system. The cost gap between DCA and grey ammonia will vary based on the financial situation of each project and developer, and it does not have to be fully covered by state funding. However, Minnesota can play a crucial role in closing the gap by providing the needed funding to developers to close offtake agreements, ensure demand, and make these projects financially viable.

Exhibit 20 **Cost Gap Between DGA and Grey Ammonia**

Note: This exhibit illustrates three cost scenarios for a DGA facility of 50 ktpa: (1) Moderate, BTM; (2) $50/MWh, FTM; and (3) $30/MWh, FTM. The 2024 and 2030 LCOA values for each of these scenarios is drawn from Exhibit 13, and those values are then compared with the cost of grey ammonia production at $5/MMBtu ($499.69/tNH_3) to establish the cost gap.

RMI Graphic. Source: RMI analysis

iv The European Hydrogen Bank uses an auction system where companies bid to win a set amount of money (the premium) per kilogram of clean hydrogen they produce over a specific period.

The auction process could have the following criteria:

- **Eligibility:** Establish eligibility criteria for producers, including offtake agreements, carbon intensity thresholds, and a minimum production capacity.

- **Bidding:** Producers submit bids specifying:
  - The amount of green ammonia they can produce over a defined period (e.g., per year).
  - The minimum subsidy required per ton to sign the offtake agreement.

- **Evaluation and awarding contracts:** The auctioneer (a Minnesota government agency) would evaluate bids based on factors such as:
  - Cost competitiveness: producers that require the lowest amount of support to fulfill the supply contract.
  - Project viability: the technical and financial feasibility of the proposed production process.

- **Subsidy to close the gap:** Winners would be awarded contracts guaranteeing the requested subsidy per ton of ammonia produced for a set period. The government would essentially pay part of the difference between the production cost of incumbent grey ammonia and the producer's production cost for green ammonia. The subsidy can be a fixed premium on top of hydrogen offtake prices.

Additional considerations:

- **Reference production cost:** Minnesota can establish a reference cost for grey ammonia. This could be based on the average market cost of conventional grey ammonia. For example, Exhibit 20 presents the cost gap of $500 per ton of ammonia with a natural gas price of $5/MMBtu for different configurations of green ammonia versus grey ammonia.

- **Budget constraints:** The total program budget available would likely influence the final subsidy provided, where only viable projects that require a lower subsidy would be competitive in the auction.

Policy Recommendation 3: Provide access to lower capital cost with guaranteed loans

Co-ops can leverage LPO loans to access capital for the equipment needed for green ammonia production at a lower interest rate than conventional loans. LPO loans require projects to be innovative, implementing a technology that is not widely currently available on the market, such as DGA.

The recently created Minnesota Climate Innovation Finance Authority is seeking public comments through a request for information to act as a State Energy Financing Institution (SEFI) and leverage federal LPO funding.[40] Since SEFI-supported projects are exempt from the innovation requirement, Minnesota's green bank could co-lend loans with the LPO to produce green ammonia using commercial technologies, improving access to low-cost capital from federal funding.

Loans guaranteed with LPO funding can provide better interest rates than commercial banks, lowering the cost of capital and boosting the projects' financials. As of June 2024, the interest rate for the LPO's Title 17 projects was around 5%, notably lower than the 7% used in this report's analysis of BTM DGA systems (see Exhibit 21).[41]

The state can also develop its own loan program. North Dakota has adopted this model, where the legislature provides the Bank of North Dakota with $150 million for its Clean Sustainable Energy Loan Fund for green fertilizer projects in the state.[42]

Exhibit 21

Comparison of the Impact of a Lower Interest Rate on LCOA in 2024

Interest Rate	LCOA $/tNH$_3$
7%	$646
5%	$630

RMI Graphic. Source: RMI analysis; LPO's Title 17 financial program, **https://www.energy.gov/lpo/articles/pricing-lpo-financing-program**.

Policy Recommendation 4: Advocate to unlock existing USDA funding streams that aim to increase national production of fertilizer

The United States Department of Agriculture (USDA) has immediate opportunities to support green ammonia production for fertilizers. The USDA's Rural Energy for America Program received $145 million in funding from the IRA for 700 loans and grants to expand access to renewable energy.[43] In addition, the Fertilizer Production Expansion Program awarded $500 million in grants to increase US-made fertilizer production to spur competition and combat price hikes on US farmers.[44] Considering the importance of fertilizer in the state, Minnesota could advocate for the USDA to launch another round of the Fertilizer Production Expansion Program, focusing on DGA systems.

Policy Recommendation 5: Ensure an enabling environment for DGA deployment in the state

- **Workforce training:** Incentives to support workforce development through training and skills programs will be necessary for the establishment and longevity of this new industry. Minnesota can adapt existing grant programs, such as the training grant programs form the Minnesota Department of Employment and Economic Development (DEED), to develop the new workforce for green ammonia and hydrogen projects.[45]

- **One-stop shop permitting:** A one-stop shop permitting initiative would expedite the deployment

of green hydrogen and ammonia production infrastructure, enhancing efficiency and reducing costs while minimizing uncertainty and simplifying project management. It should involve implementing streamlined approaches to permitting and regulatory approval, along with developing clear guidance on hydrogen and ammonia permitting, with stakeholder engagement focusing on environmental, energy, and equity priorities. The initiative should also aim to facilitate project rollout by enabling quick commissioning through centralized permitting processes and environmental impact assessments. As an example, the EU, through the Net-Zero Industry Act, sets a 12-month permitting time limit for hydrogen projects with an annual capacity equal or less than 1 GW.[46]

- **Develop clear guidance for green ammonia certification:** Leveraging Minnesota's founding role in the Midwest Renewable Energy Tracking System (M-RETS), policymakers can establish clear criteria and definitions for what constitutes green ammonia within the M-RETS system. M-RETS will play a key role in providing the tracking infrastructure that developers can use to comply with 45V federal tax credits for hydrogen production because it anticipates issuing hourly renewable energy certificates during the next 12 to 18 months.[47] This can provide a foundation for a green ammonia certification scheme.

Moving Forward

The deployment of DGA systems to help decarbonize fertilizer emissions in Minnesota faces unique challenges. The evolution of ammonia to serve new markets will have a price-setting impact that could make it difficult for new players and projects to succeed in the fertilizer industry. In addition, the lack of product differentiation for fertilizers makes it challenging to increase buyers' willingness to pay for and thereby incentivize green fertilizer offtake without a green certification or other label that adds value in the market. Given the importance of fertilizers to the state's agriculture sector and the complex market dynamics, Minnesota should take a comprehensive and coordinated approach to design and implement policies to understand the impact of the different levers available

Future Work

There are multiple avenues to explore beyond the roadmap for DGA production presented here. Additional areas for research and analysis include:

- Evaluating applications of ammonia beyond fertilizers and how demand can smooth out the seasonal demand of ammonia for fertilizers
- Exploring additional policy and market mechanisms to accelerate green ammonia production and use across the Midwest
- Identifying the most effective low-carbon nitrogen fertilizer options and alternatives to decrease overall consumption emissions and assessing the most suitable solution to fully decarbonize the fertilizer sector
- Understanding the techno-economic feasibility and CO_2 sourcing for low-carbon urea as well as the infrastructure buildout needed to guarantee effective carbon management and utilization
- Engaging an array of stakeholders, including DGA ammonia suppliers, fertilizer distributors, farm groups, and state policymakers, to raise awareness of the DGA opportunity and accelerate project deployment

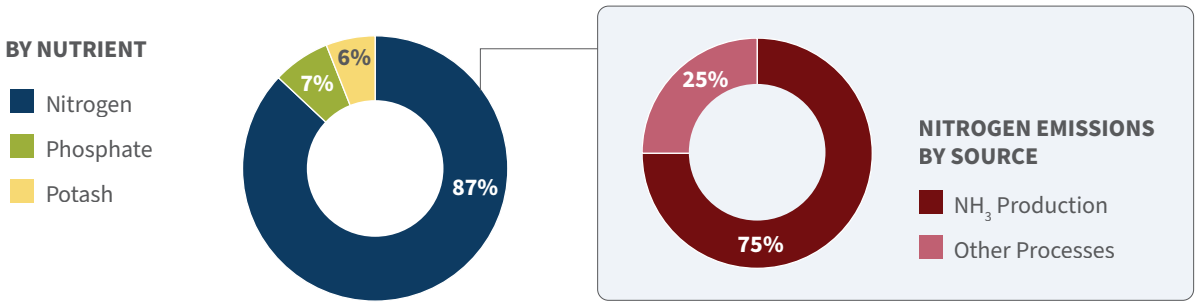
Conclusion

Minnesota is uniquely positioned to take advantage of DGA. The current centralized ammonia production system can provide farmers with low-cost fertilizer, but also exposes farmers to price volatility and supply chain disruptions. Localized, distributed ammonia production can complement the existing system to hedge against negative outcomes as well as reduce emissions from fertilizer production.

To enable the deployment of DGA projects in the state, credible consortia with effective business models and targeted policy support should be prioritized. Critically, easier access to capital tools, supplementary subsidies to offset the initially higher production cost of green ammonia, certification schemes to differentiate green ammonia from conventional production, faster permitting tracks, and in-state workforce training need to be introduced to fully realize the benefits and opportunities presented by DGA in the state. The cost of DGA is likely to fall rapidly as modular, containerized systems are able to take advantage of lessons learned by the first systems to be deployed and of rapid, iterative improvements in manufacturing.

The successful implementation of DGA projects in Minnesota and beyond hinges on collaborative efforts, innovative solutions, sound business models, and robust policy frameworks. By addressing these areas of further work and seizing opportunities, Minnesota can unlock the full potential of DGA and pave the way for a sustainable future in agriculture and beyond.

Appendices



Appendix 1: Emissions from Fertilizer Production

Emissions stemming from fertilizer production are highly dependent on the nutrient produced. Three nutrients are needed for healthy plant growth: nitrogen, phosphorus, and potassium (potash). Phosphorus and potash are extracted from deposits and have comparatively low production emissions; in contrast, conventional nitrogen fertilizers are directly reliant on fossil fuels, incurring substantial emissions. This issue is exacerbated because nitrogen is the most critical — and subsequently the most used — fertilizer nutrient for plant growth.

All synthetic nitrogen fertilizers use ammonia as a precursor. Ammonia itself can be used as a fertilizer in the form of anhydrous ammonia. Conventional ammonia synthesis begins with hydrogen production via steam methane reformation (SMR), a carbon-intense process in which hydrogen is extracted from natural gas. Next, the hydrogen is combined with atmospheric nitrogen using the Haber-Bosch process, yielding ammonia. Accounting for the natural gas and energy consumption, producing 1 ton of ammonia emits around 2.34 tons of CO_2, equaling 2.85 tons CO_2 per ton of nitrogen. For comparison, the most common potash fertilizer, muriate of potash, has a per nutrient carbon intensity of 0.42 tons CO_2 per ton potash.[v] The stark difference in per nutrient carbon emissions illustrates why nitrogen is the primary nutrient contributing to fertilizer emissions. Further processing of ammonia into other nitrogen-based fertilizers will incur additional emissions based on fuel and electricity consumption needs and will further increase the per nutrient carbon intensity.

A look at fertilizers purchased in Minnesota confirms the dominance of nitrogen as the driver of production emissions. In 2020, nitrogen sales made up half of Minnesota's nutrient tonnage purchased but accounted for 87% of total associated production emissions. Exhibit A1 illustrates that nitrogen emissions significantly outpace emissions from other nutrients, with the main driver being the production of ammonia.

Exhibit A1 Production Emissions Breakdown of Fertilizer Nutrients Purchased in Minnesota

RMI Graphic. Source: RMI Analysis; MDA, **https://www.mda.state.mn.us/pesticide-fertilizer/fertilizer-use-sales-data**; International Fertiliser Society, **https://www.fertilizerseurope.com/publications/the-carbon-footprint-of-fertilizer-production-regional-reference-values/**; Brentrup et al., **https://www.researchgate.net/publication/329774170_Updated_carbon_footprint_values_for_mineral_fertilizer_from_different_world_regions**

v Based on RMI analysis.

The SMR process to separate hydrogen from natural gas produces over half of the production emissions associated with ammonia. Since hydrogen is used a chemical feedstock, the only way to decarbonize this component of the value chain is to produce hydrogen cleanly, with electrolysis powered by renewable energy. If renewable energy is also used to power the auxiliary stages of ammonia and fertilizer production, emissions are eliminated and what remains is a zero-carbon, green ammonia product.

A special case arises with the popular and versatile fertilizer urea. In 2020, urea and other urea-based fertilizers made up over 62% of Minnesota's total nitrogen sold, reflecting a broad preference for urea. Urea is currently produced in integrated facilities where conventional ammonia production routes the CO_2 stream from the SMR flue to the ammonia outlet where they are combined to form urea. Using this method, some of the CO_2 emissions from SMR hydrogen production are temporarily captured within the urea, though they will be released downstream during usage.

Due to urea's reliance on CO_2, decarbonizing urea production must involve a net-zero source of carbon. Biogenic CO_2 emerges as the most attractive candidate for early production, as alternatives such as direct air capture are far out from commercial viability. Minnesota has ample sources of biogenic CO_2 from its ethanol refineries, as well as a number of pulp and paper mills. This route is already being considered through the Heartland Hydrogen Hub, a DOE-funded project that spans Minnesota, North Dakota, and South Dakota. As part of the hub, Xcel Energy is planning a large-scale urea plant that use CO_2 offtake from ethanol refineries combined with green ammonia.[48]

It is important to note that Minnesota does not produce its own fertilizers but instead imports fertilizer from other states. In addition to production emissions, transportation of fertilizer incurs emissions at different rates depending on method. This dimension was analyzed to gauge its impact as part of the whole fertilizer value chain.

Emissions from Fertilizer Transportation

Since conventional ammonia production relies on natural gas as a feedstock, ammonia production is found primarily in regions with large oil and gas operations, such as the US Gulf Coast. Fertilizer produced in the Gulf Coast is distributed across the country by truck, rail, water, and pipeline, with trucking and rail carrying the vast majority of fertilizer tonnage. Rail is typically used for longer distances, carrying larger volumes, whereas trucks are used for distribution along shorter routes. Trucking is much more carbon intensive than rail: in 2017, national transportation of fertilizer using only trucking contributed over 10 times the emissions as fertilizer transported by only rail.[vi]

Emissions from fertilizer transportation to Minnesota were estimated to be around 130,000 tons CO_2. Compared with the total life cycle of said fertilizers, transportation amounts to only 1.7% of total emissions. While comparatively small, emissions savings can still be achieved through distributed ammonia production by producing fertilizers onsite, negating the need for transportation.

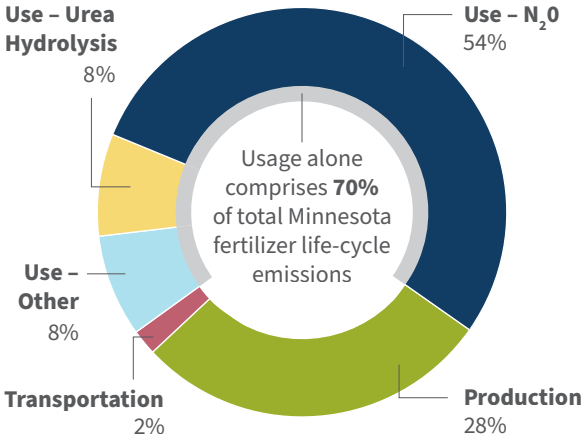
Urea, again, presents a unique scenario, this time within the discussion of transportation. A complicating factor in the integration of biogenic CO_2 for green urea production is the transportation of CO_2. Although CO_2 pipelines are an established technology, pipelines would be difficult to integrate into the decentralized model because an extensive network would be needed. An alternative would be trucked CO_2, with the trade-off being increased cost and potential associated transportation emissions. These constraints may signal green urea production is more suited for a centralized, dedicated plant position close to its CO_2 source.

Emissions from Fertilizer Usage

The usage of fertilizers releases emissions upon application to the soil. Nitrogen fertilizers are especially polluting and are responsible for nearly all use emissions. When applied, a proportion of nitrogen is lost through denitrification, in which organisms convert fertilizer to nitrous oxide (N_2O). N_2O is a greenhouse gas 298 times more potent than CO_2 that diffuses through the soil and is lost to the air. Though released in small quantities, the intensity of N_2O has significant ramifications for the climate. Assuming all fertilizer purchased in Minnesota in 2020 was used, Minnesota experienced approximately 5.6 million tons of CO_2e emitted due to fertilizer use alone, around 2.5 times the emissions associated with the production of said fertilizers.[vii]

Herein lies Minnesota's main fertilizer emissions problem. As discussed above, fertilizer production does not occur in Minnesota; it is instead imported from out-of-state. With transportation emissions low, emissions actually occurring in Minnesota are almost entirely due to fertilizer use. Unfortunately, this issue cannot be solved by green ammonia, since the end product is identical to its conventionally produce counterpart and will behave identically.

In addition to denitrification, the loss of nitrogen to the atmosphere as gaseous ammonia, or volatilization, can occur when nitrogen is reconverted to ammonia in the soil. This results in an indirect loss of nitrogen as N_2O. Gaseous losses are greatest with surface application due to proximity to the atmosphere. Another way nitrogen can be lost is with leaching, where nutrients move past the roots of plants where they cannot be absorbed. This is more likely to happen with fertilizers that are converted into nitrate in the soil, which is not held on to by soil particles. The likelihood of nitrogen loss is not only dependent on the fertilizer used. Soil conditions, such as acidity, temperature, and moisture, can affect how much nitrogen is lost.



vi RMI analysis
vii RMI analysis

Urea is unique in the emissions attributed to it. As explained above, urea requires a source of CO_2 in its production — CO_2 that is initially captured within the fertilizer but released upon usage in a process called urea hydrolysis. To have a truly green product, the CO_2 for production must come from net-zero sources such as biomass. But urea does not only emit CO_2; it is one of the highest emitters of N_2O. Urea is not readily absorbed by crops, so it must be converted to ammonium and nitrate. This process begins with the hydrolysis process mentioned above: The naturally occurring soil enzyme urease converts urea into ammonia and carbamic acid (part of carbamic acid ultimately becomes CO_2 and is released to the atmosphere). A portion of the ammonia will be lost to the atmosphere as gas before it can be converted to ammonium and nitrate. These issues are exacerbated by urea's common surface application use as a top dressing.

Fertilizer usage emissions are also exacerbated by inefficient use (see Exhibit A2). Excess nitrogen applied is lost to the environment with no benefit. An important step to addressing fertilizer emissions is increasing nitrogen use efficiency, which has been found to be the single most effective method to reduce fertilizer emissions.[49]

Exhibit A2

Total Emissions Attributable to Minnesota Fertilizer Purchases by Value Chain Component

RMI Graphic. Source: RMI Analysis; MDA, **https://www.mda.state.mn.us/pesticide-fertilizer/fertilizer-use-sales-data**; International Fertiliser Society, **https://www.fertilizerseurope.com/publications/the-carbon-footprint-of-fertilizer-production-regional-reference-values/**; Brentrup et al., **https://www.researchgate.net/publication/329774170_Updated_carbon_footprint_values_for_mineral_fertilizer_from_different_world_regions**; US CBO, **https://www.cbo.gov/publication/58861**; US Census Bureau, **https://data.census.gov/table/CFSAREA2017.CF1700A13?q=cf1700a13&comm=22**; USGS, **https://www.usgs.gov/centers/national-minerals-information-center/commodity-statistics-and-information**

Inhibitors can be deployed with fertilizers to decrease nitrogen loss. Urease inhibitors, specific to urea use, apply a coating to urea that restricts the process of urea hydrolysis and subsequently the formation of ammonia, which prevents loss of that ammonia as gas. Regulation of urea has precedent; Germany requires the addition of a urease inhibitor when urea is used. Another form of inhibitor is a nitrification inhibitor, which delays the conversion of ammonium to nitrite. This gives crops more time to absorb ammonium while reducing nitrification, the process that releases N_2O to the atmosphere. Nitrification inhibitors can also prevent leaching since ammonium is held by soil, in contrast to nitrate (which nitrite converts to), which travels past the roots. Application can affect the output of emissions, too. Quickly incorporating urea into the soil or injecting urea, rather than simply applying it the topsoil, can limit the loss of nitrogen. However, this is not always possible due to various constraints such as no-till zones.

Ultimately, the most effective mitigation method for urea involves a transition away from urea and urea-based fertilizers to alternative nitrogen fertilizers. Urea and urea ammonium nitrate could be replaced by fertilizers that perform better on a use emissions base, such as ammonium nitrate.[50] Ammonium nitrate's nitrogen is readily available for crop uptake and does not suffer from use emissions to the same degree as urea.

The issue of fertilizer use requires more investigation because it represents more than twice the emissions of fertilizer production. Emissions mitigation is best used in tandem; Gao and Serrenho have found that combining a variety of use-based emissions mitigation approaches with green ammonia production can reduce 84% of worldwide synthetic nitrogen fertilizer emissions by 2050.49 For Minnesota, a holistic reduction of agriculture emissions requires a collection of mitigation efforts that include a deep look into use emissions. However, deployment of green ammonia is an important step to decarbonization of the industry.

Appendix 2: Model Methodology and Additional Information

We utilized an optimization model to assess the competitive position of DGA in Minnesota and evaluate its main cost factors and their dynamics. This model allows the analysis of levelized cost of green ammonia production for a given geographical location under various market scenarios.

Renewable Energy Generation Assumptions

Scenario	Unit	Value
CONSERVATIVE 2024		
Wind Lifetime	years	30
Onshore Wind Capex	$/kW	1333.32

Ammonia and Nitrogen Production Assumptions

Production Scale	10 ktpa	50 ktpa	500 ktpa
Cost of a HB Reactor	$1,726/t$NH_3$	$1143/t$NH_3$	$630/t$NH_3$
Cost of Pressure Swing Adsorption (PSA)	$48/t$N_2$	$26/t$N_2$	–
Cost of Air Separation Unit (ASU)	–	–	$140/t$N_2$

Assumptions for Blue and Grey Ammonia Production Pathways

Parameter	Value
Capex Grey Steam Methane Reformer (SMR)	$713/kg$H_2$ per day
Opex Grey SMR	$22.11/kg$H_2$ per day
Capex Blue SMR	$1735/kg$H_2$ per day
Opex Blue SMR	$48.66/kg$H_2$ per day
Capture Rate Blue SMR	85%
Value of 45Q*	$0.51/kg$H_2$
HB Capex	$500/t$NH_3$
ASU Capex	$75/t$NH_2$
NH_3 Storage	$160/t$NH_3$
ASU & HB O&M	4% of Capex
Storage O&M	3% of Capex

* Section 45Q refers to the production tax credit based on the quantity of CO_2 captured and stored during the hydrogen synthesis process.

Appendix 3: Target Development

Targets for 2030 were developed using the Minnesota fertilizer sales data for 2020 as a baseline, with the assumption that sales remain flat over the decade. This approach was chosen since sales growth was slow decade over the previous decade, with only a 4% increase from 2010 to 2020. In addition, Minnesota has signaled its desire to reduce nitrogen fertilizer usage, which was assumed to offset any potential market growth.

Assuming all nitrogen fertilizer sold is synthetic with ammonia as a precursor, ammonia demand was determined by taking the total nitrogen sold (747,576 tons) and proportionally calculated based on the nitrogen content of ammonia by weight (82%), for a total of 911,678 tons of ammonia. The emissions-reduction targets of 50% for 2030 and net-zero for 2050 were chosen, in line with Minnesota's stated goals. Green ammonia was assumed to have zero production emissions associated with it, meaning half of ammonia demand by 2030 (approximately 450,000 tons) and all ammonia demand by 2050 (approximately 900,000 tons) would need to come from green ammonia.

Local ammonia project could stabilize fertilizer supply for southern Minnesota farmers

Noah Fish

BLUE EARTH, Minn. — A southern Minnesota farm cooperative is working with energy and technology partners on a project that could create the first commercially available supply of locally produced ammonia fertilizer in Minnesota.

Central Farm Service announced a partnership with TalusAg and CleanCounts to build modular ammonia production systems in the city of Blue Earth in Faribault County, that would convert electricity, air and water into anhydrous ammonia, a key nitrogen fertilizer widely used in corn production.

The project depends on $8 million in funding from Minnesota's Renewable Development Account, which supporters hope lawmakers will approve during the current legislative session.

If completed, the system would produce more than 40 tons of ammonia per day and supply most of the annual fertilizer needs of Central Farm Service members, according to project leaders.

"Ammonia prices have swung by more than 300% in recent years," said KC Graner, president and CEO of Central Farm Service. "Local production gives our member-owners a level of control and predictability they've never had before."

Major input for corn production

Anhydrous ammonia is one of the most common nitrogen fertilizers used by corn growers across the upper Midwest. Graner said Central Farm Service, a farmer-owned cooperative serving members in southern Minnesota and northern Iowa, typically supplies between about 11,000 and 16,000 tons of ammonia annually depending on weather and the length of the fall fertilizer application window.

The proposed facility could produce roughly 12,000 tons annually, supplying between 80% and 100% of the cooperative's ammonia demand.

"That would pretty well service the majority of the acres that see anhydrous ammonia application in the fall in our geography," Graner said.

At typical application rates, the project could provide fertilizer for more than 200,000 acres of cropland, he said.

State funding request

Supporters are asking the Minnesota Legislature to approve funding through the Renewable Development Account, a program established to support innovative energy technologies.

Rob Davis of CleanCounts said the funding would help establish commercial-scale ammonia production in Minnesota.

“It’ll be the first time since we’ve been growing corn in the state of Minnesota that a co-op has been able to sign a 10-year fixed price for anhydrous ammonia,” Davis said.

The proposal is expected to be introduced later this legislative session by Rep. Paul Anderson, R-Starbuck, and Sen. Aric Putnam, D-St. Cloud, who chair agriculture committees in their respective chambers.

Reducing supply volatility

Nearly all ammonia fertilizer used in Minnesota agriculture is produced outside the state and transported long distances, often from facilities along the Gulf Coast. That reliance on distant production has exposed farmers to supply disruptions and large price swings tied to global energy markets.

Graner said fertilizer prices have occasionally climbed above $1,000 per ton in recent years, sometimes rising several hundred dollars during the fertilizer application season.

“The biggest thing would be shielding farmers from the supply crunches we’ve seen every fall,” he said. “We’ve seen massive price swings in season.”

Using excess wind power

Project leaders say the ammonia systems could use electricity generated by wind turbines during periods when energy production is curtailed because the electric grid cannot absorb additional power.

Davis said using that electricity to produce ammonia could help ensure wind generation is not wasted while supporting local industries.

“Ammonia is just one more tool in the tool belt to help make productive use of those wind turbines that are already existing on the landscape,” he said.

Part of broader industry effort

The Blue Earth project is also tied to the newly formed Minnesota Made Ammonia Coalition, which brings together organizations from agriculture, energy, manufacturing and environmental sectors to support development of a local ammonia industry.

“What's exciting about this is how many different parts of Minnesota's economy this touches, and it's not some distant future — it can happen here, now,” said Rachel Stuckey, executive director of the Minnesota Conservative Energy Forum. “We have the energy, the research, and demand, from agriculture to mining to manufacturing. This coalition is about connecting all of those pieces and turning them into a real statewide industry.”

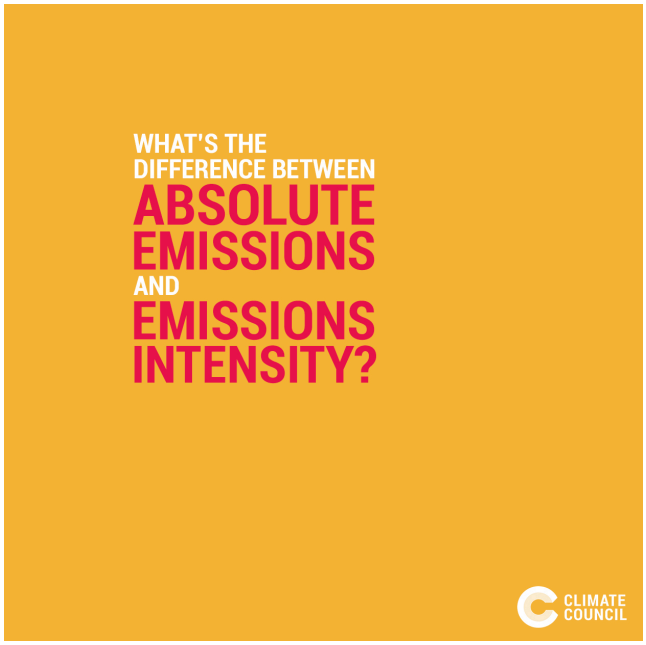
Advocates say Minnesota is well-positioned to develop the industry because of its wind resources and research conducted at the University of Minnesota’s West Central Research and Outreach Center in Morris, which has studied renewable-powered ammonia production for more than a decade.

“Local production of nitrogen fertilizer makes sense for many reasons,” said Mike Reese, Green Ammonia Research Lead and Director of Operations at University of Minnesota’s West Central Research and Outreach Center. “Primarily, farmers are able to lock in the cost of a key crop input and, the dollars that typically go elsewhere to purchase this fertilizer remain in our communities helping support rural economies.”

Graner said cooperative investments like this are intended to help farmers manage major input costs and maintain profitability.

“Our job at the cooperative is to do the types of things for growers that they don’t have the capacity to do on their own,” he said. “We’re always trying to find innovative ways to help them compete and sustain their farms.”

CLIMATE COUNCIL



News & Media / The Facts / August 4, 2015

WHAT'S THE DIFFERENCE BETWEEN ABSOLUTE EMISSIONS AND EMISSIONS INTENSITY?

By Climate Council

SHARE:

This content is **10 years old**.

Emission intensity is the volume of emissions per unit of GDP. Reducing emission intensity means that less pollution is being created per unit of GDP. BUT! And this is a big 'but' – if GDP grows then so too do total emissions. **A more concrete measure of emission reduction is an "absolute reduction"**. That's the reduction in the total emissions. To tackle climate change total emissions must go down so an absolute reduction is the most relevant measure. Developed countries, like the US and Europe, have submitted absolute emission reduction targets reflecting their intent to reduce their total emissions.

Australia's capacity to reduce emissions is very high. For example, our emission intensity is roughly twice that of the USA (twice as many tonnes of CO2-e* per $million GDP) and about 2.5 times that of Europe. So really, we have the capacity to reduce our emissions more than either the USA or Europe. However, because we start from such a high emission intensity we have a lot of "low-hanging fruit" and even relatively easy reductions in emission intensity will look large in terms of percentage.

*The 'e' in CO2-e stands for 'equivalent'. This gives other greenhouse gases such as methane, nitrous oxide, etc. a value in CO2 based on their global warming potential. That way you can total them all, rather than having a list of different gases.

Discover How U.S. Cows Are Shattering Milk Production Effficiency Records!

Friday, August 23rd, 2024

Prepare to be amazed by the U.S. dairy cows breaking and shattering milk production records. Curious about their secrets and what it means for global demand? Keep reading.

Summary: Have you ever been intrigued by the fierce competition among top-producing states in the U.S. dairy industry? This competition has led to a significant increase in milk production, with the average U.S. milk cow producing 63% more milk in 2023 than in 1990. Michigan, a key player in this competition, leads in efficiency. The U.S. dairy industry has become a global powerhouse, with increased per-cow output and butterfat levels. Over the past decade, U.S. dairy cows saw per cow output rise by 11%, from 21,722 lbs. in 2013 to 24,117 lbs. in 2023. Michigan tops the nation, producing 27,564 lbs. of milk per cow per year, an 81% increase since 1990. Advanced technology, genetic selection, and artificial insemination have led to healthier cows producing more milk, driving cash revenues to an expected $42 billion in 2022, up from $35 billion in 2013.

- Michigan leads the nation in milk production per cow, with an 81% increase since 1990.
- The average U.S. milk cow produced 63% more milk in 2023 compared to 1990.
- Butterfat levels in U.S. milk have significantly improved, contributing to increased dairy output.
- Top-producing states include Texas, New York, Wisconsin, and Idaho, with Texas leading in 2023.
- Advanced technology, genetic selection, and artificial insemination are critical drivers of increased efficiency.
- U.S. dairy cows saw an 11% rise in per-cow output over the past decade.
- The U.S. dairy industry's efficiency has made it a global powerhouse, with notable increases in cash revenues.

U.S. dairy cows, milk production, per-cow output, fat content of milk, butterfat level, milk cow, milk production efficiency, Michigan, Wyoming, Colorado, Texas, New York, Wisconsin, Idaho, milk yields, United Kingdom, Argentina, European Union, China, dairy farming innovations, advanced technology, milking machines, automated feeding systems, precision agricultural equipment, labor expenses, productivity, genetic selection, artificial insemination, healthier cows, cash revenues, dairy sector.

Over the past decade, the U.S. dairy industry has experienced a significant surge in milk production, marking a period of remarkable growth and transformation. Dairy cows have broken new milk production records, with the per-cow output increasing by an impressive 11%, from 21,722 lbs. in 2013 to 24,117 lbs. in 2023. This surge in production is not limited to the quantity of milk. Butterfat production in the United States has also seen a substantial increase of 23%, with the average butterfat content rising from 3.76% in 2013 to 4.11% in 2023. These consistent advances in efficiency have resulted in the typical U.S. milk cow producing 63% more milk in 2023 than in 1990. This unprecedented growth underscores the transformation of U.S. dairy farming, making our

cows some of the most productive in the world. But what is the key to these extraordinary accomplishments, and how have American dairy producers remained ahead of global competition? Let's delve into this record-breaking trend and explore the methods that produce these incredible outcomes.

Location	Average Milk Yield per Cow (lbs.)	% Increase Since 1990
Michigan	27,564	81%
Wyoming	26,000	100%
Colorado	24,000	51%
Texas	25,500	70%
Wisconsin	25,400	65%
Canada	23,900	Not Available
United Kingdom	19,000	Not Available
Argentina	17,000	Not Available
European Union	16,000	Not Available
China	11,000	Not Available
New Zealand	10,000	Not Available

The Golden Era of U.S. Dairy Farming: A Decade of Unparalleled Efficiency

The last decade has been nothing short of transformative, inspiring American dairy producers to reach new heights of efficiency. Have you ever wondered how much more efficient contemporary dairy farming has become? Let's look at some incredible data demonstrating the nationwide growth in milk production efficiency.

In only ten years, per-cow milk production increased by 11%, with the typical dairy cow producing 24,117 pounds of milk in 2023, up from 21,722 in 2013. Such significant increases do not end there. The fat content of milk—an important indication of quality—has also increased significantly. The average butterfat level in U.S. milk grew from 3.76% in 2013 to 4.11% in 2023, representing a 23% increase in total butterfat production.

Think about it. What exactly does this imply for the industry? This means that dairy producers may now produce more and higher-quality milk with fewer cows using innovative procedures and technologies created and perfected over time. These numbers highlight a remarkable trend of increased efficiency and production, establishing a new standard for dairy farming throughout the globe.

State-by-State Breakdown: The Top Performers in Milk Production

Let's look at the top milk producers in each state. Michigan has taken the top rank in terms of production. Michigan's dairy cows produce an astonishing 27,564 pounds of milk per cow per year, representing an 81% increase since 1990. This gigantic tower exemplifies the state's continuous pursuit of efficiency.

Wyoming is just a little behind, and it is also seeing remarkable development. Despite being a minor player, Wyoming's handful of dairy cattle have improved their game by more than tripling their milk supply since 1990, achieving second place. Colorado isn't slacking either; the state ranked third with a 51% increase in milk output over the same time.

The battle for fourth place is fierce among several central dairy states. Texas, for example, leads with yields surprisingly close to those of other heavyweights like New York, Wisconsin, and Idaho, averaging roughly 25,500 pounds per cow annually. However, the Lone Star State edged the competition to take the top spot in 2023.

Each state provides something unique, yet all are dedicated to pushing the limits of dairy efficiency. These states are boosting the dairy business in the United States to new heights by combining innovation, innovative technology, and a never-ending pursuit of progress.

How Do U.S. Dairy Farms Stack Up Against Their International Counterparts?

How do U.S. dairy farms compare to their overseas counterparts? Let's look at the data to discover why milk production in the United States is the industry gold standard.

Dairy cows in the United States are outperforming all other countries regarding milk production. In 2023, cows in the United States produced an average of 24,117 pounds of milk each year. In contrast, Canadian dairy cows generated 3% less milk while being the second most efficient globally. This implies that each cow in the United States produced around 724 pounds of extra milk yearly.

Looking farther out, the margin of advantage becomes much more enormous. The United Kingdom ranked third, behind by a considerable 24%, implying that its cows generated around 5,788 lbs. less milk per head. Argentina has significantly lower yields, behind the United States by 30%. Argentine cows generate around 7,235 kg. Less milk is produced per cow each year.

The European Union, a significant participant in the global dairy market, also lagged. With 34% lower yields than U.S. cows, this equates to an annual deficit of around 8,200 pounds per cow. Moving to Asia, China's dairy farming innovations have yet to overcome the gap; their outputs still fall short of what American cows generated in 1990. This reflects the United States' longtime leadership in efficient milk production.

Finally, consider New Zealand, which is known for its dairy exports. Despite worldwide renown, New Zealand's milk per cow fell 59% behind the United States. That's a stunning discrepancy, meaning that New Zealand cows generated roughly 14,235 pounds less milk each cow each year.

These figures show that American dairy farms are competing and improving milk production efficiency. This unprecedented productivity enables U.S. farmers to supply local and worldwide dairy demand successfully.

Ever Wondered What's Behind This Surge in Efficiency? Let's Dive into the Magic Formula Transforming U.S. Dairy Farming

Ever wonder what's behind this spike in efficiency? Look at the golden recipe revolutionizing dairy farming in the United States. Technology is playing an important role. Advanced milking machines, automated feeding systems, and precision agricultural equipment have transformed farm operations. These advancements are more than flashy gadgets; they are game changers that lower labor expenses and boost productivity.

However, technology alone does not tell the whole story. Breeding procedures have undergone a significant revision, and this is a crucial factor behind the surge in efficiency in U.S. dairy farming. Genetic selection and

artificial insemination enable producers to raise cows with better characteristics, leading to healthier cows that produce more milk. According to the USDA, selective breeding has considerably increased milk output per cow over the previous several decades. This, combined with advanced technology and cutting-edge agricultural management strategies, forms a multidimensional approach that keeps U.S. dairy farms at the forefront of global milk production, establishing new benchmarks for efficiency and productivity.

Let us remember cutting-edge agricultural management strategies. Farmers use data analytics to track cow health, milk quality, and overall farm performance. These data-driven solutions facilitate informed decision-making, improving resource use and cow wellbeing.

It is a multidimensional method that combines technology, research, and intelligent management. This comprehensive plan keeps U.S. dairy farms at the forefront of global milk production, establishing new benchmarks for efficiency and productivity. So, the next time you drink a glass of milk, know there's much thought and creativity behind that creamy pleasure.

The Ripple Effect: How Higher Milk Yields Are Transforming the Entire Dairy Industry

Higher milk yields aren't beneficial to individual dairy farms; they're practically rewriting the economic script for the dairy sector. Let us break it down. Dairy producers benefit immediately from improved milk output. Additional milk production produces additional products, including butter, cheese, and yogurt, resulting in a more diverse income stream. According to USDA research, the U.S. dairy sector's cash revenues would amount to $42 billion in 2022, up from $35 billion in 2013 [USDA research]. That's about a 20% increase in a little under a decade!

Furthermore, higher efficiency leads to decreased expenses per unit of milk produced. This is crucial because it increases farmers' competitiveness in the global market. Farmers in the United States have maintained operating expenses roughly unchanged while increasing output by optimizing feed, improving genetic selection programs, and introducing modern milking technology. This efficiency makes U.S. dairy goods appealing to overseas purchasers, increasing profitability. According to the National Milk Producers Federation, exports accounted for around 16% of total U.S. milk output in 2022, up from 9% a decade before [NMPF Statistics].

These advances impact the whole economy, not just the agriculture sector. Increased milk production benefits downstream businesses in transportation, retailing, and equipment manufacturing. Dairy farming has the potential to generate significant economic multiplier effects. In Michigan, for example, the dairy business provides more than $15 billion to the state's economy yearly, sustaining approximately 40,000 employees directly and indirectly. These figures demonstrate how increases in agricultural efficiency may benefit the whole area's economy.

The increase in milk output has far-reaching economic consequences. For dairy producers in the United States, this implies more profitability and a more decisive competitive advantage. For the larger economy, it represents strong growth and employment creation. These interconnected advantages demonstrate why efficiency in milk production is more than simply a source of pride; it is also a cornerstone of economic health.

The Bottom Line

In today's dairy sector, U.S. dairy cows' increasing efficiency and production are extraordinary. Over the past decade, milk yields and component levels have improved significantly, propelling American dairy farmers to the forefront of global dairy production. States such as Michigan, Wyoming, and Colorado have established remarkable standards, with milk production continually increasing due to agricultural discoveries and developments.

Globally, the United States outperforms other major dairy-exporting countries such as Canada, the United Kingdom, and New Zealand. This domination fulfills the increasing demand for dairy products and establishes new industry norms globally.

How can you use these insights and improvements to improve dairy operations? What actions can you take to make your dairy farm more efficient and join the ranks of these record-breaking producers?

ABSTRACT

Dairy farms in the United States have changed in many ways over the past 50 yr. Milk production efficiency has increased greatly, with ~30% fewer cows producing about twice the amount of milk today. Other improvements include increases in crop yields, fuel efficiency of farm equipment, and efficiency in producing most resources used on farms (e.g. electricity, fuel, fertilizer). These improvements have led to changes in the environmental impact of farms. Through simulation of representative dairy farms in 1971 and 2020, changes in nutrient losses and farmgate life cycle assessments of greenhouse gas (GHG) emissions, fossil energy use, and blue (ground and surface) water use were determined for 6 regions and the United States. For all environmental metrics studied, intensities expressed per unit of fat- and protein-corrected milk produced were reduced, but the total effects over all farms or milk produced increased for 5 of the 13 environmental metrics. Reductions in the impacts of dairy farms in the eastern United States were offset by large increases in western regions because of a major increase in cow numbers in the West. The national average intensity of GHG emissions decreased by 42%, which gave just a 14% increase in the total GHG emissions of all dairy farms over the 50-yr period. The intensity of fossil energy use decreased by 54%, with the total for all farms decreasing by 9%. Water use related to milk production decreased in intensity by 28%, but due to the large increase in dairy production in the dry western regions that have a greater dependence on irrigated feed crops, total blue water use increased by 42%. Major pathways of nitrogen loss included ammonia volatilization, leaching, and denitrification, where total ammonia emissions related to US dairy farms increased by 29%, while leaching losses decreased by 39%, with little change in nitrous oxide emissions. Simulated nitrogen and phosphorus runoff losses totaled for all dairy farms decreased by 27% to 51% through more efficient fertilizer use, reduced tillage, and greater use of cover crops. Emissions of methane and reactive non-methane volatile organic compounds increased by 32% and 53%, respectively, due to greater use of long-term manure storage and silage stored in bunkers and piles. Although much progress has been made in improving production efficiency, continued improvements with new strategies and technologies are needed to meet the demand for dairy products and mitigate total environmental impacts, particularly in view of projected climate variability.
Key words: dairy farm, life cycle assessment, gaseous emission, environmental impact, Integrated Farm System Model (IFSM)

INTRODUCTION

Changes have occurred in the technology, management, and resultant performance of US dairy farms over the past 50 yr. The most important change has been a major increase in milk production per cow and a subsequent improvement in feed efficiency (Capper et al., 2009; USDA NASS, 2023a). Crop yields have also increased, particularly for corn harvested as silage and grain (USDA NASS, 2023a). Tractors and other equipment have become more efficient in the use of fuel, and farm inputs such as fuel, electricity, and fertilizers have benefited through improved efficiency and reduced fossil energy use in production. A shift toward the use of fewer tillage operations and greater use of cover crops

has provided environmental benefits primarily through reduced runoff loss of sediment and nutrients (Kleinman et al., 2019). Farm size and related manure handling strategies have also seen major changes (USDA NASS, 2023b), and their resulting effects on the environment are mixed.

Previous studies have looked at historical changes in the US dairy industry to document improvements in production efficiency and their resulting effects on environmental impacts (Naranjo et al., 2020; Capper et al., 2009; Capper and Cady, 2020). These studies were based upon general representations of dairy production in different time periods. They focused on greenhouse gas (**GHG**) emissions along with fossil energy, water, and land use. These studies emphasized environmental intensities, which provide the impact per unit of milk produced. The improvement made in feed efficiency has provided substantial reductions in these intensities. Although environmental intensities have improved, the amount of milk produced has also increased, which has increased the total impacts over all milk produced (Capper et al., 2009; Capper and Cady, 2020). A more comprehensive life cycle assessment is needed to explore a broader array of environmental metrics at the farm scale. Although intensity measures are important, a more in-depth study of the totals over all farms is needed.

A procedure has been developed and used to quantify the current national environmental impacts of US dairy farms using the Integrated Farm System Model (**IFSM**; Rotz et al., 2021). This procedure includes assessments of important resources used, gaseous emissions, and nutrient losses to the environment. Related issues such as biodiversity, soil quality, and animal welfare are also important, but they were beyond the scope of this work. By applying this modeling procedure to dairy farms around 1970, changes can be determined for various measures of farm performance and environmental impact. Farm data generated can also provide inventory for a more comprehensive life cycle assessment (**LCA**) covering more categories of environmental effects. This type of linkage of the farm model and LCA software has been demonstrated in the assessment of beef production in the United States (Rotz et al., 2019; Putman et al., 2023) and mitigation strategies applied to a dairy farm in the eastern United States (Kim et al., 2019).

Our objective was to model dairy farms throughout 6 regions of the United States and the full country for 1971 and 2020 to quantify improvements made in performance and environmental impacts, including both intensities and totals over of all farms or milk produced. Environmental metrics included differences in various forms of N, P, and C loss from farms and the farmgate LCA of GHG emissions, fossil energy use, and water use from ground and surface sources.

MATERIALS AND METHODS

Dairy farms were modeled in 2020 and 1971 using the procedure developed by Rotz et al. (2021). For each period, farms in each of 6 regions of the United States (Figure 1) were represented using 20 production systems. This gave a total of 120 systems representing US dairy production (Supplemental Tables S1 and S2; see Notes). Production systems, referred to as farms, were located in counties within each region where most of the milk was produced at that time (USDA NASS, 2023a). Farms were modeled to represent the range of sizes and associated management strategies found in those locations during each period. No human or animal subjects were used, so this analysis did not require approval by an Institutional Animal Care and Use Committee or Institutional Review Board.

As described by Holly et al. (2019), production systems consisted of 5 management types, defined as confined, semi-confined, management intensive grazing, organic, and Amish. All farm types were considered in 2020, but management intensive grazing and certified organic dairy farms were not common in 1971. To accommodate the diversity within each region, the number of farms of each size and associated management were set considering the portion that each contributed to the total milk produced in the region (USDA NASS, 2023b).

Modeling Procedure

Dairy production systems were simulated using the IFSM (USDA ARS, 2023). The IFSM used process-level simulation to predict the performance and environmental effects of each production system. The model simulated crop production, feed use, animal production, and the return of manure nutrients back to the land for 20 to 25 years of weather (Rotz et al., 2022). Daily growth and development of crops were a function of soil water and N availability and weather. Simulated tillage, planting, and harvest operations determined labor, fuel, and other resources used, the timeliness of operations, crop losses, and the nutritive quality of feeds produced. Animal feed intake, milk production, and nutrient excretion were a function of the type and nutrient contents of the feeds fed.

Nutrients (N, P, K) and C were tracked within the model to predict losses to the environment and whole-farm balances (Rotz et al., 2022). Paths of N loss included NH_3 volatilization, NO_3^- losses through leaching and runoff, and N_2O, N oxide, and dinitrogen emissions through nitrification and denitrification processes and engine emissions. Carbon emissions included CH_4 from enteric and manure sources, along with biogenic CO_2. Anthropogenic CO_2 emissions were released through fossil

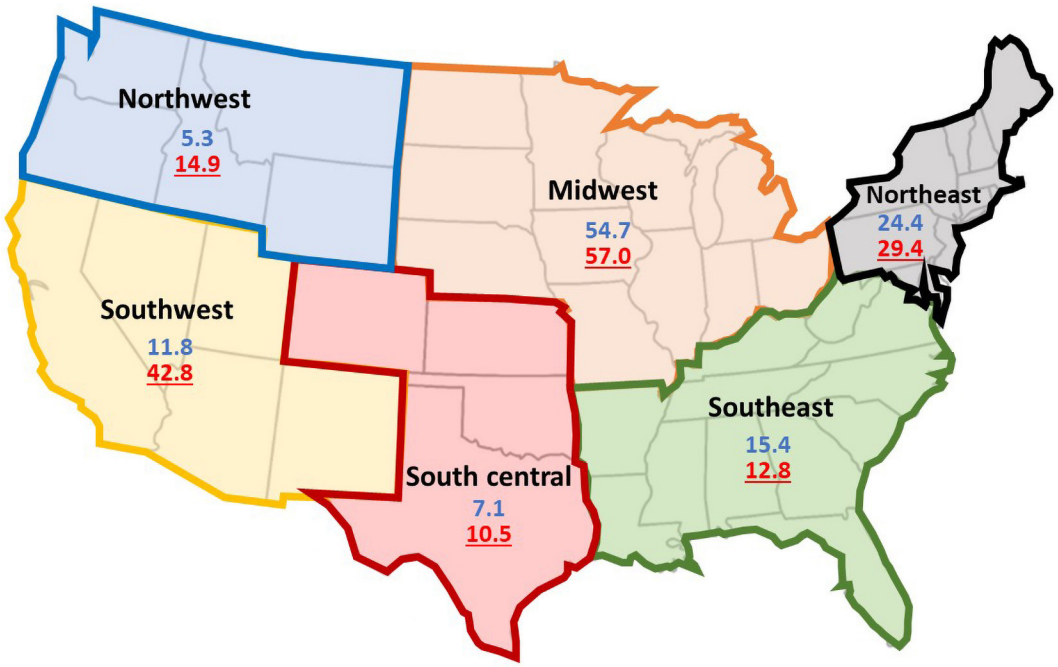

Figure 1. Regions of the United States as defined for our evaluation and comparison of the environmental impacts of dairy farms. Numbers are billion pounds of milk produced for each region in 1971 (blue) and 2020 (red; USDA NASS, 2023a).

fuel combustion and the decomposition of lime and urea fertilizer (IPCC, 2006). Other simulated losses included erosion of sediment and runoff across farm boundaries of sediment-bound and dissolved P (Rotz et al., 2022). Reactive volatile organic compound (**VOC**) emissions were predicted using a mass transfer model and estimated initial concentrations of important VOC when silage or manure were exposed to ambient air (Bonifacio et al., 2017). Emission processes were modeled using dynamic relationships influenced by temperature, wind speed, precipitation, soil conditions, and management practices (Rotz et al., 2014; Bonifacio et al., 2015; Rotz et al., 2022). Whole-farm mass balances of N, P, K, and C were the sum of nutrient imports in feed, fertilizer, deposition, and fixation, minus the exports in losses, manure leaving the farm, and feeds, milk, and animals sold.

The C balance did not include a change in long-term soil C concentration. Over this 50-yr period, some shifting occurred from the use of perennial forages to greater use of corn silage, which would indicate the potential for a loss of soil C (Gamble et al., 2021). The increased use of cover crops and no-till crop establishment may partially offset this loss (Blanco-Canqui, 2022). Considering the lack and uncertainty of available information, we chose to assume no change in soil C levels.

Following Livestock Environmental Assessment and Performance (LEAP, 2016) guidelines, a cradle-to-farmgate LCA was performed within IFSM (Rotz et al., 2022). The system boundary was that of the farm. Major components included the soil, feed crops, machinery operations for tillage, planting, harvest, feeding, and manure handling, cattle, animal facilities, and manure handling processes. Cattle included lactating and non-lactating cows, replacement heifers less than a year old, and older heifers. System inputs or resources used included fuel, electricity, fertilizer, purchased feeds and supplements, purchased animals, machinery, seed, and pesticides. Outputs or products were milk, animals sold, excess feeds sold, and various forms of C, N, and P losses. The resource inputs required and the various emissions were determined through the dynamic simulation.

The farmgate LCA determined the annual net GHG emissions, fossil energy use, and blue water use (Rotz et al., 2022). The annual GHG emission was the sum of the emissions of CH_4, N_2O, and anthropogenic CO_2 converted to CO_2 equivalents (**CO_2e**) using 100-yr global warming potentials of 28 for CH_4, 265 for N_2O, and 1 for CO_2 (Myhre et al., 2013). Emissions included direct emissions from the production system, as well as indirect N_2O emissions that occurred elsewhere in the environment resulting from transformation of NH_3 and NO_3^- lost from the production system (IPCC, 2006). Fossil energy use included fuel used in farm operations (machinery and truck use) along with that used to produce resources consumed on the operation. Blue water was defined as freshwater from ground and surface water sources, which was primarily water used for irrigated crop production,

along with that used for parlor cleaning, drinking, and cooling of cattle.

Environmental metrics associated with the production of resources used on dairy operations (upstream sources) were included in the LCA (Rotz et al., 2022). Upstream sources were those associated with production of the farm inputs (e.g. fuel, electricity, fertilizer). Annual quantities of each used were obtained through the farm simulations. Emission or consumption factors used for these upstream sources were set to reflect those of each period (Table 1).

Allocation was used to remove environmental effects associated with farm coproducts. A method recommended by the International Dairy Federation (IDF, 2015) was used to determine the portion of the farm impacts appropriated between milk and animals leaving farms for use in beef production. This was a physical allocation method reflecting feed energy used to produce the total annual body weight of culled calves, heifers, and cows exported relative to the weight of milk sold. Replacement heifers were produced on farms as part of the production system. The number produced was set to meet the replacement rate of the herd allowing for mortality and a few culled heifers. Calves not retained for replacements were sold soon after birth. When excess feeds produced on the farm were sold, all metrics associated with their production were removed from the dairy system.

Emissions and resource requirements for handling manure on the farm, including composting and anaerobic digestion on some operations, were included in our assessment of dairy production. Manure exported from

Table 1. Environmental intensities for the production of purchased resources and feeds, including transport and upstream sources, used in IFSM to assess cradle-to-farm gate environmental impacts of dairy production systems[1]

[6]Water use is a weighted average of irrigated and non-irrigated crops in the United States (USDA NASS, 2023a). For irrigated crops in the western regions of the country, values are 300 and 700 L/kg DM for corn silage and alfalfa hay, respectively.

[7]Derived from simulations of crop farms using the IFSM (USDA ARS, 2023) and processing resource use with an economic allocation among the coproducts of the grains produced.

[8]Unpublished data (Greg Thoma, University of Arkansas, Fayetteville, AR).

farms was treated as a residual, i.e., no environmental effects associated with manure handling and storage were allocated to manure leaving the farm. When manure was applied to crops on the farm that were not used as dairy feed, that manure was also considered as exported because it was no longer part of the dairy system. Emissions from manure after removal from the farm were not included in the dairy system (LEAP, 2016).

Individual emissions of methane (CH_4), nitrous oxide (N_2O), and anthropogenic carbon dioxide (CO_2) were also studied. Nitrogen losses from farms included ammonia (NH_3) emissions to the atmosphere and nitrate (NO_3^-) losses through leaching to groundwater and runoff in surface water. Phosphorus runoff losses across farm boundaries in both soluble and sediment-bound forms were also compared. Emissions of reactive non-methane VOC were considered from silage and manure sources on the farms. The VOC included several compounds, but alcohols were the predominant forms (Bonifacio et al., 2017; Rotz et al., 2022).

Both the intensity expressed per unit of milk produced and the total of all farms or milk produced were compared between the 2 periods in time. Milk produced was converted to fat- and protein-corrected milk (**FPCM**) based upon 4.0% fat and 3.3% protein (IDF, 2015; Rotz et al., 2022). This correction accounted for differences in the solids content of milk among production systems.

Dairy Production Systems in 2020

For 2020, dairy production systems were modeled as documented by Rotz et al. (2021) (Supplemental Table S2). Minor adjustments were made to update this analysis from 2019 to 2020. The major change was to update the milk production data to that reported for 2020 (USDA NASS, 2023a). This increased the national production by 2.6%, with most of the increase coming in the western regions. Milk fat content also increased to 3.92% (USDA NASS, 2023a), which further increased the calculated value of FPCM (Rotz et al., 2021). This increase in milk production had minor effects throughout the system, as predicted by the model, including changes in feed consumption, manure production, and nutrient cycling.

Another important change was an update of the environmental intensities assumed for producing purchased resources and feeds used on farms (Table 1). This change was made to be more consistent with other recent life cycle assessments done with IFSM in conjunction with LCA software (Putman et al., 2023). We also wanted to be consistent in representing the changes that occurred in these upstream intensities from 1971 to 2020. The current upstream intensities did not change much, with some increasing and some decreasing. The greatest change was a decrease in GHG emissions in electricity production, which was partly due to recent improvements in production efficiency and greater use of renewable energy sources. Environmental intensities of purchased feeds were updated by simulating the production of feed crops with IFSM to determine their individual environmental intensities. Transportation effects were added, considering the weight transported and general transportation distances. Following processing, total production and transport intensities were allocated among feed components (e.g. hulls, meal, oil) based upon their relative economic values (Rotz et al., 2021).

Dairy Production Systems in 1971

Representative dairy production systems (farms) in 1971 were modeled using the same general procedure. However, with less data available for the earlier period, some differences were present in information sources. For the more important parameters, such as milk production, milk fat content, animal numbers, farm size, dairy locations, crops grown, and crop yields, data from the USDA National Agricultural Statistics Service (USDA NASS, 2023a,b) were used to guide the parameterization of farms (Table 2; Supplemental Table S1). Other survey information was also consulted (USDA APHIS, 2003; USDA ERS, 2007). For other parameters that were not as critical in our analysis, we relied on expert opinion obtained through interviews with producers and those working with dairy producers at that time.

As was done for the 2020 assessment, milk production per cow on individual farms was set so that the weighted average production per cow equaled that reported for each region in 1971 (USDA NASS, 2023a). Values for individual farms were set considering cattle breed and grazing use, with a trend toward greater production on larger farms (Supplemental Table S1). Milk production was converted to FPCM using reported values for fat content (USDA NASS, 2023a). Reported values were only available since 1981, but values before 2000 were relatively constant with an increase since 2010. Thus, the 1981 average fat content of 3.65% was used for 1971. The weighting among farms was based on farm size (number of cows). The distribution of farm sizes within each state was obtained from the Agricultural Census (USDA NASS, 2023b) for that period. The weight factor for each farm was the percentage of farms of that size in the region, which represented the portion of milk produced on farms of that size.

Farm locations were determined using county-level dairy cow records for that period (USDA NASS, 2023a). Counties containing a major portion of the cows were selected within each of the major dairy states of the region with different locations for each farm. Farms were

Table 2. Characteristics of representative dairy farms simulated across the United States for 1971 and 2020[1]

Characteristic	Unit	1971			2020		
		Minimum	Maximum	Mean	Minimum	Maximum	Mean

[1]Characteristics of individual farms can be found in Supplemental Tables S1 and S2 (see Notes).

[2]USDA NASS (2023a).

[3]Total land grazed primarily as pasture. Most pasture is used for heifers and dry cows, particularly in 1971. Some intensively managed grazing of lactating cows in 2020. Pasture is part of grassland.

[4]Includes manure applied to crops not producing feed.

simulated using 25 yr of historical daily weather for the selected location. Most weather data were obtained from the Integrated Surface Database of the National Climatic Data Center (NOAA, 2019). When measured weather data were not available, data were obtained from the University of Idaho (Moscow, ID) gridMET meteorological data system (Abatzoglou, 2013; Hardegree, 2023). Daily data included solar radiation; minimum, maximum, and mean temperature; precipitation; and wind speed. Available data did not always go back to 1971, but the oldest data available were used.

As was done for the 2020 simulated farms, soils were selected to represent those most common at the location. Predominant soils in the county were identified using the Web Soil Survey (NRCS, 2019) by defining an area of interest over agricultural land in the county. Characteristics of a predominant soil were used, which included clay, silt, and sand content, bulk density, available water-holding capacity, and pH. A different soil was used for each farm to get a broad representation of the region.

Feed crop production on each farm was guided by the predominant crops found in the selected county at that time (USDA NASS, 2023a). Crop options included corn silage, corn grain, alfalfa hay or silage, grass hay or silage, winter wheat or barley, spring oat grain, or spring oat silage planted with alfalfa. Wheat or barley grain were sold as cash crops, with straw harvested for bedding. Using soil and weather data for the farm location, model parameters for each simulated crop were adjusted to obtain an average yield within the range reported by USDA NASS (2023a) for that period at the location. Corn plant population was also reduced in 1971 (USDA NASS, 2023a; Table 3), which contributed to changes in grain and silage yields.

Table 3. Technical and management changes for dairy farms from 1971 to 2020

Characteristic	Unit	1971	2020
Diesel fuel use[1]	% of tractors and trucks	50	90
Diesel fuel efficiency[2]	% improvement	—	17
Corn plant population[3]	Plants/ha	60,000	84,000
Cover/double crop use	% of farms	8	30
Anaerobic digesters[4]	% of milk produced	0	7
Dry cow portion of herd	% of cows	15	15
Cow mortality	%/yr	4	5
Calf mortality	% of births	10	10
Heifer mortality	%/yr	2	2
Twin rate	%	4	4
Artificial insemination use[5]	% of farms	80	95

[1]Portion of engines using diesel fuel vs. gasoline.

[3]From USDA NASS (2023a).

[4]Portion of total milk produced on farms using anaerobic digesters (US EPA, 2020).

[5]Bulls were included on farms where artificial insemination was not used.

To complete parameterization of the representative farms, additional information was needed on management procedures. This included tillage, cropping, grazing, feeding, housing, and manure management practices. These less critical parameters were set based upon the expert opinion of producers and those working with dairy producers at that time. This included most of the following management practices where quantifiable information did not exist.

Full tillage systems using multiple tillage tools were normally used in 1971. In the eastern regions, this often included a moldboard plow followed by disk and harrow operations. Complete inversion and disaggregation of the soil led to greater sediment and nutrient runoff. In western regions, multiple tillage operations were used, but chisel or disk plows were often the primary tillage operation.

Compared with current farms, inorganic fertilizers were used more heavily in 1971 with less consideration of nutrients available from manure. Application rates varied across regions as influenced by soil conditions and crops grown (Supplemental Table S1). Nitrogen fertilizer rates varied from 50 to 200 kg N/ha for corn and 0 to 300 kg N/ha for grass depending upon crop needs and expert opinion on common application rates (Table 2). Annual phosphate fertilization rates varied from 10 to 50 kg P_2O_5/ha, with average values of 31 kg P_2O_5/ha for alfalfa and corn and 17 kg P_2O_5/ha on grassland (Table 2). Lime (calcium carbonate) was applied on farms where a low soil pH was reported, with average annual rates varying from 0 to 2.0 t/ha, with a mean of 1.0 t/ha for alfalfa and 0.5 t/ha for all other crops (Table 2).

Planting and harvest dates of crops and the relative maturity index of corn were set to best represent agronomic practices at the farm location and to provide appropriate yields and suitable harvest moisture contents for corn silage. Corn was harvested as silage on all dairies that grew corn. When corn production exceeded silage needs, the remaining corn was harvested and fed as high-moisture or dry grain. Grain harvest primarily occurred on northeastern and midwestern farms. Alfalfa and grass were harvested as silage or dry hay for preservation. Tower silos were used on most farms in the midwestern and eastern regions, with bunkers and piles primarily used in the western regions. Dry hay was normally harvested in small rectangular bales and stored inside a barn or shed to reduce losses and preserve nutrients. On farms where excess feed or a cash-crop was produced and sold, the resource use and emissions associated with the feed sold were excluded from the LCA.

Pasture was used for lactating cows on grazing, Amish, and semi-confinement farms (Supplemental Table S1). On smaller confinement farms in the eastern regions, grazing was also used for heifers. Grazing occurred for 5 to 12 mo of the year depending upon the location. Pasture was not a large portion of land on most farms, averaging about 13% of total dairy farmland in 1971 (Table 2). The pastureland available was set to reflect the continuous grazing and often overstocking practices at that time. For lactating cows, a portion of their forage need was met through grazing during summer months, but the major portion of their diet most often came through conserved feeds. When grazing was used for heifers and nonlactating cows, pasture met most of their feed needs during summer months.

Most dairies produced enough forage to meet herd requirements. Corn grain was commonly grown for feed in eastern regions, but additional grain and other concentrates were often required to meet energy requirements of the herd. Purchased supplemental feeds were also used to

meet or exceed protein and mineral requirements of all animal groups (Rotz et al., 2022). Byproduct feeds, including distiller's grain, were used to supplement energy and protein needs (Table 1). Diet protein and P contents were assigned to each farm to average 6% greater protein and 23% greater P compared with 2020 (Table 2). Values were assigned to individual farms considering the forage used (greater values when alfalfa or grazing were used) with a trend toward more efficient use on larger farms.

Cattle genetics were primarily Holstein, with 12% of farms using Jersey or cross-bred cattle (Supplemental Table S1). Lactating cow replacement rates varied from a low of 20% for some grazing farms to a high of 30% in high-producing confined herds. This rate averaged 24% less than that used in 2020 (Table 2). A random calving cycle was used on all dairies except for a few grazing farms where spring calving was used to better align pasture availability with animal needs.

Animal housing and manure handling systems varied among farms and over time (Supplemental Tables S1 and S2). In 1971, smaller farms (<100 cows) in the East normally used tiestall barns with daily manure hauling and short-term manure storage. Heifers were often housed in bedded pack barns where accumulated manure was removed and applied to fields in the spring and fall. Thus, manure from these farms was handled in semisolid and solid forms. On larger farms (≥100 cows) in the East and sometimes in the West, cattle were housed in freestall barns where manure was removed daily, stored in a slurry or liquid form for 4 to 12 mo in a tank or earthen basin, and then applied to cropland. In the western regions, cows on larger farms were often housed in open lots where solid manure was collected and stored before spreading on cropland. Manure was normally broadcast on cropland where it remained on the surface for an extended time, but it was incorporated by tillage soon after spreading on a few farms (Supplemental Table S1).

Fuel efficiency improved over time through increased use of diesel engines on tractors and other farm equipment, improvements in engine design, and the use of larger and more efficient machinery. Fuels used varied, with more gasoline use in 1971, primarily for older tractors and trucks commonly found on farms at that time. Along with this, diesel fuel efficiency was 17% less in 1971 (Table 3).

Regional and National Analyses

Milk production was a critical factor in the comparison of dairy farms of 1971 and 2020. A check was made to ensure that the average milk production per cow simulated for each region agreed with that reported by USDA NASS (2023a) for 1971 or 2020. Average per cow production of each region was determined as the total of the reported milk production of all states of the region divided by the total number of dairy cows reported in those states. This value was compared with the weighted average milk production per cow of the simulated dairies in the region to ensure that they were equal. Average production per cow for the United States was also determined as the total milk produced in the country divided by the reported total number of dairy cows. The weighted average of the 6 regions equaled this value.

All effects were compared using weighted average intensities and regional and national totals. Weighted intensities were determined for each region, where the weight factor was the portion of the regional milk coming from the state where the farm was located multiplied by the portion of farms in the state of similar size. In 2020, anaerobic digesters were used, which required a special weighting factor. For regions where digesters were found, one of the farms was simulated using a digester, where the weight factor was the portion of cows in the region on farms using digesters (Rotz et al., 2021).

Life cycle feed consumption was determined for each period as the feed consumed by heifers and cows on each farm, as simulated by IFSM (Rotz et al., 2022). This included forages, grain, and other concentrates. The total feed consumed on dairy farms was allocated between dairy and beef production using the allocation method described previously (IDF, 2015). Although variation existed among farms, on average, 73% of the feed consumed in 1971 was allocated to dairy production, with 86% allocated in 2020. This difference was due to the much greater amount of milk produced per animal sold in 2020. The intensity of feed consumption was calculated as the feed allocated to dairy divided by the FPCM produced.

Life cycle environmental metrics (GHG emissions, fossil energy use, and blue water use) and other emissions and losses were summarized for each region and the nation. The intensity of each metric or loss on each farm was determined by dividing the total emission or use by the amount of FPCM produced. Individual emissions of C, N, and P were also compared on both an intensity and total basis. These included the emission from the dairy farm along with that from farms producing feed purchased by the dairy. Those associated with purchased feed were determined by simulating crop farms to obtain typical losses per unit of feed produced (Rotz et al., 2021). This was primarily grain crops and byproduct feeds derived from grain crops, particularly in 1971, when most of the forage was produced on the dairy farm.

National totals for the various environmental metrics were determined as the weighted total of all regions. This was the amount of FPCM produced multiplied by the weighted average intensity of the region summed across the 6 regions. A national average intensity was then de-

termined as the national total divided by the total FPCM produced in the United States. Changes over the 50 yr were determined by comparing the regional and national totals and intensities of the 2 periods.

Sensitivity Analysis

An analysis was conducted to examine the sensitivity of the resulting environmental intensity to changes in some of the farm parameters or assumptions. Because some farm characteristics were based upon the expert opinion of those working with the dairy industry in the early 1970s, the sensitivity analysis determined how much of an effect the characteristics used had on the results. A low sensitivity indicated that changes in those assumptions would have little effect on the results; thus, error in the expert assumption would not affect the results.

For this analysis, simulating all farms with each change was infeasible and unnecessary. A farm was chosen from each region that best represented that region. The sensitivity analysis was done by making changes to each of these 6 farms and determining the impact on each of the environmental metrics studied. The regional values were totaled and weighted by the amount of milk produced in each region to determine a national result.

A sensitivity index was calculated as the ratio of the percent change in the assessed output over a change in the tested parameter or assumption. A sensitivity index near 0 indicated low sensitivity, and indexes close to or greater than 1 indicated high sensitivity. As sensitivity increases, higher quality data are needed for an accurate evaluation. The tested change was 10% of the difference between the values used for 1971 and 2020. For example, the difference in annual milk yield over this period was 5,495 kg/cow (Table 2). Therefore, each farm was simulated in 1971 with annual milk production increased by 550 kg/cow to reduce the difference by 10%. After making this change, the percent change in the difference determined for each environmental metric was divided by 10 to obtain the sensitivity index.

Parameters or assumptions tested included milk yield per cow, farm size, cow replacement rate, diet CP content, diet P content, portion of manure exported, N fertilizer use, P fertilizer use, manure handling, irrigation water use, and water runoff across farm boundaries. To test the effect of farm size, the crop areas and animal numbers were increased by 10% on the farms in 1971, along with a few minor changes (such as silo size) to ensure feed production and use remained the same. To test the effect of manure handling, the dairy farm in the Southwest was changed from an open lot dairy with stacked manure storage to a freestall operation with liquid manure collection and storage. This was used to generally represent a 10% change in manure handling over all farms. Sensitivity to irrigation water use was determined by reducing the simulated efficiency of irrigation water use in 1971 by 10%, which decreased the difference in the amount of irrigation water used to produce on-farm and purchased feeds between 1971 and 2020. The difference in other tested parameters were determined from Table 2.

RESULTS AND DISCUSSION

Changes in management and performance of dairy farms over the past 50 yr have provided substantial improvements in production. Feed efficiency has improved as more energy intake is used to produce milk compared with that required for maintenance of the animal (VandeHaar and St-Pierre, 2006). The maintenance energy requirement has increased due to an increase in cow size, but that used to produce milk has increased at a greater rate. This dilution of maintenance effect has increased production efficiency, which has reduced the intensity of environmental impacts (Capper et al., 2009).

Milk production per cow increased 2.4-fold over these years (USDA NASS, 2023a; Table 4), which has decreased intensities expressed per unit of FPCM for nearly all metrics studied. Changes in the total impacts over all milk produced varied greatly among regions of the United States due to a large increase in cow numbers in the western (south central, northwest, and southwest) regions, with declining numbers in the eastern regions (USDA NASS, 2023a; Table 4).

Changes in animal management and feeding have affected the amount and type of feeds consumed over the life cycle of milk production (Table 5). Our simulations indicate that nationally, 14% more feed was used in 2020 than 1971. Although the number of cows has decreased and feed efficiency has improved, more feed energy and other nutrients were required to produce the additional milk. Considering the large increase in milk produced, this increase in feed consumed to produce that milk was relatively small due to the maintenance requirement dilution.

Changes also occurred in the feeds being fed. Purchased concentrate feeds composed of many different byproduct feeds, as well as grain, increased by 82% (Table 4). Forage consumption did not change much over this time, but less forage was consumed by grazing in 2020. In the eastern regions, life cycle feed consumption decreased by 25%, with a slightly higher reduction in forage consumption than concentrate use. Due to the large growth in animal numbers in the western regions, feed consumption increased by 187% in the West, with a greater increase in concentrate feed use than forage.

Table 4. Changes in cow numbers and milk production from 1971 to 2020 (USDA NASS, 2023a)

Item	Unit	1971	2020	% Increase

[1]Fat- and protein-corrected milk (FPCM) is milk corrected to 4% fat and 3.3% protein.

GHG Emissions

Across regions, changes in GHG emission intensities were relatively consistent with decreases of 37% to 44% (Table 6). The weighted national average intensity of 1.0 kg CO_2e/kg FPCM in 2020 was 42% less than the 1.7 kg CO_2e/kg FPCM found in 1971 (Table 6). Intensities calculated for individual farms in 1971 varied from 1.3 to 2.3 kg CO_2e/kg FPCM, with similar ranges in all regions. No farm type, size, or management approach was found to consistently provide the lowest or highest values within this range. Many factors affect the environmental intensity of milk production including climate, soil properties, and management interactions. These factors contribute to the variation among farms along, with trends related to farm size and management (Rotz et al., 2020).

Our change in GHG emission intensity of dairy farms compares well with similar studies. In an assessment of California dairy farms, a 45% reduction was found over a similar time interval (Naranjo et al., 2020). Over 64 yr from 1944 to 2007, Capper et al. (2009) reported a 63% reduction. An assessment of raw milk production in the Netherlands has shown a 35% reduction over the past 30 yr (Hospers et al., 2022). These studies all indicate that

[2]Total farmgate emission or use allocated to milk production in 1971 and 2020, respectively.

[3]CO_2e = CO_2 equivalents.

GHG emission intensity of dairy production has been improving at a rate near 1% per year in the United States and other developed countries.

The change in total GHG emissions associated with all dairy farms varied greatly across regions, from a decrease of 64% in the Southeast to 3-fold increases in the northwest and southwest regions (Table 6). This was due to the decreasing cow numbers in the eastern regions with large increases in the western regions (Table 4). The total emissions related to US dairy farms increased by 14% from about 88 Tg CO_2e in 1971 to 100 Tg CO_2e in 2020. This indicates that US dairy farms are now producing about twice the FPCM with just 14% more GHG emissions compared with those in 1971.

Fossil Energy Use

The farmgate life cycle fossil energy use includes that used on the farm as well as that used to produce electricity, fertilizer, purchased feeds, equipment, and other resources used on dairy farms. As previously reported (Rotz et al., 2021), most of the energy was used off-farm to produce these resources.

The intensity of fossil energy use related to dairy farm production varied from 4.8 to 6.0 MJ/kg FPCM across regions in 1971, with the lowest values in the Southwest and the highest in the Northeast and Midwest. This regional variation was influenced by farm size and climate. The smaller farms in these cooler regions were less energy efficient in producing feed, handling manure, and housing animals. The national average was 5.8 MJ/kg FPCM, which was more than double that found for 2020. As with GHG emissions, much of this reduction in intensity over the 50 yr was due to improvements in milk production efficiency. In addition, improvements in fuel efficiency of machinery operations (including greater use of diesel engines) and the efficiency in producing fuel, electricity, fertilizer, and other farm inputs have reduced the energy input into dairy farms (Table 1). Use of anaerobic digesters to generate electricity for on-farm use also contributed to lower fossil energy use in 2020 (Rotz et al., 2021).

Little has been done previously to compare life cycle energy use in dairy production over time. For a similar 50-yr period, Naranjo et al. (2020) reported a reduction in the intensity of electricity and fuel use on California farms of about 58%. This compares well to the 54% reduction we found for the United States but is greater than the 41% we found for the southwest region (Table 6).

The total upstream and on-farm use of fossil energy on dairy farms was found to decrease 9% from 294 PJ to 268 PJ (Table 6). This implies that the larger and more efficiently operated dairy farms today are using similar and perhaps a little less fossil energy than that used to produce milk in 1971. This is partly due to greater efficiency in on-farm use, but also the improved efficiency in producing electricity, increased use of renewable energy, and more efficient off-farm production of resource inputs. As found with GHG, this change varied greatly across regions, from a 70% decrease in the Southeast to a 3-fold increase in the Southwest. This was heavily influenced by a relatively small increase in the milk produced in the eastern regions with a nearly 5-fold increase in the western regions (Table 4; USDA NASS, 2023a).

Blue Water Use

Water obtained from surface and groundwater sources varied greatly across regions, with a large majority of this water used to irrigate feed crops (Rotz et al., 2021). In eastern regions where irrigation was rarely used on dairy farms in the 1970s, the intensity of water use was about 35 kg/kg FPCM (Table 6). This included drinking water and milking equipment cleaning with some production of purchased feeds that were irrigated. This intensity of water use did not change much over the 50-yr period in the eastern regions, but the use of irrigated feed crops in the Southeast did increase somewhat. In the western regions, where feed was heavily dependent upon irrigated crops, the intensity of water use in 1971 varied from 176 kg/kg FPCM in the south central region to 576 kg/kg FPCM in the Southwest. The national intensity decreased by about 50% over the 50-yr period due to conversion from furrow irrigation to more efficient center pivot irrigation systems, along with the improvement in cattle feed efficiency.

A couple of other studies have quantified changes in dairy farm water use intensity in the United States. In California, Naranjo et al. (2020) found about an 89% reduction in the intensity of water use over the past 50 yrs. For our southwest region, which is primarily California dairy farms, we found a little lower reduction of 60% (Table 6). Capper et al. (2009) reported a reduction of 55% over their 64-yr period, which is similar to our result, but a little less on a per-year basis.

Total water use by US dairy farms was found to increase 42% over the 50-yr period (Table 6). This increase was due to the shift in milk production from the humid eastern climate to the dry climate of the western regions (Table 4). Although the intensity of water use improved, total water use increased dramatically, with much more milk produced in the West using irrigated production of feed crops.

Water requirements are a concern for the sustainability of dairy farms in western regions. Water shortages have increased in recent years, creating limits on availability for crop irrigation (US EPA, 2023). Increasing ambient temperatures and reductions in precipitation have exac-

erbated issues of water availability (Melillo et al., 2014). Warmer temperatures and sometimes reduced snowfall are reducing snowpack in the mountains, which is a major source of irrigation water for some areas (US EPA, 2023). Climate projections for these regions also predict further increases in temperature and longer periods of drought, worsening the problem of water availability (Melillo et al., 2014). The demand for water and projections for reduced water availability suggest a need for strategies to further improve water use efficiency and otherwise reduce the use of water in dairy production (Mpanga and Idowu, 2021).

Nitrogen Losses

Important forms of N loss across farm boundaries include NH_3 volatilization, NO_3^- leaching to groundwater, N runoff in surface water, and denitrification loss as N_2O. The intensity of NH_3 emissions decreased by 35% over the 50-yr period, with a somewhat greater decrease in the western regions than the eastern regions (Table 7). This decrease in intensity was again due to the large increase in milk production per cow which reduced the loss per unit of milk produced. Total NH_3 emissions from all dairy farms increased by 29%, primarily due to the increased use of long-term manure storage and more cows on open lots in the western regions. Ammonia emissions are relatively high from these sources (Rotz et al., 2014).

Percentage changes in N leaching and N runoff were similar. Nitrogen leaching loss was modeled as N that moves through the soil profile to below the root zone (Rotz et al., 2022). Runoff was modeled as N moving across the farm boundaries. These values were not necessarily the N lost to the environment, but the change in loss across the 50-yr span should reflect the change in loss to the environment. National intensities showed

decreases of 69% and 63% for leaching and runoff, respectively (Table 7). Considering the large increase in milk production, predicted total losses on a national scale decreased by 39% and 27%, respectively. The implementation of nutrient management plans has made better use of manure N with reduced use of inorganic fertilizer, contributing to these reductions. Increased N loss in the form of NH_3 also meant less manure N was incorporated into the soil, where leaching and runoff losses occur. Greater use of cover crops and reduced tillage practices also contributed to reduced losses (Castaño-Sánchez et al., 2022).

The emission of nitrous oxide is a concern due to its warming potential as a GHG. As with the other N emissions, the intensity decreased considerably over the 50 yr (Table 7). The total emissions from all farms showed little change, so the reduction in intensity offset the large increase in milk production. Similar to leaching and runoff losses, this offset can be attributed to greater NH_3 emissions (less manure N incorporated into soil), more efficient use of inorganic N fertilizer, and the use of cover crops to carry more of the soil N through the winter months (Castaño-Sánchez et al., 2022).

Among the various forms of N loss from dairy farms, NH_3 emissions may be the greatest threat to future sustainability. Ammonia is recognized as an important air pollutant that has harmful effects on human health and sensitive ecosystems (NRC, 2003). Through the Clean Air Act, ammonia emissions can be regulated, but regulation of farm sources has been challenging due to difficulty in measurement and control. Dairy farms are a major source, contributing as much as 24% of the national inventory of NH_3 emissions (Rotz et al., 2021). Projected future increases in ambient temperatures across the country will tend to further increase NH_3 emissions (Hristov et al., 2018). Strategies for mitigating NH_3 emissions are available, but finding economical solutions is challenging (Veltman et al., 2021).

Phosphorus Runoff

Simulated P runoff losses also decreased substantially over the 50-yr span. Total soluble and sediment-bound P runoff losses decreased by 28% and 51%, respectively (Table 7). Several factors contributed to this substantial decrease. Greater use of cover crops and fewer tillage operations reduced nutrient and sediment runoff (Veltman et al., 2021). More rapid incorporation of manure into the soil, including some use of subsurface injection, has also reduced the potential for runoff. These management changes have provided greater reductions in sediment-bound P, with less reduction in soluble P runoff. With less tillage being used, more manure nutrients remain on the surface, contributing to more runoff of soluble P compared with sediment-bound P. The shift of dairy production from the eastern regions to the dry western climate also contributed to less runoff in the production of milk.

Reduced feeding of supplemental P in cattle diets and reduced use of inorganic P fertilizer have led to substantial reductions in the overall farm balance (P in minus P out). This has provided a reduction in the accumulation rate of surplus P in farm soils (Table 7). Reduced feeding of P in recent years (Table 2) also reduced the P excreted in manure and thus the potential for soluble runoff. Most of the benefit from reduced accumulation of soil P comes through the long-term future reduction in potential runoff losses.

Another influence on P runoff losses is the way they are being predicted by the model. Simulated losses are those moving across the farm boundaries. With much larger farms in 2020, there was less boundary per unit of cropland, and this reduced predicted runoff losses. Although this latter influence is a real consideration, this modeled effect may tend to overestimate the environmental benefit. Nutrients crossing the farm boundaries do not directly represent those leaving the watershed or entering sensitive water bodies such as the Chesapeake Bay or Gulf of Mexico. However, the relative change over time should reflect the change in that leaving the watershed.

Although major improvements have been made in reducing P runoff, eutrophication from P in surface waters continues to be a challenge, particularly in the eastern regions (Kleinman et al., 2019). Predicted increases in precipitation in eastern regions through more intense storms will exacerbate P runoff losses (Hristov et al., 2018; Veltman et al., 2021). Practices and technologies such as greater use of perennial crops and cover crops, reduced tillage, and subsurface manure injection help mitigate this pollutant source from dairy farms (Sharpley et al., 2006).

Volatile Organic Compounds

The emission of CH_4 decreased in intensity by ~33% across all regions and nationally, but total national emissions increased by 32% (Table 7). Dairy farms in the eastern regions produced 13% less total CH_4 in 2020 due primarily to fewer cows with greater milk yield and improved feed efficiency, with some offset through greater use of long-term slurry and liquid forms of manure storage. In western regions, total CH_4 emissions increased by 220% due to the large increase in cow numbers and greater use of long-term manure storage, particularly that stored in lagoons.

Emissions of non-CH_4 VOC have also benefited through improvements in milk production efficiency. Nationally, the intensity of this pollutant decreased by 22%,

Table 8. Sensitivity[1] of the difference in environmental metrics between 1971 and 2020 to a change in various farm parameters

Item	GHG emission	Energy use	Water use	Ammonia emission	VOC emission	Soluble P loss	Sediment P loss	Soil P buildup	Runoff N loss

[1]Sensitivity index defined as the ratio of the percent change in the difference in an environmental output parameter caused by a 10% change in the difference of the input parameter between 1971 and 2020. An index of 1 means that a 10% change in the input difference causes a 10% change in the environmental output difference. An index greater than 1 is very sensitive, between 0.6 and 1 is sensitive, 0.3 to 0.6 is moderately sensitive, and below 0.3 is not sensitive.

[2]Animal numbers and crop areas were each increased 10% along with other minor changes to ensure the correct portions of feed were produced and fed.

[3]Open lot housing with stack storage was replaced with a freestall barn and liquid storage on the Southwest dairy farm to generally represent a 10% change in manure handling practice.

with most of this improvement coming in the western regions. This improvement has been offset by greater use of long-term manure storage and large bunker or pile silos. These relatively large open surfaces and the biological processes in the material generate greater emissions (Bonifacio et al., 2017). With all factors considered, our analysis shows a 53% increase in reactive non-CH_4 VOC emissions from all US dairy farms, with most of this increase coming from farms in the western regions (Table 7). This increase is due to the large increase in cow numbers and the associated increases in feed and manure storage.

Like other gaseous emissions, VOC emissions (primarily alcohols from dairy farms) are sensitive to temperature (Bonifacio et al., 2017). With projected increases in ambient temperature, increases in CH_4 and other VOC from manure and silage are anticipated (Bonifacio et al., 2017; Hristov et al., 2018). Strategies such as covered manure storage, subsurface injection of manure, and reduced exposure of silage surfaces can help mitigate these emission sources (Bonifacio et al., 2017).

Sensitivity to Model Inputs

The sensitivity analysis was done to evaluate the robustness of the results as influenced by assumptions made, particularly those determined through expert opinion. Predicted differences in most environmental metrics between 1971 and 2020 were sensitive to the increased difference in milk yield per cow used across the 50 yr (Table 8). Water use and NH_3 and VOC emissions were highly sensitive, where a 10% decrease in the assumed increase in milk yield gave a similar decrease in their differences. This shows that the difference in milk yield had little effect on the simulated difference in farm-level effects of these emissions. Because the farm impact did not change much, the 10% reduction in milk per cow created about a 10% reduction in their total impact. Greenhouse gas emissions, fossil energy use, and P and N runoff losses were moderately sensitive to the difference in milk yield where the 10% reduction in increased milk yield created a 3 to 7% reduction in their total farm impacts (sensitivity indexes of 0.31–0.66; Table 8). Historical milk production data for US dairy farms were accurately documented (USDA NASS, 2023a). Although our results were sensitive to milk production data, the data used have a high accuracy and thus were not improperly biasing the results.

Greenhouse gas emissions and fossil energy use were slightly sensitive to a change in the difference in farm size, but this change had little effect on the other environmental metrics studied (Table 8). With all other factors held as constant as possible, the increase in the difference in farm size between 1971 and 2020 decreased the difference in total energy use. Changes in assumed differences through time in cow replacement rate, diet protein content, diet P content, manure export, N fertilizer use, and P fertilizer use had little or no effect on the difference in total environmental impacts (Table 8). The increase in ammonia emissions was slightly influenced by the change in the difference in protein content of cow diets, and the accumulated soil P on the farm was slightly sensitive to a decrease in the difference in P fertilizer use.

Our assumed change in handling some manure from an open lot with stacked storage to a freestall barn with liquid storage created a substantial change in the difference in NH_3 emissions over the 50 yr, with little effect on all other changes in environmental impacts (Table 8).

Although this type of change in manure handling would affect CH_4 and N_2O emissions, in this case, these changes did not have much effect on the difference in total GHG emissions between 1971 and 2020. Other changes in animal housing and manure handling may affect various environmental concerns, but the largest effects would likely be on NH_3 and VOC emissions. As illustrated by this example, differences in all other environmental metrics between 1971 and 2020 were not sensitive to changes in manure handling practices.

Irrigation water use had a major effect on the increase in water use over the 50-yr period. A 10% change in the efficiency of irrigation water use caused a similar change in total water use (sensitivity index of 0.79; Table 8). Energy use and GHG emissions were just slightly sensitive to irrigation water use due to the energy used to pump irrigation water. The changes in other environmental metrics were not affected by this change (Table 8).

Our assumed change in tillage practices over the 50 yr had some effect on runoff of N and P (Table 7). A 10% reduction in the difference in modeled surface water runoff created a moderate 2% to 3% change in the runoff of soluble and sediment-bound P and N (sensitivity indexes of 0.16–0.31; Table 8). Although the assumed changes in tillage practices created large changes in runoff, major changes in tillage practices would be required to make much of a change in the predicted decreases in nutrient runoff losses found in our assessment.

The sensitivity analysis shows that the results compared across the 50-yr span were not highly sensitive to our assumptions coming through expert opinion or other limited information. Where sensitivities were found, major changes in our assumptions would be required to create substantial changes in our comparisons across time. This supports the robustness of our analysis. If more accurate data or information were available on dairy farm management in 1970, improved assumptions would not likely have much effect on the results and overall conclusions of this analysis.

CONCLUSIONS

Through substantial improvements made in the efficiency of producing milk, feed, and resources used in dairy production, much progress has been made in reducing farmgate environmental intensities of milk production in the United States. Across all environmental metrics studied, intensities expressed per unit of FPCM produced decreased from 25% to 75%. Totals from all dairy farms in the United States show increases in NH_3, CH_4, and reactive non-CH_4 VOC emissions. Total GHG emissions related to dairy farms have increased by just 14%, while total fossil energy use has shown little change, and nutrient losses to ground and surface waters have shown substantial improvements. The movement of dairy production from the humid eastern climate to the dry climate of the West has contributed to a 42% increase in water use, which is an important concern for future sustainability. Although much progress has been made in improving production efficiency and reducing or controlling environmental impacts, further mitigation strategies and technologies are needed to continue improving the sustainability of the dairy industry.

NOTES

The authors thank the Cooperative Extension staff, producers, and others in the dairy industry who provided information on the management practices of dairy farms for the various regions of the United States in the early 1970s. The USDA is an equal opportunity provider and employer. Funding for this work was provided by the USDA Agricultural Research Service (University Park, PA) under project no. 1902-11130-003 (Sustainable Intensification of Crop and Integrated Crop-Livestock Systems at Multiple Scales). The supplemental material for this article is available at https://doi.org/10.15482/USDA.ADC/24970164.v1. No human or animal subjects were used, so this analysis did not require approval by an Institutional Animal Care and Use Committee or Institutional Review Board. The authors have not stated any conflicts of interest.

Abbreviations used: CO_2e = CO_2 equivalents; FPCM = fat- and protein-corrected milk, GHG = greenhouse gas, IFSM = Integrated Farm System Model, LCA = life cycle assessment, VOC = volatile organic compound.

Symposium review: Greenhouse gas emissions from liquid dairy manure: Prediction and mitigation[1]

Søren O. Petersen[2]
Department of Agroecology, Aarhus University, Blichers allé 20, 8830 Tjele, Denmark

ABSTRACT

The handling and use of manure on livestock farms contributes to emissions of the greenhouse gases (GHG) CH_4 and N_2O, especially with liquid manure management. Dairy farms are diverse with respect to manure management, with practices ranging from daily spreading to long-term storage for more efficient recycling of manure nutrients for crop production. Opportunities for GHG mitigation will depend on the baseline situation with respect to handling and storage, and therefore prediction and mitigation at the farm level requires a dynamic description of housing systems and storage conditions, and use of treatment technologies. Also, effects of treatment and handling on the properties of field-applied manure must be taken into account. Storage conditions and manure composition importantly define carbon and nitrogen transformations, and the resulting emissions of CH_4 and N_2O, as well as CO_2 and NH_3, which are all important for the GHG balance. Currently, inventories for CH_4 and N_2O emissions from manure are based on emission factors for a limited number of production systems, together with average annual temperature, but the inherent uncertainty of this approach is a barrier toward prediction and mitigation. Although more representative emission factors may be determined at country level, this is both challenging and costly, and effects of management changes for GHG mitigation are not easily quantified. An empirical model of CH_4 emissions during storage is discussed that is based on daily time steps, and a parameterization based on measurements. A distinction between emissions from manure in barns and outside storage facilities is important for assessing effects of treatment technologies, such as anaerobic digestion, where only posttreatment emissions are affected. Upon field application, manure and soil together define the equilibrium distribution of labile carbon and nitrogen between bulk soil and manure hotspots. This introduces heterogeneity with respect to potential for N_2O emissions, which is not represented in existing prediction models. Manure treatment and management options for GHG mitigation are discussed with emphasis on effects on manure volatile solids and N availability. Anaerobic digestion and acidification represent treatment technologies that are relevant for GHG mitigation on dairy farms.

Key words: manure management, methane, nitrous oxide, volatile solids

INTRODUCTION

According to a recent life cycle analysis (Thoma et al., 2013a), the United States dairy sector is responsible for 1.9% of total national greenhouse gas (**GHG**) emissions, whereas globally this contribution is 3 to 5% (FAO, 2010). Main sources are CH_4 emissions associated with enteric fermentation and manure management, and N_2O emissions from feed and food production, which are therefore also key targets of efforts to quantify emissions and mitigation potentials (Henriksson et al., 2011; Thoma et al., 2013a).

Dairy production systems are extremely diverse with respect to manure management practices and environmental conditions (Sommer et al., 2009; Thoma et al., 2013b), and this will influence the effectiveness of GHG mitigation measures. For example, Sommer et al. (2009) showed that CH_4 emissions from manure in 5 European countries were affected differently by several treatment technologies due to differences in management and storage temperature. Similarly, the 2 states in the United States with the largest dairy herds, California (**CA**) and Wisconsin (**WI**), are different with respect to both climate and manure management practices; a survey found that 50 to 67% of WI dairy farms spread manure year-round without storage, representing on average 45% of the manure volume (Turnquist et al., 2006), whereas this was the case on only 26 to 27% of CA dairy farms in a survey of 2 counties (Meyer et

Received June 7, 2017.

[2]Corresponding author: sop@agro.au.dk

al., 2011). As a consequence, the potential for mitigating CH_4 emissions during storage would be greater for CA dairy farms, whereas the potential for improved N use efficiency and, in turn, N_2O mitigation would be greater for WI dairy farms. Effective mitigation strategies thus depend on an accurate description of on-farm conditions.

Contributions from CH_4 and N_2O

Greenhouse gas emissions on dairy farms are dominated by CH_4 and N_2O (Chianese et al., 2009; Kristensen et al., 2011). Even in regions where the number of cows have declined, such as North America and Western Europe, a change toward liquid manure management and extended storage have increased emissions of both gases (Wightman and Woodbury, 2016). The global warming potential (**GWP**) of CH_4 and N_2O are normally considered for a time horizon of 100 yr, and current estimates of GWP_{100} for CH_4 and N_2O are, respectively, 34 and 298 times the GWP_{100} of CO_2 (Myhre et al., 2013). However, CH_4 has a half-life in the atmosphere of only 12 to 13 yr, and thus for a 20-yr time horizon, GWP_{20}, the contribution of CH_4 is 2.5-fold higher at 86, which increases the relevance of CH_4 mitigation efforts to curb global warming in the short term.

Emissions of N_2O are associated with N transformations via nitrification and denitrification under oxygen-limited conditions (Maharjan and Venterea, 2013). Sustained emissions require that aerobic and anaerobic environments exist in close proximity, which may be the case in organic crusts formed during liquid manure storage (Wood et al., 2012), and in solid manure (Webb et al., 2011). Upon field application, factors such as manure composition, application method and soil conditions together determine the potential for N_2O emissions, but given the unpredictable effects of climate, effects of treatment and management can vary dramatically. A recent meta-analysis (Charles et al., 2017) found that liquid and solid organic residues (including manure) are characterized by N_2O emissions that are, respectively, above and below the emission factor currently used by most countries. However, the analysis also found strong positive interactions with soil N status, clay content, and precipitation, indicating that defining local conditions, as for CH_4, is critical for more accurate estimation of emissions.

Gaseous N losses through NH_3, nitrogen oxides (NO_x), and N_2, and leaching losses mainly as NO_3^-, are quantitatively much more important than direct emissions of N_2O (Venterea et al., 2012). Because both NH_3 volatilization and NO_3^- leaching are indirect sources of N_2O, the prevention of these losses through better N use efficiency is an effective strategy for N_2O mitigation.

Objectives

Predicting CH_4 and N_2O emissions from livestock farms is a significant challenge, and currently the uncertainty associated with emission estimates effectively prevents accountability, regulation, and mitigation. Several recent papers and meta analyses have reviewed GHG emissions from manure management and mitigation options (e.g., Hristov et al., 2011; Petersen et al., 2013a; Hou et al., 2015; Jayasundara et al., 2016). In this review, I will instead highlight selected aspects of manure treatment and management that research, from laboratory to practical scale, has shown to be of particular importance for gaseous emissions of carbon (CH_4, CO_2) and nitrogen (N_2O, NH_3). The main emphasis will be on dairy production systems. In view of the many potential interactions between different management stages, the discussion will address both manure management on the farm and subsequent field application.

DRIVERS OF GHG EMISSIONS FROM MANURE

Gerber et al. (2011) reported that the shares of solid and liquid manure management on dairy farms in North America were, respectively, 31 and 36%, whereas the corresponding numbers for Western Europe were 36 and 38%. In many parts of the world, the share of liquid manure management is increasing due to intensification of livestock production (Bouwman et al., 2013) and due to recommendations to store manure to recycle manure nutrients for crop production (Oenema et al., 2011). Because the potential for CH_4 production is estimated to be 4- to 20-fold higher with liquid compared with solid manure management depending on storage temperature (IPCC, 2006), it can be estimated that, for example, in Western Europe liquid manure accounts for >90% of total CH_4 emissions from solid and liquid storage. As stated above, the potential for N_2O emissions after field application is also higher from liquid manure (Charles et al., 2017), and the focus of this review is therefore on liquid manure management. It should be noted, however, that recently introduced deep litter systems also may have a high potential for CH_4 as well as N_2O emissions (Barberg et al., 2007; Galama, 2011).

Storage Environment

An overview of livestock manure handling systems was presented by Sørensen et al. (2013). Collection

inside barns may occur in deep or shallow pits, and excreta may be scraped or flushed, or exported by gravity flow, for outside storage. Outside storage can take place in a concrete tank or pond, or lagoon(s). Dairy farms rely on an in-house pit or outside storage, or both. In pits beneath slatted floors, a significant volume of manure may be maintained to enable mobilization of settling solids during export; a recent survey found that in Denmark the resulting hydraulic retention time (**HRT**) for cattle slurry was 30 to 40 d (Kai et al., 2015). Anaerobic lagoons are widely used in North America as a cost-effective method to stabilize effluents through biodegradation of organic matter and settling of solids, but due to the prolonged retention time and large surface area, the potential for CH_4 and NH_3 emissions is high compared with storage tanks (IPCC, 2006; McGinn et al., 2008). Depending on in-barn and outside storage temperatures, the retention time in barns and outside storage, and any treatment in between, can significantly influence the fate of manure organic matter and nutrients before land application.

A storage design parameter of potential importance for the GHG balance of manure management is surface-to-volume ratio. It is well established that the loss of N via NH_3 emission is high in the absence of a cover such as a natural crust, floating membrane, or roof structure on storages to restrict gas exchange (Sommer et al., 1993). However, C metabolism is also influenced by gas exchange across the manure-air interface because manure represents a sink for atmospheric O_2. The flux of O_2 is proportional to the concentration gradient across the diffusive boundary layer (Jørgensen and Revsbech, 1985; Hafner et al., 2017). Thus, with uncovered liquid manure the mass transfer of dissolved organic C to the surface through the effect of wind or convective heat transfer (Hafner et al., 2017) will result in steep dissolved organic C concentration gradients that enhance O_2 consumption compared with storages with a synthetic membrane or natural crust cover, because here the diffusive boundary layer is much greater and mixing less. Because the end product of aerobic heterotrophic activity is CO_2, processes at manure surfaces will influence the proportions of volatile solids (**VS**) lost as CH_4 and CO_2 (Møller et al., 2004). Furthermore, both $CO_2/HCO_3^-/CO_3^{2-}$ and NH_3/NH_4^+ are important components of the buffer system of manure (Sommer and Husted, 1995), and CO_2 emissions from manure can enhance NH_3 emissions by raising pH at the manure-air interface (Hafner et al., 2017). The relative importance of processes at this interface will also depend on the degree of filling; the surface-to-volume ratio thus increases after manure removal for field application.

The presence of active methanogens is a precondition for CH_4 emissions during storage, but methanogens in fresh excreta may not thrive in harsh liquid manure environments (Chen et al., 2008a), and this can delay the appearance of CH_4 emissions for weeks or even months (Sommer et al., 2007). Adaptation is therefore required, or inoculation with methanogens from residual manure in the pit, which is already adapted to this environment. Flushing and emptying of manure pits or storage tanks have been shown to delay the onset of methanogenesis (e.g., Haeussermann et al., 2006), but under practical storage conditions this can be difficult to achieve. Recently, Baldé et al. (2016) reported that removal of sludge from concrete tanks on a dairy farm in autumn had no detectable effect on CH_4 emissions during storage the following summer.

Manure Volatile Solids

Volatile solids in liquid cattle manure typically constitute 75 to 85% of TS, the rest being sand and minerals (Møller et al., 2002; Petersen et al., 2003). According to Møller et al. (2004), labile fractions (VFA, protein, lipids, degradable carbohydrate) constitute around 69% of VS in cattle manure, and 79% in finishing pig manure. Any bedding will add to the concentration of DM, whereas effects on VS concentration will depend on the material used, such as straw, sawdust, sand, or recycled manure solids, which differ with respect to CH_4 production potential, but also animal welfare, cost, and labor (Møller et al., 2004; Zdanowicz et al., 2004). Møller et al. (2002) found that 50% of TS in cattle manure were degraded during 7 mo of storage at 20°C. Assuming that labile pools of manure OM were lost to a greater extent than more recalcitrant components, the potential is significant for loss of labile VS, and thus CH_4 emissions, even within a few weeks of storage, which has implications for manure treatment and management.

During storage, organic particles may remain suspended, settle, or float to the surface to form a natural crust. Up-drift may be created by gas bubbles (consisting mainly of CH_4 and CO_2) derived from methanogenic activity, and crust formation on dairy cattle manure has been observed to coincide with the onset of CH_4 emissions (Misselbrook et al., 2005c; Wood et al., 2012). Also, Misselbrook et al. (2005c) reported that a glucose-starch additive promoted crust formation. Buoyancy of a crust is further supported by pockets of gas beneath the crust, which are intermittently deflated through cracks, as observed by Duan et al. (2017) using an oxygen microsensor. Thus, crust formation is a product of both recalcitrant and labile manure OM.

Depending on weather conditions (rainfall, temperature), a variety of microbial populations may develop in surface crusts. The microbial community will include populations of CH_4 oxidizing bacteria, or methano-

trophs (e.g., Petersen et al., 2005; Duan et al., 2017). Their activity depends on both availability of substrates (CH_4, O_2) and inhibitory effects of mineral N, but recent evidence suggests that mainly the activity of so-called type 1 methanotrophs responds to elevated CH_4 availability in aerated parts of the crust (Duan et al., 2017). However, at this time limited information is available about the importance of methanotrophic activity in surface crusts for CH_4 emissions. Natural crusts on manure storages are also a potential source of N_2O; this will be discussed later.

Manure Nitrogen

Manure recycling for crop production can significantly reduce the need for imported fertilizers, although ensuring a balanced nutrient supply with respect to N, P, K, and S can be difficult with manure alone. For dairy cattle manure a direct relationship exists between N intake and excretion (Kebreab et al., 2001). The N excreted is partly unavoidable losses associated with, for example, microbial cell walls and residual protein, and partly a variable fraction of excess N excreted mainly as urea in the urine (Petersen et al., 1998). Urea is rapidly hydrolyzed to form NH_4^+ and NH_3 (total ammoniacal N, **TAN**), whereas mineralization of organic N is slower and temperature dependent. Sommer et al. (2007) found that mineralization of organic N in liquid pig and cattle manure varied between 5 and 85% when stored at 10, 15, or 20°C for up to 200 d. Mineralization of organic N will increase manure N availability and pH (Eriksen et al., 2012), and therefore also the potential for environmental loss of TAN through NH_3 emission. Depending on length of storage and ambient temperature, effective recycling of N for crop production will require NH_3 mitigation measures.

Upon field application, both particle size distribution and soil properties influence redistribution of manure constituents. Vadas (2006) found that around 80% of the DM in liquid dairy and swine manure applied on top of a fine-loamy soil was retained at the surface, whereas the 20% of manure solids entering the soil was predominantly recovered within 10 mm distance from the surface. This is in accordance with the distribution of dissolved organic C and NH_4^+ observed in soil around cattle manure layers, that is, 2-dimensional manure hotspots, in laboratory setups (e.g., Petersen et al., 1996), suggesting that C and N transformations and N_2O emissions are concentrated within a limited soil volume in close contact with manure after field application. The VS in manure has a high water retention capacity compared with mineral soil; exponential relationships between manure VS concentration and water retention were described by Petersen et al. (2003).

PREDICTING GHG EMISSIONS FROM MANURE

The need to use a transparent and consistent methodology for national GHG inventories is widely accepted, and the United Nations' Framework Convention on Climate Change has recommended the use of guidelines developed by the Intergovernmental Panel on Climate Change (**IPCC**). This methodology is based on annual emission factors defined for a limited number of production systems, but several studies have pointed out that quantifying farm-level emissions is problematic with a methodology that is insensitive to local management (Weiske et al., 2006; Schils et al., 2007; Crosson et al., 2011; VanderZaag et al., 2013). Hence, more dynamic, yet transparent and consistent, methods to estimate GHG sources and sinks are needed, as well as mitigation potentials of treatment and management. This section discusses challenges and opportunities in relation to prediction of CH_4 and N_2O emissions from manure.

Controls of CH_4 Emissions

The IPCC methodology for estimating CH_4 emissions from manure management recommends use of a so-called methane conversion factor (**MCF**) to represent local manure storage conditions (IPCC, 2006). Default MCF values are proposed for a range of production systems based on average annual temperature, although countries are recommended to develop national or regional MCF through measurements, if possible. An MCF value must account for timing and length of storage, manure composition, presence of inoculum with adapted methanogens from older manure, daily and seasonal temperature variations, and retention time in the barn (IPCC, 2006). With such a wide range of storage conditions to be represented by a single value, the uncertainty associated with MCF is necessarily high, and it is relevant to consider the scope for a more dynamic description of key drivers.

Time is a key variable because management decisions influence storage conditions on a daily basis, and storage time before/after manure treatment if applicable. Manure volume and retention time in barns and outside storage facilities are readily calculated by day knowing the number of animals and grazing periods, excretion rate, and timing of transfer from barn to outside storage. This information can then be used to define storage temperature with daily time steps, which is critical to account for regional and seasonal differences in temperature that may be significant. For example, the average annual temperature in Milwaukee, WI, varied moderately between 4.4 and 13.1°C in the period from 1981 to 2010, but average monthly temperature

varied between −9.1 and 26.7°C (Prism Climate Group, 2017). Detailed information about local temperature is generally accessible and hence may support a better spatio-temporal resolution of CH_4 emission estimates.

The greatest challenge in predicting CH_4 emissions may be the documentation of CH_4 production rates. Four contrasting manure materials (pig manure, cattle manure, fresh digestate, and aged digestate) were found to have very similar activation energies, E_a (i.e., temperature sensitivity), of methanogenesis in the range of 5 to 37°C (Elsgaard et al., 2016), whereas actual CH_4 production rates were very different (Figure 1). The latter was partly explained by the differences in origin and treatment, but in practice CH_4 production potential also varies with feeding (Jayasundara et al., 2016), as well as age and storage temperature (Sommer et al., 2007), and storage environment (Barret et al., 2013). Across 90 individual manure samples from 4 storage tanks with either pig or dairy cattle manure, Barret et al. (2013) observed a negative effect of VFA (and positive effect of pH), presumably because methanogens were inhibited by the acidification associated with VFA accumulation (Chen et al., 2008a). There was also inter-storage and temporal variability in methangenic community composition, and a lower potential for CH_4 production near the surface in pig manure, but not dairy manure. Although a multiple linear regression equation was able to describe the observed CH_4 emissions based on 16 microbiological and chemical manure characteristics, it was acknowledged that additional complexity is introduced under practical storage conditions (Barret et al., 2013). Notably, the average age of the manure in a storage, and hence the extent of VS degradation at the time of observation, is typically unknown. In accordance with this, a sensitivity analysis found that estimates of CH_4 production rate in individual manure materials were much more sensitive to CH_4 production potential, as represented by lnA (see next section), than to temperature or VS composition (Petersen et al., 2016).

Aerobic degradation near the manure-air interface (Patni and Jui, 1987; Møller et al., 2004; Barret et al., 2013) further complicates the prediction of CH_4 emissions, since the removal of labile VS in the manure via aerobic degradation to CO_2 will change the balance between CH_4 and CO_2 associated with loss of VS during storage. Implications of aerobic degradation for CH_4 emissions will be greater for a pond with a surface area of up to several hectares (Leytem et al., 2011) compared with slurry tanks of 20 m diameter (Baldé et al., 2016). Observations from practical and pilot-scale storage confirm that proportions of CH_4 and CO_2 emitted are highly variable. In a study of emissions from a slurry tank, Laguë et al. (2005) observed CH_4-C/(CH_4-C + CO_2-C) ratios in 3 seasons that ranged from 0.36 to 0.45, whereas these ratios for 2 earthen basins averaged 0.24 (no cover) and 0.06 (straw cover). Viguria et al. (2015) found proportions of CH_4 in emissions from 2 lagoons during spring corresponding to 0.15 to 0.2 (range: 0.1 to 0.4). Sommer et al. (2007) compared CH_4-C/(CH_4-C + CO_2-C) ratios of slurry during simulated pit storage at 10, 15, and 20°C; whereas at 10°C the ratios were 0.1 to 0.3, at 20°C the ratios for cattle slurry shifted during storage from 0.2 to 0.5, and to 0.65 in pig slurry. For the data presented by Leytem et al. (2011), CH_4-C/(CH_4-C + CO_2-C) ratios of emissions from a dairy wastewater pond in early May, late May, August, and October were, respectively, 0.08, 0.25, 0.38, and 0.45 at temperatures of 5.0, 15.4, 20.8, and 15.3. The importance of methanogenesis may increase over time as a result of microbial adaptation or changes in the storage environment (Sommer et al., 2007; Barret et al., 2013), but will then, as mentioned above, be constrained by the remaining substrate.

Estimating On-Farm CH_4 Emissions from Manure

A dynamic method is needed to accurately estimate CH_4 emissions from manure management; some main drivers (retention time, storage temperature, and methanogenic potential) were discussed above. Production systems may be classified on the basis of housing and

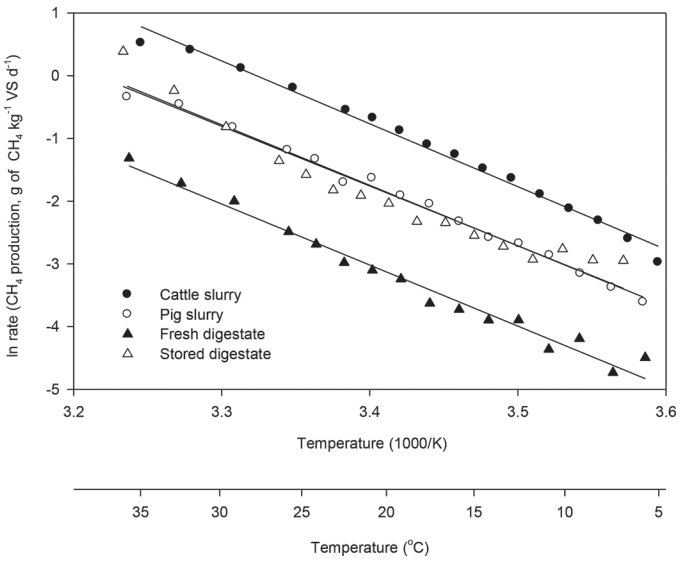

Figure 1. Arrhenius plots (ln rate versus inverse temperature, K) of the temperature response of CH_4 production in 4 contrasting liquid manure materials for the temperature range of 5 to 37°C. The manure materials were cattle slurry, pig slurry, fresh digestate from a thermophilic digester, and digestate from the same digester after several weeks of storage. The slopes of regression lines were not significantly different and averaged 81 kJ/mol. VS = volatile solids. Reproduced with permission from Elsgaard et al. (2016).

storage design, whereas treatment and management practices define manure retention times and storage temperatures in barn and outside storage. Estimation of daily emissions is needed to analyze effects of storage conditions and management in detail. Models using daily time steps for manure management include the Integrated Farm Systems Model (Chianese et al., 2009) and Manure-DNDC (Li et al., 2012). Both models depend on external parameters; that is, the temperature relationship of Integrated Farm Systems Model was adopted from Sommer et al. (2004) who in turn based values on a compilation of data from storage experiments, whereas Manure-DNDC relies on a submodel developed for soil environments, and a constant redox potential of −300 mV is used (Li et al., 2012). As an alternative approach, Petersen et al. (2016) proposed a method where estimation of CH_4 emissions is based on an in vitro anaerobic assay of CH_4 production rates in freshly collected samples when incubated at near-ambient temperature. Assuming this represents CH_4 emissions from the bulk liquid phase, rate measurements were used to parameterize a simple algorithm relating CH_4 emissions to temperature:

$$F_t = \left(\mathrm{VS_d} + 0.01\mathrm{VS_{nd}}\right) e^{\left(\mathrm{lnA} - \frac{E_a}{RT}\right)}. \quad [1]$$

In this equation, originally proposed by Sommer et al. (2004), F_t is CH_4 production rate (mg of CH_4/kg of VS/h); VS_d and VS_{nd} (kg/kg of VS) are degradable and recalcitrant ("nondegradable") manure organic matter; E_a is activation energy [81,000 J/mol (Elsgaard et al., 2016)] and lnA represents the pre-exponential factor (g of CH_4/kg of VS per hour) of an Arrhenius equation describing temperature sensitivity. Finally, R is the universal gas constant R (8.314 J/K/mol), and T is the ambient temperature at sampling (K). Sommer et al. (2004) calculated the VS_d from the biochemical composition of fresh excreta, but this approach is not feasible with partly degraded manure collected from a storage facility or pit, and Petersen et al. (2016) instead used an aerobic incubation assay to estimate VS degradability. This parameter, as well as the scaling factor of 0.01 between VS_d and VS_{nd} degradability, require further documentation, but a sensitivity analysis showed that model results mainly depended on the term lnA which represents the CH_4 production potential. The value of lnA can be estimated for the individual manure samples by rearrangement of Equation [1] once F_t has been determined. Although the individual estimate of lnA has little predictive power, a database of measurements for a given production system can provide an estimate and uncertainty range, the representativeness of which would improve as the database of system-specific CH_4 production rates expands.

Prediction of CH_4 emissions, however, also requires information about VS degradation during manure storage (Petersen et al., 2016). Existing models assume a constant ratio between CH_4 and CO_2 for estimation of VS loss (IPCC, 2006; Mangino et al., 2001; Sommer et al., 2004; Li et al., 2012), but as shown above this ratio is highly variable and may change with manure treatment and storage time. A separate assay would be needed to estimate C loss as CH_4 and CO_2 at the manure-air interface, and such an incubation system has yet to be developed. The method described thus requires further development, but has a potential for dynamic modeling of CH_4 emissions and VS loss during manure storage with direct reference to experimental data, where information about total C loss can help constrain estimates of VS_d.

Daily emission estimates can be recalculated to an MCF value for reporting, or separate MCF values can be calculated for in-barn and outside storage (Mikkelsen et al., 2016). This is important if manure treatment takes place following export from the barn because then only posttreatment emissions are affected. By reducing uncertainties for individual sources, it would allow for more effective GHG mitigation.

Controls of N_2O Emissions

Ammonia losses during manure management are a significant indirect source of N_2O (Hristov et al., 2011). McGinn et al. (2008) found that 13% of TAN was lost from a lagoon with cattle manure during summer storage in Western Canada. They further reported that wind speed and surface temperature together explained 59% of the variability in NH_3 emissions, and in accordance with this up to 35% of TAN may be lost in warmer climates (McGinn et al., 2008). Ammonia losses during manure storage can be reduced by around 80% with a cover in the form of a natural crust or synthetic membrane (Sommer et al., 1993; Miner et al., 2003). With a natural crust, however, the reduction of NH_3 emissions may be accompanied by direct emissions of N_2O produced around aerobic-anaerobic interfaces (Duan et al., 2017).

For liquid manure developing a natural crust, the IPCC (2006) guidelines recommend an N_2O emission factor of 0.005 kg of N_2O-N/kg of N stored, with an uncertainty range of 0.0025 to 0.01 kg of N_2O-N/kg of N. Available results from pilot-scale data are mostly within this range (Jayasundara et al., 2016), but there is a need for documenting emissions at a practical scale, and to better understand what constrains this source.

Typically crust formation is followed by a lag phase of several weeks before N_2O is observed (Sommer et al., 2000; Wood et al., 2012; Petersen et al., 2013b), which indicates that conditions in the crust do not support nitrification and denitrification activity during this period. Sommer et al. (2000) found that temporal dynamics were related to the water balance of the crust (precipitation minus evapotranspiration), suggesting that initially crust wetness is the limiting factor, but interactions between microbial activities and the physical and chemical environment of the crust are not well characterized at present.

For field-applied manure, as for mineral N fertilizers, an emission factor of 0.01 kg of N_2O-N/kg of N is recommended (IPCC, 2006). An increasing number of both experimental and model studies report that the relationship between N input and N_2O emissions is exponential rather than linear (e.g., McSwiney and Robertson, 2005; Philibert et al., 2012), and it has been proposed that high emissions are mainly associated with conditions where N input exceeds crop demand (i.e., where mineral N accumulates in the soil). However, meta-analyses also indicate that the uncertainty of N_2O emission estimates can be reduced by including aspects of management or soil characteristics (Shcherbak et al., 2014; Charles et al., 2017).

One source of variability, which has so far not been addressed in prediction models, is the spatial heterogeneity of manure in soil. The liquid phase of manure will partly infiltrate the soil in response to water potential gradients (Petersen et al., 2003), a process that is largely complete within 24 h (Misselbrook et al., 2005b). Temporally stable gradients in volumetric water content are established (Petersen et al., 2003), which therefore represent also the distribution of dissolved (and mostly labile) C and N shortly after manure application. The potential for partial reallocation of both C and N constituents is important for N_2O emissions because turnover of components infiltrating the bulk soil takes place in an environment with a higher O_2 availability than manure "hotspots" where both water content and O_2 demand is much higher than in the surrounding soil (Petersen et al., 1996; Baral et al., 2016). It is probably important to acknowledge that N_2O emissions associated with organic hotspots that are dominated by manure (or crop residues) follow different dynamics compared with N_2O emissions from bulk soil where the potential for emissions depends mainly on bulk soil properties such as gas diffusivity (Balaine et al., 2013).

Manure application method will evidently influence the size distribution of manure hotspots, with direct injection, band-spreading, and broadcasting representing methods with increasing contact between manure and soil. Manure distribution in soil following application has, however, mainly been described for injection methods (Petersen et al., 2003; Rahman et al., 2004) and surface application (Misselbrook et al., 2005b).

Estimating N_2O Emissions After Field Application

The IPCC methodology for estimating N_2O emissions from field-applied manure is based on annual emission factors, where the default (Tier 1) emission factor is 0.01 kg of N_2O-N/kg of N. The associated uncertainty range of 0.003 to 0.3 kg of N_2O-N/kg of N of the Tier 1 emission factor probably reflects inherent diversity of soil conditions that the emission factor is expected to represent because little improvement in precision was achieved by expanding the database (Stehfest and Bouwman, 2006). There is thus a pressing need for more informed estimates of N_2O emissions from N applied to soil. Experimental determination of N_2O emissions can provide Tier 2 emission factors at country level, although this requires a significant effort (e.g., Bell et al., 2015) and is not realistically done for all relevant combinations of N input and soil conditions. Dynamic models, referred to as Tier 3 in the IPCC terminology, have also been investigated for prediction of N_2O emissions from soil, but data requirement for parameterization is high, and deviations in the reproduction of temporal dynamics (e.g., Li et al., 2012) suggest that underlying processes are not fully understood.

Chen et al. (2008b) reviewed several process-based models for estimating N_2O emissions from soil, including NGAS-DAYCENT, DNDC, *ecosys*, NLOSS, Expert-N, WNMM, FASSET, and CERES-NOE. A common feature of these models is that they define soil layers assumed to be uniform with respect to physical, chemical, and microbiological characteristics. The application of liquid manure and other residues presents a challenge for such models insofar as individual constituents (water, C pools, N pools), and therefore labile C and N are in fact not evenly distributed within a given layer, but will be partly concentrated in manure-affected volumes that may be viewed as hotspots of intense C and N cycling. Size and distribution of manure hotspots will depend on application method and any subsequent tillage. Many studies have demonstrated how interactions between aerobic heterotrophic activity, nitrification, and denitrification in the gradient environment around such hotspots interact with soil conditions in determining the extent of denitrification and N_2O emissions (Nielsen and Revsbech, 1994; Petersen et al., 1996; Markfoged et al., 2011; Baral et al., 2016). Presumably the surface-to-volume ratio of manure hotspots is critical for predicting N_2O emissions, by determining the balance between aerobic and anaerobic degradation of labile C and N (Baral et al., 2016), and this could be

the reason why models that distribute manure constituents uniformly throughout a 2-dimensional soil layer fail to reproduce the dynamics of observed emissions (Chen et al., 2008b).

The distribution of manure C and N will approach a new equilibrium distribution within 24 h after field application of liquid manure (Misselbrook et al., 2005b). One way to account for this heterogeneity could be to use this new distribution as boundary conditions for transformations of labile manure C and N (including mineral N) after field application. Bulk soil conditions in the relevant soil layer could then be assumed for manure C and N transformations of the fraction infiltrating the soil. In contrast, separate conditions would need to be defined for an environment representing manure hotspots, to account for the co-occurrence of elevated water content and O_2 demand, and the coupling of nitrification and denitrification around aerobic-anaerobic interfaces (see Nielsen and Revsbech, 1994, and references therein). One requirement for this hypothetical model for manure distribution in soil is an estimate of the allocation of labile C and N between bulk soil and manure hotspots. An approach was proposed by Sommer et al. (2004) based on previously observed exponential relationships between water potential and VS in 22 manure materials including cattle manure, pig manure, and digestates:

$$f_R = 1 - 1/(1 + aVS), \quad [2]$$

and

$$a = 0.063 + 1.33e^{77.8\psi}, \quad [3]$$

where f_R is the proportion of manure water retained by VS, ψ (MPa) is soil water potential at the time of application, and a is a parameter defined by Ψ. Assuming that water retention in manure hotspots is a function of particulate VS (VS_{nd}, g/100 g) and a variable fraction (f_R) of labile VS (VS_d, g/100 g), that is, $VS_{hotspots} = VS_{nd} + f_R VS_d$, then f_R also defines the fraction of VS_d (and labile N) retained in hotspots, which can be determined by iteration. This empirical approach requires further validation, but could be a starting point for attempts to integrate heterogeneity in simulations of manure C and N turnover in soil.

MITIGATING GHG EMISSIONS FROM MANURE

The previous sections have indicated that both particulate (recalcitrant) and dissolved (labile) VS are important determinants of both CH_4 and N_2O emissions from manure management and after field application. During storage, labile C and N are sources of CH_4 and N_2O (in part via NH_3 emissions), whereas particulate VS may restrict atmospheric emissions if a natural crust forms. Surface crusts are themselves a potential site of CH_4 and N_2O metabolism. Upon field application, the amount and composition of VS in manure are important controls of the redistribution of labile C and N which, together with soil properties, determine the potential for N_2O emissions. In view of these and other mechanisms, by which manure VS can affect emissions, it may be useful to also discuss potential mitigation strategies in terms of their effect on manure VS composition or turnover.

Feeding

Jayasundara et al. (2016) presented a thorough review of relationships between cattle dietary changes and additives, and CH_4 emissions. The most consistent effects have been seen for lipid supplements, where a regression analysis indicated that a 9 to 12% reduction is achievable, but it was stressed that such effects may be reciprocated by higher CH_4 emissions from the manure, as exemplified by Hellwing et al. (2014). This negative interaction is compounded in warmer climates and stresses the need to consider GHG mitigation at farm level. Among additives, the most promising results have been with nitrate and 3-nitrooxypropanol, in some cases with CH_4 mitigation effects of 30 to 60% (Jayasundara et al., 2016). For these additives, however, more research is needed to fully document implications for environment and animal health. Reducing the protein in DMI of dairy cows will also influence the N content and composition of excretal returns, by selectively reducing the amount of N excreted as urea in the urine. A reduction of urinary N can reduce NH_3 losses (Petersen et al., 1998; Misselbrook et al., 2005a) and hence indirect N_2O emissions.

In-House Acidification

Ammonia emissions from liquid manure can be reduced by commercially available technologies for acidification. The manure in pits below slatted floors is acidified by pumping manure to an external treatment tank for daily adjustment to pH 5.5 with sulfuric acid (H_2SO_4) in a strictly contained and automated process, or acidification can take place directly in storage tanks or during field application (Fangueiro et al., 2015). Acidification effectively reduces NH_3 emissions from the liquid manure, but not from slats and soiled surfaces, and thus for cattle barns a reduction of 50% is acknowledged for regulatory purposes (http://www.vera-verification.eu/).

Table 1. Reduction in CH_4 emissions by anaerobic digestion (AD), and interaction with shorter hydraulic retention time (HRT) in the pit before digestion (Mikkelsen et al., 2016); model parameters are from Petersen et al. (2016)

Item	kg of CO_2 eq[1]/Mg of slurry, cattle	kg of CO_2 eq/Mg of slurry, pig	Gg of CO_2 eq/PJ of energy
Untreated	19.25	62.25	NA[2]
AD,[3] HRT of 20 d	−7.88	−15.32	−8.72
AD,[3] HRT of 7 d[4]	−13.75	−42.33	−20.75

[1]eq = equivalent.

[2]NA = not applicable.

[3]Digestate assumed to contain 58% cattle slurry and 42% pig slurry by volume, in accordance with national statistics for Denmark.

[4]Where possible.

Interestingly, storage experiments have also shown that H_2SO_4 addition inhibits CH_4 emissions from manure during storage. For example, reductions of 67 to 87% (Petersen et al., 2012) and 61 to 75% (Misselbrook et al., 2016) were observed in experiments with cattle manure stored for up to 3 mo, indicating that a 60% reduction of CH_4 emissions from manure management is realistic by in-house acidification. Petersen et al. (2012) also found significant CH_4 mitigation by SO_4^{2-} or methionine addition without pH change, and by acidification with an alternative acid, and it was speculated that different mechanisms contribute to inhibition of methanogenesis. Environmental issues to be considered with this technology are changes in the odor profile, and field application of S in excess of crop needs, because 5 to 6 kg/t of H_2SO_4 is needed for acidification of cattle slurry (Danish Centre for Verification of Climate and Environmental Technologies, 2012).

Anaerobic Digestion

Anaerobic digestion of livestock manure has several environmental benefits, including CH_4 and odor mitigation, and improved plant N availability (Massé et al., 2011). Anaerobic digestion (**AD**) technologies range from on-farm covers of pits or lagoons, with or without heating, to centralized reactors with heating and active mixing, and often organic co-digestates are included to boost gas production. According to Key and Sneeringer (2011), 60% of US dairy production takes place on farms where manure management systems allow AD treatment. Due to the moderate methanogenic potential of manure, profitability of AD is low, but it has been argued that environmental and societal benefits should also be taken into account (Yiridoe et al., 2009).

Manure can only be treated by AD following export from the barn, and therefore only posttreatment emissions are affected. Because VS degradation takes place also during the collection period, the in-barn HRT becomes critical for GHG mitigation (i.e., a shorter retention time in the pit before treatment can reduce CH_4 emissions and VS loss during collection while also boosting biogas yields). Annual MCF are evidently not useful for evaluating scenarios with different retention times. Instead the method represented by Equation [1] could be applied, as exemplified in Table 1 (Mikkelsen et al., 2016). Here, CH_4 mitigation by AD treatment of pig and cattle manure in Denmark was estimated for HRT in the barn of either 20 or 7 d before digestion. Increasing the frequency of export was in this example projected to increase the CH_4 mitigation potential of AD 2- to 3-fold. The most recent Danish national inventory for agricultural GHG emissions estimated a 41% reduction of CH_4 emissions by AD treatment of cattle manure using this approach (Nielsen et al., 2016).

Cover on Storage Facilities

It is well established that methanotrophs inhabit surface crusts on manure, and the 2006 IPCC guidelines assumed a 40% reduction of CH_4 emissions due to this activity (IPCC, 2006). However, no strong support has been found for an effect of this magnitude, and if in fact CH_4 escapes mainly via cracks, as discussed above, then CH_4 availability in the crust could be limiting. It has been proposed that an additional cover on manure storages combined with a crust, and with passive or active ventilation to maintain elevated CH_4 concentrations in the headspace, could enhance methanotrophic activity by increasing CH_4 availability in the air above the crust (Petersen and Miller, 2006). The most recent evidence regarding methanotrophs in surface crusts, their requirements for CH_4 and O_2, and sensitivity toward mineral N, indicates that there is indeed a potential for stimulating CH_4 oxidation in well-established natural crusts through controlled ventilation which should be explored (Duan et al., 2017). Covers for slurry tanks of concrete or tarpaulin are already available for protec-

tion against NH_3 losses, and could be adopted together with surveillance or even active control of O_2 and CH_4 availability.

Reducing Nitrogen Surplus

Several opportunities for management and treatment have already been discussed that can increase the manure N use efficiency (dietary changes, shorter HRT, cover on storages, acidification, and AD), although in some cases mitigation measures must be combined to avoid negative interactions between stages of management with respect to NH_3 emissions (Hutchings et al., 1996). Powell and Rotz (2015) discussed several strategies for mitigating N surplus in dairy production systems and concluded that in many cases both dietary CP intake and mineral fertilizer N can be reduced with little effect on productivity. Schils et al. (2006) reported a reduction of N surplus on Dutch dairy farms of 20%, from 300 to 240 kg of N/ha, between 1990 and 1999 as a result of less mineral fertilizer N applied and fewer grazing days, but because more manure was collected and stored on the farm, emissions of CH_4 increased. An overall reduction of GHG emissions of 6% was calculated, though with a potential for improvement by adopting mitigation measures against CH_4 emissions during manure storage.

Nitrification inhibitors have a potential to reduce N_2O emissions, as well as N leaching from manure and fertilizers, and the reduction may be as high as 40 to 50% according to some meta-analyses (e.g., Qiao et al., 2015). This is accompanied by positive trends in crop N uptake and N recovery, although for individual experiments these effects are often not statistically significant. This mitigation strategy certainly deserves attention, but to achieve GHG mitigation the N surplus should also be reduced to prevent that direct N_2O emissions are replaced by indirect emissions. In documenting effects of nitrification inhibitors, it is important to acknowledge the great diversity of active compounds in terms of water solubility, volatility, and persistence in the soil environment (Subbarao et al., 2007), and to investigate potential side effects (Kong et al., 2016).

Enteric Emissions vs. Manure Management

The relative importance of enteric fermentation and manure as sources of CH_4 emissions on dairy farms will depend on housing system, management, and storage conditions, including climate. In temperate regions the proportion of CH_4 emissions from liquid manure management on dairy farms is typically 15 to 20% (Chianese et al., 2009; Kristensen et al., 2011). However, in warmer climates the relative importance of CH_4 emissions from manure may be much greater. Thus, Owen and Silver (2015) reported that for US dairy farms the average proportion of CH_4 from manure management in 2011 was 43%, and in California as high as 54%.

Referring to the numbers given in previous subsections for effects of mitigation strategies, the CH_4 mitigation potential of dietary changes on dairy farms in temperate climates would be in the range of 7 to 10% (i.e., a 9–12% reduction of enteric emissions constituting 80 to 85% of total CH_4 emissions on dairy farms), and this assumes any increase in CH_4 emissions from manure is avoided. By comparison, the potential for mitigation of CH_4 emissions from manure through in-barn acidification may be 9 to 12% in temperate climates, and by AD treatment the potential may be 6 to 8%. Here, indirect effects on NH_3 emissions and N use efficiency should also be estimated. In warmer climates the CH_4 mitigation potential and relative importance of manure treatment technologies would be greater. Although uncertainties are present and further documentation is required for both dietary changes and manure treatment technologies, these estimated mitigation potentials do highlight the relevance of considering GHG mitigation for manure management.

CONCLUSIONS

The diversity of manure management practices on dairy farms is high, with intensification favoring liquid manure management. This trend increases the potential for both CH_4 and N_2O emissions, and the need for mitigation. The existing IPCC methodology for estimating emissions from manure is not well suited to describe management at the farm level, and effects of management changes or manure treatment are not easily quantified, which is also a barrier toward future regulation of emissions. Both recalcitrant and labile fractions of VS in liquid manure were shown to be important for CH_4 and N_2O emissions during storage and after field application. For accurate estimation of CH_4 emissions from manure, and CH_4 mitigation potentials, it is important to estimate VS loss during storage in barns and outside storages separately. Accounting for manure N availability in fertilizer plans is a precondition for effective N_2O mitigation. Adoption of GHG estimation methods with a better representation of temporal and spatial variability may offer the flexibility needed to quantify effects of manure treatment and management, and mitigation potentials.

Acknowledgments

The Environmental Protection Agency would like to acknowledge the many individual and organizational contributors to this document, without whose efforts this report would not be complete. Although the complete list of researchers, government employees, and consultants who have provided technical and editorial support is too long to list here, EPA would like to thank some key contributors and reviewers whose work has significantly improved this year's report.

Within EPA's Office of Atmospheric Protection (OAP), development and compilation of emissions from fuel combustion was led by Vincent Camobreco. Sarah Roberts (EPA Office of Transportation and Air Quality (OTAQ)) directed the work to compile estimates of emissions from mobile sources. Work on fugitive methane emissions from the Energy sector was directed by Julie Powers, Melissa Weitz and Chris Sherry. Development and compilation of emissions estimates for the Waste sector were led by Lauren Aepli and Mausami Desai. John Steller and Kenna Rewcastle directed work to compile estimates for the Agriculture and the Land Use, Land-Use Change, and Forestry chapters with support from Jake Beaulieu and Alex Hall (EPA Office of Research and Development (ORD) on compiling the inventories for CO_2 and CH_4 associated with flooded lands. Development and compilation of Industrial Processes and Product Use (IPPU) CO_2, CH_4, and N_2O emissions was directed by Amanda Chiu and Vincent Camobreco. Development and compilation of emissions of HFCs, PFCs, SF_6, and NF_3 from the IPPU sector was directed by Deborah Ottinger, Dave Godwin, and Stephanie Bogle. Cross-cutting work was directed by Mausami Desai. We thank Bill Irving for general advice, guidance, and cross-cutting review.

Other EPA offices and programs also contributed data, analysis, and technical review for this report. OAP's Greenhouse Gas Reporting Program staff facilitated aggregation and review of facility-level data for use in the Inventory, in particular aggregation of confidential business information data. The Office of Air Quality Planning and Standards (OAQPS) with contributions from OTAQ provided analysis for precursor estimates and review for several of the source categories (i.e., natural gas and petroleum systems) included in this report. ORD conducted field research and developed estimates associated with flooded lands. The Office of Land and Emergency Management (OLEM) also contributed analysis and research.

The Energy Information Administration (EIA) and the Department of Energy (DOE) contributed invaluable data and analysis on numerous energy-related topics. William Sanchez and Kevin Nakolan at EIA provided annual energy data that are used in fossil fuel combustion estimates. We also thank Chris Tremper, Soudeh Motamedi, and Ashley Ruocco at the Department of Energy for providing data and information on emissions of SF_6 and PFCs from Other Product Use. Other government agencies have contributed data as well, including the U.S. Geological Survey (USGS), the Federal Highway Administration (FHWA), the Department of Transportation (DOT), the Bureau of Transportation Statistics (BTS), the Department of Commerce, the Mine Safety and Health Administration (MSHA), and the National Agricultural Statistics Service (NASS).

We thank the Department of Defense (DOD) (David Asiello, DoD and Matthew Cleaver of Leidos) for compiling the data on military bunker fuel use.

We thank the Federal Aviation Administration (FAA) (Ralph Lovinelli and Jeetendra Upadhyay) for compiling the inventory of emissions from commercial aircraft jet fuel consumption.

We thank the United States Department of Agriculture's Office of the Chief Economist (USDA-OCE) (Meg Xiarchos) and Economic Research Service (USDA-ERS) (Jeffrey Hopkins) for providing data on agricultural energy use.

We thank the U.S. Forest Service (USFS) (Grant Domke, Brian Walters, James Smith, and Courtney Giebink) for compiling the inventories for CO_2, CH_4, and N_2O fluxes associated with forest land.

We thank the Department of Agriculture's Agricultural Research Service (USDA-ARS) (Stephen Del Grosso) and the Natural Resource Ecology Laboratory and Department of Statistics at Colorado State University (CSU) (Stephen Ogle, Bill Parton, Shannon Spencer, Alisa Keyser, Lauren Hoskovec, Ram Gurung, Ryan Scheiderer, Veronica Thompson, Stephen Williams, and Guhan Dheenadayalan Sivakami) for compiling the inventories for CH_4 emissions, N_2O emissions, and CO_2 fluxes associated with soils in croplands, grasslands and settlements.

We thank the National Oceanic and Atmospheric Administration (NOAA) (Nate Herold, Ben DeAngelo and Meredith Muth), Silvestrum Climate Associates (Stephen Crooks, Lisa Schile Beers, Rebeca Brenes), the Smithsonian Environmental Research Center (J. Patrick Megonigal, James Holmquist, Jaxine Wolfe and Meng Lu), and Florida International University (Tiffany Troxler) as well as members of the U.S. Coastal Wetland Carbon Working Group for compiling inventories of land use change, soil carbon stocks and stock change, CH_4 emissions, and N_2O emissions from aquaculture in coastal wetlands. We also thank NOAA's Global Monitoring Lab (Stephen Montzka and Lei Hu) for information on atmospheric measurements and derived emissions of HFCs and SF_6.

We thank Marian Martin Van Pelt, Leslie Chinery, Alexander Lataille, Mollie Carroll, and the full Inventory team at ICF including Diana Pape, Robert Lanza, Mollie Averyt, Larry O'Rourke, Ted Atwood, Skyler Brown, Deborah Harris, Rebecca Ferenchiak, Fiona Wissell, Bikash Acharya, Sophie Johnson, Kyle Herdegen, Hazelle Tomlin, Lou Browning, Johanna Garfinkel, Anna Cliche, Valerie Hammer, Mallory Giesie, David Landolfi, Emily Carr, Georgia Kerkezis, Isabella Scornaienchi, Katie O'Malley, Maris Welch, Emily Adkins, Zeyu Hu, Alex Da Silva, Sneha Balakrishnan, Kenny Yerardi, Leah Hartung, Molly Rickles, Seth Hartley and Ajo Rabemiarisoa for technical support in compiling synthesis information across the report and preparing many of the individual analyses for specific report chapters including fluorinated emissions and fuel combustion.

We thank Eastern Research Group for their analytical support. Deborah Bartram, Kara Edquist and Madison Eaton support the development of emissions estimates for wastewater. Kara Edquist, Cortney Itle, Amber Allen, Spencer Sauter, Sarah Wagner, and Madison Eaton support the development of emission estimates for manure management, enteric fermentation, peatlands (included in wetlands remaining wetlands*)*, and landfilled yard trimmings and food scraps (included in settlements remaining settlements). Brandon Long, Gopi Manne, and Marty Wolf support the development of estimates for natural gas and petroleum systems. Gopi Manne and Tara Stout support the development of emission estimates for coal mine methane.

Finally, we thank the RTI International team: Kate Bronstein, Emily Thompson, Jeff Coburn, and Keith Weitz for their analytical support in development of the estimates of emissions from landfills; Melissa Icenhour, David Randall, Gabrielle Raymond, Karen Schaffner, Riley Vanek, Ricky Strott, Libby Robinson, Matt Hakos, Betty GEtano, Keegan Waggener, and Jeremy Kaelin for their analytical support in development of IPPU CO_2, CH_4, and N_2O emissions; Karen Schaffner and Haley Key for their analytical support in the development of the estimates of emissions from fluorochemical production; and Tiffany Moore and Matt Hakos for their analytical support on disaggregating industrial sector fossil fuel combustion emissions.

Preface

The United States Environmental Protection Agency (EPA) prepares the official U.S. Inventory of Greenhouse Gas Emissions and Sinks to fulfill annual existing commitments under the Paris Agreement and the United Nations Framework Convention on Climate Change (UNFCCC). National greenhouse gas (GHG) inventory reports are to be submitted each year by April 15.

In an effort to engage the public and researchers across the country, the EPA has instituted an annual public review and comment process for this document. The draft document was announced via Federal Register Notice and published for a 30-day comment period on the EPA Greenhouse Gas Emissions and Removals web site from February 14 through March 15, 2024, and comments received during the public review period are posted to the docket EPA-HQ-OAR-2024-0004. Comments received after the closure of the public comment period will be considered for the next edition of this annual report. Responses to comments are typically posted to EPA's website 2-4 weeks following publication of the final report in April 2024.

Table of Contents

TABLE OF CONTENTS ..... **VI**
LIST OF TABLES, FIGURES, BOXES, AND EQUATIONS ..... **IX**
EXECUTIVE SUMMARY **ES-1**
ES.1 Background Information ES-2
ES.2 Recent Trends in U.S. Greenhouse Gas Emissions and Sinks ES-4
ES.3 Overview of Sector Emissions and Trends ES-16
ES.4 Other Information ES-20
1. INTRODUCTION **1-1**
1.1 Background Information 1-2
1.2 National Inventory Arrangements 1-11
1.3 Inventory Preparation Process 1-14
1.4 Methodology and Data Sources 1-18
1.5 Key Categories 1-18
1.6 Quality Assurance and Quality Control (QA/QC) 1-25
1.7 Uncertainty Analysis 1-29
1.8 Completeness 1-32
1.9 Organization of Report 1-33
2. TRENDS IN GREENHOUSE GAS EMISSIONS AND REMOVALS **2-1**
2.1 Overview of U.S. Greenhouse Gas Emissions and Sinks Trends 2-1
2.2 Emissions and Sinks by Economic Sector 2-29
2.3 Precursor Greenhouse Gas Emissions (CO, NO_x, NMVOCs, and SO_2) 2-42
3. ENERGY **3-1**
3.1 Fossil Fuel Combustion (CRT Source Category 1A) 3-6
3.2 Carbon Emitted from Non-Energy Uses of Fossil Fuels (CRT Source Category 1A) 3-50
3.3 Incineration of Waste (CRT Source Category 1A) 3-58
3.4 Coal Mining (CRT Source Category 1B1a) 3-62

3.5 Abandoned Underground Coal Mines (CRT Source Category 1B1a) 3-69
3.6 Petroleum Systems (CRT Source Category 1B2a) 3-74
3.7 Natural Gas Systems (CRT Source Category 1B2b) 3-94
3.8 Abandoned Oil and Gas Wells (CRT Source Categories 1B2a and 1B2b) 3-117
3.9 International Bunker Fuels (CRT Source Category 1: Memo Items) 3-121
3.10 Biomass and Biofuels Consumption (CRT Source Category 1A) 3-127
3.11 Energy Sources of Precursor Greenhouse Gases 3-131
4. INDUSTRIAL PROCESSES AND PRODUCT USE 4-1
4.1 Cement Production (CRT Source Category 2A1) 4-10
4.2 Lime Production (CRT Source Category 2A2) 4-15
4.3 Glass Production (CRT Source Category 2A3) 4-21
4.4 Other Process Uses of Carbonates (CRT Source Category 2A4) 4-25
4.5 Ammonia Production (CRT Source Category 2B1) 4-32
4.6 Urea Consumption for Non-Agricultural Purposes (CRT Source Category 2B10) 4-37
4.7 Nitric Acid Production (CRT Source Category 2B2) 4-41
4.8 Adipic Acid Production (CRT Source Category 2B3) 4-45
4.9 Caprolactam, Glyoxal and Glyoxylic Acid Production (CRT Source Category 2B4) 4-49
4.10 Carbide Production and Consumption (CRT Source Category 2B5 & 2B10) 4-53
4.11 Titanium Dioxide Production (CRT Source Category 2B6) 4-57
4.12 Soda Ash Production (CRT Source Category 2B7) 4-61
4.13 Petrochemical Production (CRT Source Category 2B8) 4-64
4.14 HCFC-22 Production (CRT Source Category 2B9a) 4-73
4.15 Production of Fluorochemicals Other Than HCFC-22 (CRT Source Category 2B9b) 4-76
4.16 Carbon Dioxide Consumption (CRT Source Category 2B10) 4-96
4.17 Phosphoric Acid Production (CRT Source Category 2B10) 4-100
4.18 Iron and Steel Production (CRT Source Category 2C1) and Metallurgical Coke Production 4-104
4.19 Ferroalloy Production (CRT Source Category 2C2) 4-116
4.20 Aluminum Production (CRT Source Category 2C3) 4-121
4.21 Magnesium Production and Processing (CRT Source Category 2C4) 4-127
4.22 Lead Production (CRT Source Category 2C5) 4-133
4.23 Zinc Production (CRT Source Category 2C6) 4-137
4.24 Electronics Industry (CRT Source Category 2E) 4-143
4.25 Substitution of Ozone Depleting Substances (CRT Source Category 2F) 4-161
4.26 Electrical Equipment (CRT Source Category 2G1) 4-168
4.27 SF_6 and PFCs from Other Product Use (CRT Source Category 2G.2) 4-178

4.28 Nitrous Oxide from Product Uses (CRT Source Category 2G3) 4-183
4.29 Industrial Processes and Product Use Sources of Precursor Gases 4-186
5. AGRICULTURE 5-1
5.1 Enteric Fermentation (CRT Source Category 3A) 5-4
5.2 Manure Management (CRT Source Category 3B) 5-11
5.3 Rice Cultivation (CRT Source Category 3C) 5-21
5.4 Agricultural Soil Management (CRT Source Category 3D) 5-28
5.5 Liming (CRT Source Category 3G) 5-47
5.6 Urea Fertilization (CRT Source Category 3H) 5-50
5.7 Field Burning of Agricultural Residues (CRT Source Category 3F) 5-53
6. LAND USE, LAND-USE CHANGE, AND FORESTRY 6-1
6.1 Representation of the U.S. Land Base 6-9
6.2 Forest Land Remaining Forest Land (CRT Category 4A1) 6-25
6.3 Land Converted to Forest Land (CRT Category 4A2) 6-53
6.4 Cropland Remaining Cropland (CRT Category 4B1) 6-61
6.5 Land Converted to Cropland (CRT Category 4B2) 6-74
6.6 Grassland Remaining Grassland (CRT Category 4C1) 6-81
6.7 Land Converted to Grassland (CRT Category 4C2) 6-93
6.8 Wetlands Remaining Wetlands (CRT Category 4D1) 6-101
6.9 Land Converted to Wetlands (CRT Source Category 4D2) 6-144
6.10 Settlements Remaining Settlements (CRT Category 4E1) 6-166
6.11 Land Converted to Settlements (CRT Category 4E2) 6-187
6.12 Other Land Remaining Other Land (CRT Category 4F1) 6-194
6.13 Land Converted to Other Land (CRT Category 4F2) 6-194
7. WASTE 7-1
7.1 Landfills (CRT Source Category 5A1) 7-4
7.2 Wastewater Treatment and Discharge (CRT Source Category 5D) 7-19
7.3 Composting (CRT Source Category 5B1) 7-54
7.4 Anaerobic Digestion at Biogas Facilities (CRT Source Category 5B2) 7-58
7.5 Waste Incineration (CRT Source Category 5C1) 7-64
7.6 Waste Sources of Precursor Greenhouse Gases 7-65
8. OTHER 8-1

Executive Summary

An inventory that identifies and quantifies a country's anthropogenic[1] sources and sinks of greenhouse gas emissions and removals is essential for addressing climate change. This *Inventory* adheres to both (1) a comprehensive and detailed set of methodologies for estimating national sources and sinks of anthropogenic greenhouse gases, and (2) a common and consistent format that enables Parties to the Paris Agreement and United Nations Framework Convention on Climate Change (UNFCCC) to compare the relative contribution of different greenhouse gases emissions and removals to climate change.

The United States is party to both the 1992 UNFCCC and the 2015 Paris Agreement. The Paris Agreement set a global temperature goal – holding the increase in the global average temperature to well below 2°C above pre-industrial levels and pursuing efforts to limit the increase to 1.5°C – that articulates with greater precision States' views on what is necessary to meet the UNFCCC's objective of "stabiliz[ing] … greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system.[2]

The United States is committed to submitting a national inventory of anthropogenic emission sources and removals by sinks of greenhouse gases by April 15 of each year. The United States has prepared this report, in conjunction with Common Reporting Tables (CRTs) that accompany this report, consistent with its obligations under those agreements.

This Executive Summary provides the latest information on U.S. anthropogenic greenhouse gas emission trends from 1990 through 2022. The structure of this report is consistent with requirements under the Paris Agreement and the UNFCCC on national greenhouse gas inventory reporting, as discussed in Box ES-1. Throughout this report, emission and sink estimates are grouped into five reporting sectors (i.e., chapters): Energy, IPPU, Agriculture, Land Use, Land-Use Change, and Forestry (LULUCF), and Waste. In describing trends (Chapter 2), emissions and sinks are also summarized according to commonly used economic sector categories: residential, commercial, industry, transportation, electric power, and agriculture. See Box 2-1 for more information on how economic sectors are defined.

Box ES-1: Methodological Approach for Estimating and Reporting U.S. Emissions and Removals, including Relationship to EPA's Greenhouse Gas Reporting Program

Consistent with Article 13.7(a) of the Paris Agreement and Article 4.1(a) of the UNFCCC as well as relevant decisions under those agreements, the emissions and removals presented in this report and this chapter are organized by source and sink categories and calculated using internationally accepted methods in the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (*2006 IPCC Guidelines)* and, where appropriate, its supplements and refinements. Additionally, the calculated emissions and removals in a given year for the United States are presented in a common manner in line with the reporting guidelines for the reporting of inventories

[1] The term "anthropogenic," in this context, refers to greenhouse gas emissions and removals that are a direct result of human activities or are the result of natural processes that have been affected by human activities (IPCC 2006).

[2] See Paris Agreement, Article 2.1(a); UNFCCC, Article 2.

under the Paris Agreement and the UNFCCC. The Parties' use of consistent methods to calculate emissions and removals for their inventories helps to ensure that these reports are comparable. The presentation of emissions and removals provided in this *Inventory* does not preclude alternative examinations (e.g., economic sectors). Rather, this *Inventory* presents emissions and removals in a common format consistent with how Parties are to report their national inventories under the Paris Agreement and the UNFCCC. The report itself, and this chapter, follows this common format, and provides an explanation of the application of methods used to calculate emissions and removals.

EPA also collects greenhouse gas emissions data from individual facilities and suppliers of certain fossil fuels and industrial gases through its Greenhouse Gas Reporting Program (GHGRP), which is complementary to the U.S. Inventory.[3] The GHGRP applies to direct greenhouse gas emitters, fossil fuel suppliers, industrial greenhouse gas suppliers, and facilities that inject carbon dioxide (CO_2) underground for sequestration or other reasons and requires reporting by over 8,000 sources or suppliers in 41 industrial categories.[4] Annual reporting is at the facility level, except for certain suppliers of fossil fuels and industrial greenhouse gases. In general, the threshold for reporting is 25,000 metric tons or more of CO_2 Eq. per year. Facilities in most source categories subject to GHGRP began reporting for the 2010 reporting year while additional types of industrial operations began reporting for reporting year 2011.[5] Methodologies used in EPA's GHGRP are consistent with the 2006 IPCC Guidelines. While the GHGRP does not provide full coverage of total annual U.S. greenhouse gas emissions and removals (e.g., the GHGRP excludes emissions from the agricultural, land use, and forestry sectors), it is an important input to the calculations of national-level emissions in this *Inventory*.

The GHGRP dataset provides not only annual emissions information, but also other annual information such as activity data and emission factors that can improve and refine national emission estimates over time. GHGRP data also allow EPA to disaggregate national inventory estimates in new ways that can highlight differences across regions and subcategories of emissions, along with enhancing the application of QA/QC procedures and assessment of uncertainties. See Annex 9 for more information on specific uses of GHGRP data in the Inventory (e.g., use of Subpart W data in compiling estimates for natural gas systems).

ES.1 Background Information

Greenhouse gases absorb infrared radiation, trapping heat in the atmosphere and making the planet warmer. The most important greenhouse gases directly emitted by human activities include carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), and several fluorine-containing halogenated substances (HFCs, PFCs, SF_6 and NF_3). Although CO_2, CH_4, and N_2O occur naturally in the atmosphere, human activities have changed their atmospheric concentrations. From the pre-industrial era (i.e., ending about 1750) to 2022, concentrations of these greenhouse gases have increased globally by 49.5, 161.9, and 24.3 percent, respectively (IPCC 2013; NOAA/ESRL 2024a, 2024b, 2024c). This annual report estimates the total national greenhouse gas emissions and removals associated with human activities across the United States.

[3] On October 30, 2009, EPA promulgated a rule requiring annual reporting of greenhouse gas data from large greenhouse gas emissions sources in the United States. Implementation of the rule, codified at 40 CFR Part 98, is referred to as EPA's Greenhouse Gas Reporting Program (GHGRP).

Global Warming Potentials

The IPCC developed the global warming potential (GWP) concept to compare the ability of a greenhouse gas to trap heat in the atmosphere relative to another gas. A GWP is a quantified measure of the relative globally averaged radiative forcing impacts of emissions of a particular greenhouse gas over time. The GWP of a greenhouse gas is defined as the ratio of the accumulated radiative forcing within a specific time horizon caused by emitting 1 kilogram of the gas, relative to that of the reference gas CO_2 (IPCC 2021); therefore, CO_2-equivalent emissions are provided in million metric tons of CO_2 equivalent (MMT CO_2 Eq.) for non-CO_2 greenhouse gases.[6,7] All estimates are provided throughout the main report in both CO_2 equivalents and unweighted units, while estimates for all gases in this Executive Summary are presented in units of MMT CO_2 Eq. Emissions by gas in unweighted mass kilotons are also provided in the Trends chapter and individual sector chapters of this report, and in the CRTs that are included in the submission to the UNFCCC.

Recent decisions under the Paris Agreement[8] and the UNFCCC[9] require Parties to use 100-year GWP values from the IPCC *Fifth Assessment Report* (AR5) for calculating CO_2-equivalents in their national reporting (IPCC 2013) by the end of 2024. This reflects updated science and ensures that national greenhouse gas inventories reported by all nations are comparable. This report reflects CO_2-equivalent greenhouse gas emission totals using 100-year AR5 GWP values. A comparison of emission values with the IPCC *Sixth Assessment Report* (AR6) (IPCC 2021) values can be found in Annex 6.1 of this report. The 100-year GWP values used in this report are listed below in Table ES-1.

Table ES-1: Global Warming Potentials (100-Year Time Horizon) Used in this Report

Gas	GWP
CO_2	1
CH_4[a]	28
N_2O	265
HFCs	up to 12,400
PFCs	up to 11,100
SF_6	23,500
NF_3	16,100
Other Fluorinated Gases	See Annex 6

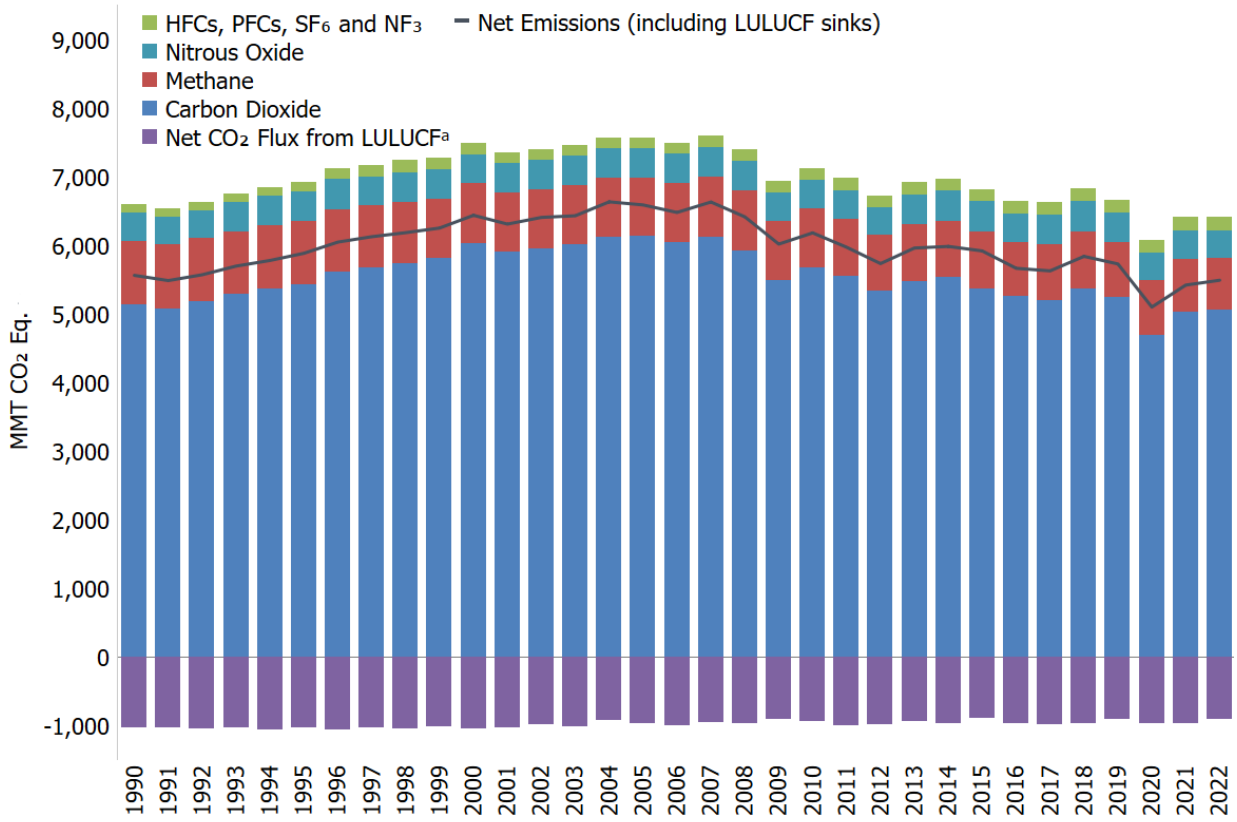
[a] The GWP of CH_4 includes the direct effects and those indirect effects due to the production of tropospheric ozone and stratospheric water vapor. The indirect effect due to production of CO_2 is not included. See Annex 6 for additional information.
Source: IPCC (2013).

[6] Carbon comprises 12/44 of carbon dioxide by weight.

[7] One million metric ton is equal to 10^{12} grams or one teragram.

[8] See Annex to decision 18/CMA.1, available online at https://unfccc.int/sites/default/files/resource/CMA2018_03a02E.pdf.

[9] See paragraphs 1 and 2 of the decision on common metrics adopted at the 27th UNFCCC Conference of Parties (COP27), available online at https://unfccc.int/sites/default/files/resource/cp2022_10a01_E.pdf.



ES.2 Recent Trends in U.S. Greenhouse Gas Emissions and Sinks

In 2022, total gross U.S. greenhouse gas emissions were 6,343.2 million metric tons of carbon dioxide equivalent (MMT CO_2 Eq.).[10] Total gross U.S. emissions decreased by 3.0 percent from 1990 to 2022, down from a high of 15.2 percent above 1990 levels in 2007. Gross emissions increased from 2021 to 2022 by 0.2 percent (14.4 MMT CO_2 Eq.). Net emissions (including sinks) were 5,489.0 MMT CO_2 Eq. in 2022. Overall, net emissions increased by 1.3 percent from 2021 to 2022 and decreased by 16.7 percent from 2005 levels as shown in Table ES-2. Between 2021 and 2022, the increase in total greenhouse gas emissions was driven largely by an increase in CO_2 emissions from fossil fuel combustion across most end-use sectors due in part to increased energy use from the continued rebound of economic activity after the height of the COVID-19 pandemic. In 2022, CO_2 emissions from fossil fuel combustion increased by 1.0 percent relative to the previous year and were 1.1 percent below emissions in 1990. Carbon dioxide emissions from natural gas use increased by 5.2 percent (84.8 MMT CO_2 Eq.) from 2021, while CO_2 emissions from coal consumption decreased by 6.1 percent (58.6 MMT CO_2 Eq.) from 2021 to 2022. The increase in natural gas consumption and associated emissions in 2022 is observed across all sectors except U.S. Territories, while the coal decrease is due to reduced use in the electric power sector. Emissions from petroleum use also increased by 0.9 percent (19.0 MMT CO_2 Eq.) from 2021 to 2022. Carbon sequestration from the Land Use, Land-Use Change, and Forestry (LULUCF) sector offset 14.5 percent of total emissions in 2022.

Figure ES-1 and Figure ES-2 illustrate the overall trends in total U.S. emissions by gas and annual percent changes, and Table ES-2 provides information on trends in gross U.S. greenhouse gas emissions and sinks for 1990 through 2022. Unless otherwise stated, all tables and figures provide total gross emissions and exclude the greenhouse gas fluxes from the LULUCF sector. For more information about the LULUCF sector, see Section ES-3.

[10] The gross emissions total presented in this report for the United States excludes emissions and removals from Land Use, Land-Use Change, and Forestry (LULUCF). The net emissions total presented in this report for the United States includes emissions and removals from LULUCF.

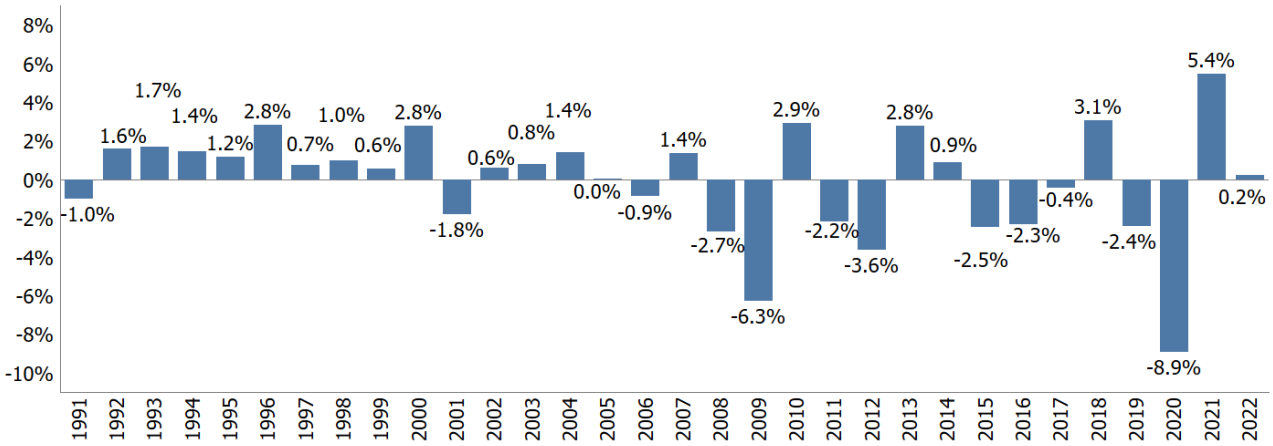
Figure ES-1: U.S. Greenhouse Gas Emissions and Sinks by Gas

[a] The term "flux" is used to describe the exchange of CO_2 to and from the atmosphere, with net flux being either positive or negative depending on the overall balance. Removal and long-term storage of CO_2 from the atmosphere is also referred to as "carbon sequestration."

Table ES-2: Recent Trends in U.S. Greenhouse Gas Emissions and Sinks (MMT CO_2 Eq.)

Gas/Source	1990	2005	2018	2019	2020	2021	2022	Percent Change Since 1990
CO_2	5,131.6	6,126.9	5,362.2	5,234.5	4,689.0	5,017.2	5,053.0	-1.5%
CH_4 (excludes LULUCF sources)[a]	871.7	795.4	771.5	754.3	735.3	720.5	702.4	-19.4%
N_2O (excludes LULUCF sources)[a]	408.2	419.2	439.5	416.4	391.2	398.2	389.7	-4.5%
HFCs	47.7	121.7	163.9	168.2	170.3	177.0	182.8	282.9%
PFCs	39.5	10.2	7.4	7.3	6.6	6.3	6.7	-83.1%
SF_6	37.9	20.2	7.6	8.4	8.1	8.5	7.6	-80.0%
NF_3	0.3	1.0	0.7	1.1	1.3	1.1	1.1	238.3%
Total Gross Emissions (Sources)[a]	**6,536.9**	**7,494.6**	**6,752.7**	**6,590.1**	**6,001.8**	**6,328.8**	**6,343.2**	**-3.0%**
LULUCF Emissions[b]	58.0	68.9	62.8	58.0	68.4	72.9	67.6	16.5%
CH_4	53.1	58.5	55.5	52.5	59.3	62.1	58.4	10.0%
N_2O	4.8	10.3	7.3	5.5	9.1	10.7	9.1	88.3%
LULUCF Carbon Stock Change[c]	(1034.7)	(976.6)	(978.3)	(921.6)	(972.8)	(983.4)	(921.8)	-10.9%
LULUCF Sector Net Total[d]	(976.7)	(907.7)	(915.5)	(863.6)	(904.4)	(910.6)	(854.2)	-12.5%
Net Emissions (Sources and Sinks)	**5,560.2**	**6,586.9**	**5,837.3**	**5,726.6**	**5,097.4**	**5,418.2**	**5,489.0**	**-1.3%**

[a] Gross emissions totals do not include CH_4 and N_2O emissions from LULUCF. LULUCF CH_4 and N_2O emissions are included in net emission totals.



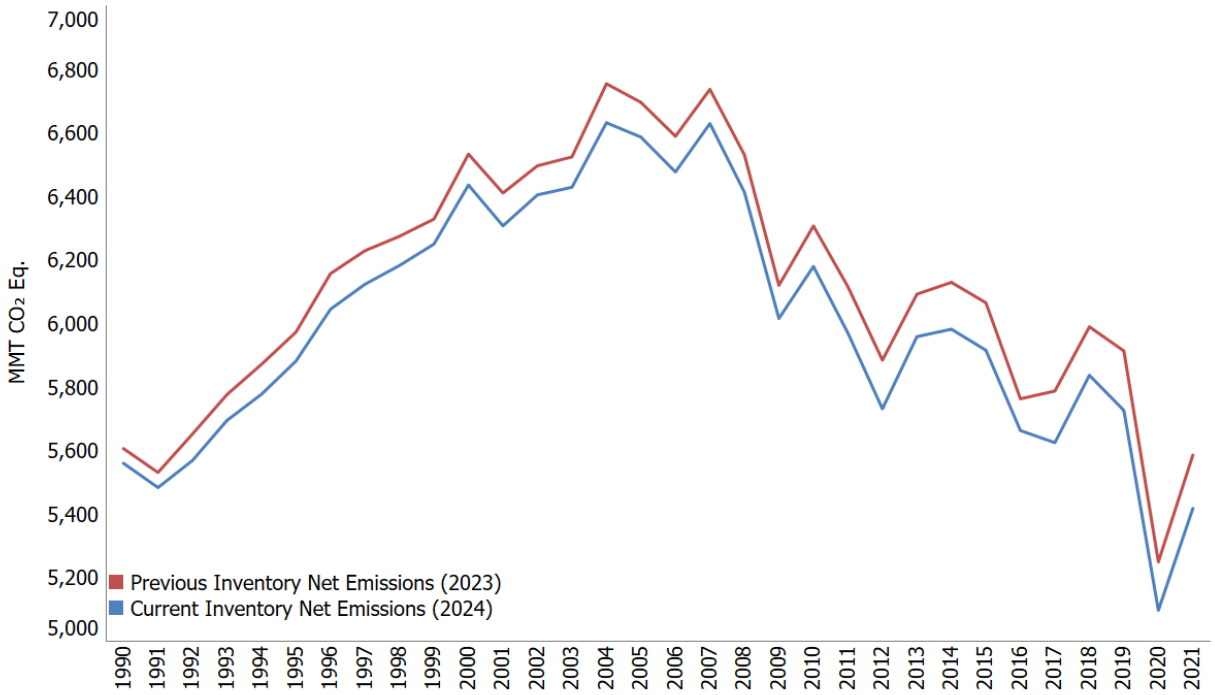
[b] LULUCF emissions subtotal of CH_4 and N_2O are reported separately from gross emissions totals. LULUCF emissions include the CH_4 and N_2O emissions reported for peatlands remaining peatlands, forest fires, drained organic soils, grassland fires, and coastal wetlands remaining coastal wetlands; CH_4 emissions from land converted to coastal wetlands, flooded land remaining flooded land, and land converted to flooded land; and N_2O emissions from forest soils and settlement soils.

[c] LULUCF carbon stock change is the net carbon stock change from the following categories: forest land remaining forest land, land converted to forest land, cropland remaining cropland, land converted to cropland, grassland remaining grassland, land converted to grassland, wetlands remaining wetlands, land converted to wetlands, settlements remaining settlements, and land converted to settlements.

[d] The LULUCF sector net total is the net sum of all LULUCF CH_4 and N_2O emissions to the atmosphere plus LULUCF net carbon stock changes.

Notes: Total (gross) are emissions presented without LULUCF. Net emissions are presented with LULUCF. Totals may not sum due to independent rounding. Parentheses indicate negative values or sequestration.

Figure ES-2: Annual Percent Change in Gross U.S. Greenhouse Gas Emissions and Sinks Relative to the Previous Year



Improvements and Recalculations Relative to the Previous Inventory

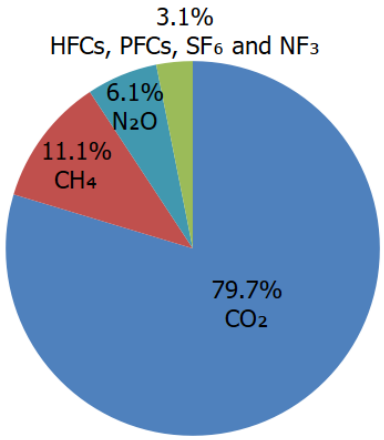
Each year, some emission and removal estimates in the *Inventory* are recalculated and revised to incorporate improved methods and/or data. The most common reason for recalculating U.S. greenhouse gas emission estimates is to update recent historical data. Changes in historical data are generally the result of changes in data supplied by other U.S. government agencies or organizations, as they continue to make refinements and improvements. These improvements are implemented consistently across the previous *Inventory's* time series, as necessary, (i.e., 1990 to 2021) to ensure that the trend is accurate.

Collectively, all methodological changes and historical data updates made in the current *Inventory* resulted in an annual average decrease of 114.8 MMT CO_2 Eq. (1.9 percent) for net emissions.

Figure ES-3: Impacts of Recalculations on Net Emissions

Below are categories with methodological and data-related recalculations resulting in an average change of greater than 2.0 MMT CO_2 Eq. over the time series.

- Forest land remaining forest land: changes in forest carbon stocks (CO_2)
- Land converted to grassland: changes in all ecosystem carbon stocks (CO_2)
- Land converted to cropland: changes in all ecosystem carbon stocks (CO_2)
- Grassland remaining grassland: changes in all ecosystem carbon stocks (CO_2)
- Non-energy use of fuels (CO_2)
- Land converted to settlements: changes in all ecosystem carbon stocks (CO_2)
- Fluorochemical production (HFCs)
- Fossil fuel combustion (CO_2)
- Cropland remaining cropland: changes in all ecosystem carbon stocks (CO_2)
- Agricultural Soil Management (N_2O)
- Petroleum Systems (CH_4)
- Wetlands Remaining Wetlands: changes in soil carbon stocks in coastal wetlands (CO_2)



In addition, the current *Inventory* includes new categories not included in the previous *Inventory* that improve completeness of the national estimates: CO_2 emissions from ceramics production and non-metallurgical magnesia production within other process use of carbonates category, fluorinated gases from fluorochemical production other than HCFC-22 within the fluorochemical production category, and managed forest land in Hawaii and several U.S. Territories. This report also now includes SF_6 and PFCs from product uses.

In each *Inventory*, the results of all methodological changes and historical data updates and the inclusion of new sources and sink estimates are summarized in the Recalculations and Improvements chapter (Chapter 9). For more detailed descriptions of each recalculation including references for data, please see the respective source or sink category description(s) within the relevant report chapter (the Energy chapter [Chapter 3], the Industrial Processes and Product Use [IPPU] chapter [Chapter 4], the Agriculture chapter [Chapter 5], the Land Use, Land-Use Change, and Forestry [LULUCF] chapter [Chapter 6], and the Waste chapter [Chapter 7]).

Emissions and Sinks by Greenhouse Gas

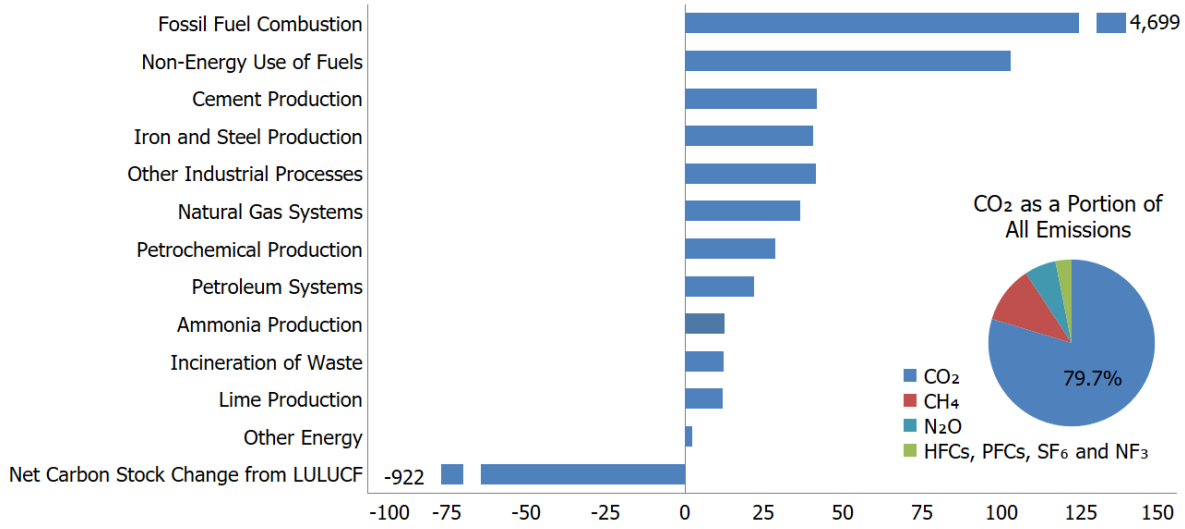
Figure ES-4 illustrates the relative contribution of the greenhouse gases to total gross U.S. emissions in 2022, weighted by GWP. The primary greenhouse gas emitted by human activities in the United States is CO_2, representing 79.7 percent of total greenhouse gas emissions. The largest source of CO_2 and of overall greenhouse gas emissions is fossil fuel combustion, primarily from transportation and power generation. Methane (CH_4) emissions account for 11.1 percent of emissions. The major sources of methane include enteric fermentation associated with domestic livestock, natural gas systems, and decomposition of wastes in landfills. Agricultural soil management, wastewater treatment, stationary sources of fuel combustion, and manure management are the major sources of N_2O emissions. Emissions of substitutes for ozone depleting substances are the primary contributor to aggregate hydrofluorocarbon (HFC) emissions. Perfluorocarbon (PFC) emissions are primarily attributable to electronics manufacturing, fluorochemical production, and primary aluminum production. Electrical equipment systems account for most sulfur hexafluoride (SF_6) emissions. The electronics industry and fluorochemical production are the only sources of nitrogen trifluoride (NF_3) emissions. U.S. greenhouse gas emissions were partly offset by carbon (C) sequestration in forests, trees in urban areas, agricultural soils, landfilled yard trimmings and food scraps, and coastal wetlands, which together offset 14.5 percent of gross total emissions in 2022 (as reflected in Figure ES-1). The following sections describe each gas's contribution to total U.S. greenhouse gas emissions in more detail.

Figure ES-4: 2022 Total Gross U.S. Greenhouse Gas Emissions by Gas (Percentages based on MMT CO_2 Eq.)

Note: Emissions and removals from Land Use, Land-Use Change, and Forestry are excluded from the figure above.

Carbon Dioxide Emissions

The global carbon cycle is made up of large carbon flows and reservoirs. Billions of tons of carbon in the form of CO_2 are absorbed by oceans and living biomass (i.e., sinks) and are emitted to the atmosphere annually through natural processes (i.e., sources). When in equilibrium, global carbon fluxes among these various reservoirs are roughly balanced.[11]



Since the Industrial Revolution (i.e., about 1750), global atmospheric concentrations of CO_2 have risen 49.5 percent (IPCC 2013; NOAA/ESRL 2024a), principally due to the combustion of fossil fuels for energy. Globally, an estimated

[11] The term "flux" is used to describe the exchange of CO_2 to and from the atmosphere, with net flux being either positive or negative depending on the overall balance. Removal and long-term storage of CO_2 from the atmosphere is also referred to as "carbon sequestration."

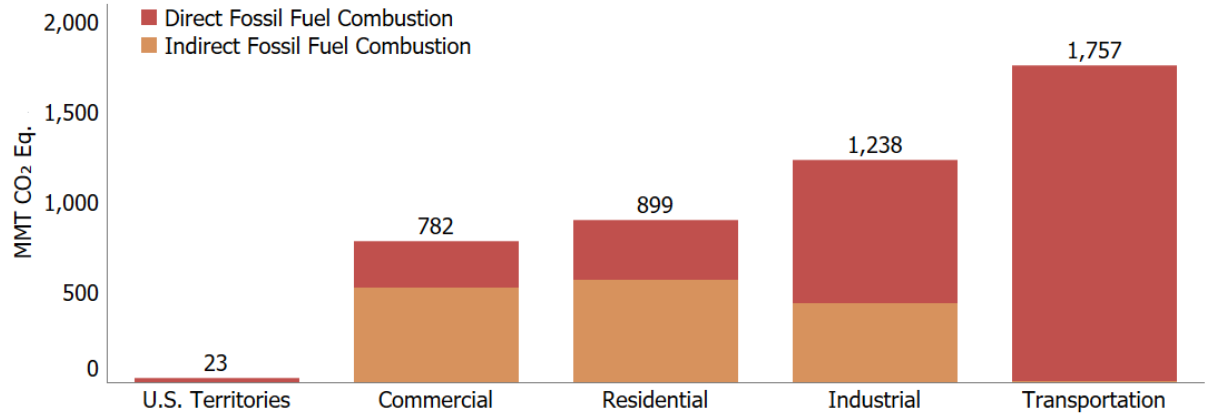
33,423 MMT of CO_2 were added to the atmosphere through the combustion of fossil fuels in 2022, of which the United States accounted for approximately 14.1 percent.[12]

Overall CO_2 emissions have decreased by 1.5 percent since 1990 and increased by 0.7 percent since 2021, consistent with trends in fuel combustion emissions. Within the United States, fossil fuel combustion accounted for 93.0 percent of CO_2 gross emissions in 2022. Nationally, the transportation sector was the largest emitter of CO_2 in 2022 followed by electric power generation. There are 27 additional sources of CO_2 emissions included in the *Inventory* (see [Table 2-1 in Trends]). Although not illustrated in Table ES-4, changes in land use and forestry practices can also lead to net CO_2 emissions (e.g., through conversion of forest land to agricultural or urban use) or to a net sink for CO_2 (e.g., through net additions to forest biomass). See more on these emissions and removals in Table ES-4.

Figure ES-5: 2022 Sources of CO_2 Emissions

Note: "Other Industrial Processes" includes emissions from aluminum production, carbide production and consumption, carbon dioxide consumption, ferroalloy production, glass production, lead production, magnesium production, other process uses of carbonates, phosphoric acid production, substitution of ozone depleting substances, soda ash production, titanium dioxide production, urea consumption for non-agricultural purposes, and zinc production. "Other Energy" includes emissions from abandoned oil and gas wells and coal mining.

Between 1990 and 2022, CO_2 emissions from fossil fuel combustion decreased by 1.1 percent; emissions decreased by 18.2 percent (1,044.7 MMT CO_2 Eq.) from 2005 levels; and from 2021 to 2022, these emissions increased by 1.0 percent (45.1 MMT CO_2 Eq.).



Historically, changes in emissions from fossil fuel combustion have been the driving factor affecting U.S. emission trends. Important drivers include changes in demand for energy and a general decline in the overall carbon intensity of fuels combusted for energy in recent years by non-transport sectors of the economy. Between 2019 and 2021, changes in economic activity and travel due to the COVID-19 pandemic and the subsequent recovery had significant impacts on energy use and fossil fuel combustion emissions.

The five major fuel-consuming economic sectors are transportation, electric power, industrial, residential, and commercial and are described below. Carbon dioxide emissions are produced by the electric power sector as fossil fuel is consumed to provide electricity to one of the other four economic sectors, or "end-use" sectors. In Figure

[12] Global CO_2 emissions from fossil fuel combustion were taken from International Energy Agency *Global energy-related CO_2 emissions, 1990-2022 – Charts.* Available at: https://www.iea.org/reports/co2-emissions-in-2022 (IEA 2022).

ES-6, electric power emissions have been distributed to each end-use sector on the basis of each sector's share of aggregate electricity use (i.e., indirect fossil fuel combustion). Greenhouse gas emissions from the commercial and residential and industry increase substantially when indirect emissions from electricity end-use are distributed, due to the relatively large share of electricity use by buildings (e.g., heating, ventilation, and air conditioning; lighting; and appliances) and use of electricity for powering industrial machinery.

Figure ES-6: 2022 End-Use Sector Emissions of CO_2 from Fossil Fuel Combustion

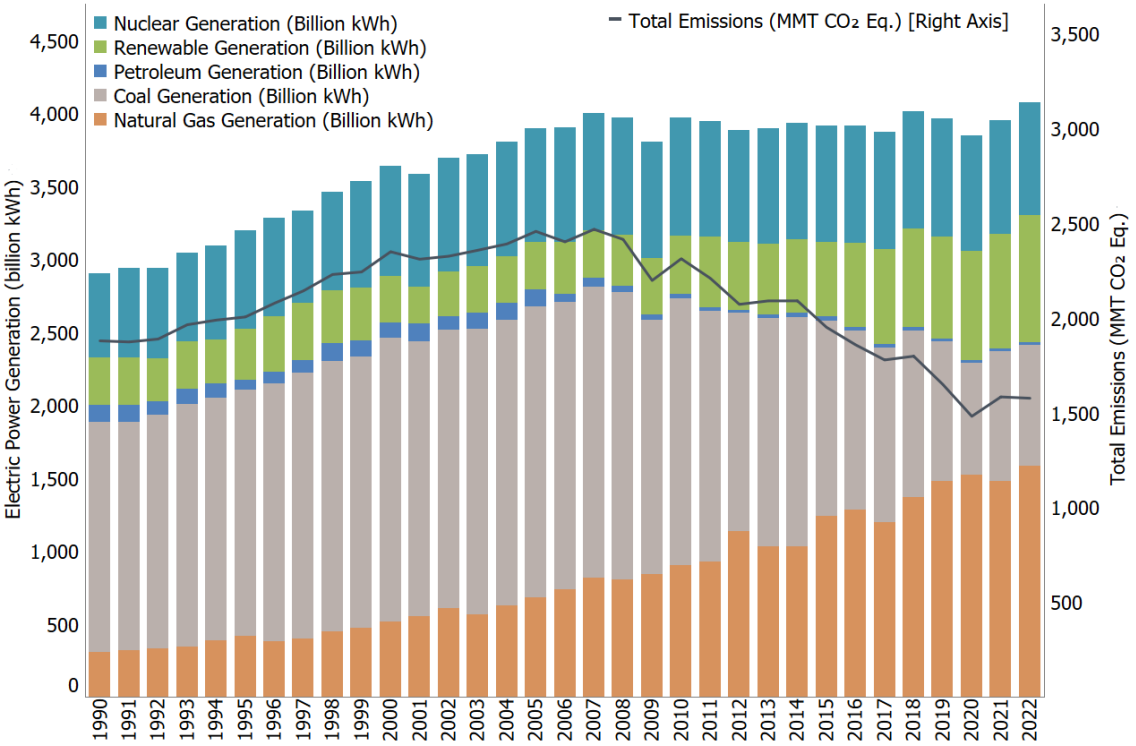
Transportation End-Use Sector. Transportation activities accounted for 37.4 percent of U.S. CO_2 emissions from fossil fuel combustion in 2022, with the largest contributors being light-duty trucks (36.8 percent), followed by medium- and heavy-duty trucks (23.0 percent) and passenger vehicles (20.6 percent). In terms of the overall trend from 1990 to 2022, total transportation CO_2 emissions increased due largely to increased demand for travel, which was a result of a confluence of factors including population growth, economic growth, urban sprawl, and low fuel prices during the beginning of this period. While an increased demand for travel has led to generally increasing CO_2 emissions since 1990, improvements in average new vehicle fuel economy since 2005 have slowed the rate of increase of CO_2 emissions. In 2022, petroleum-based products supplied 94.3 percent of the energy consumed for transportation, primarily from gasoline consumption in automobiles and other highway vehicles (51.9 percent).

Industrial End-Use Sector. Industrial CO_2 emissions, resulting both directly from the combustion of fossil fuels[13] and indirectly from the generation of electricity that is used by industry, accounted for 26.3 percent of CO_2 emissions from fossil fuel combustion in 2022. Approximately 64.7 percent of these emissions resulted from direct fossil fuel combustion to produce steam and/or heat for industrial processes. The remaining emissions resulted from the use of electricity for motors, electric furnaces, ovens, lighting, and other applications. Total direct and indirect emissions from the industrial sector have declined by 20.8 percent since 1990. This decline is due to structural changes in the U.S. economy (i.e., shifts from a manufacturing-based to a service-based economy), fuel switching, and efficiency improvements. From 2021 to 2022, total energy use in the industrial sector increased by 1.8 percent due to an increase in total industrial production and manufacturing output.

Residential and Commercial End-Use Sectors. The residential and commercial end-use sectors accounted for 19.1 and 16.6 percent, respectively, of CO_2 emissions from fossil fuel combustion in 2022 including indirect emissions from electricity. The residential and commercial sectors relied heavily on electricity for meeting energy demands, with 62.9 and 66.9 percent, respectively, of their emissions attributable to electricity use for building -related activities such as lighting, heating, cooling, and operating appliances. The remaining emissions were due to the consumption of natural gas and petroleum for heating and cooking. Total direct and indirect emissions from the residential sector have decreased by 3.4 percent since 1990, and total direct and indirect emissions from the commercial sector have increased by 2.1 percent since 1990. From 2021 to 2022, an increase in heating degree

[13] This does not include fossil fuels used as feedstocks and reductants, which are reported under IPPU emissions.

days (7.9 percent) increased energy demand for heating in the residential and commercial sectors; also, a 4.3 percent increase in cooling degree days compared to 2021 increased demand for air conditioning in the residential and commercial sectors. Combined, this resulted in a 2.5 percent increase in residential sector energy use. From 2021 to 2022, energy use in the commercial sector increased by 4.7 percent.



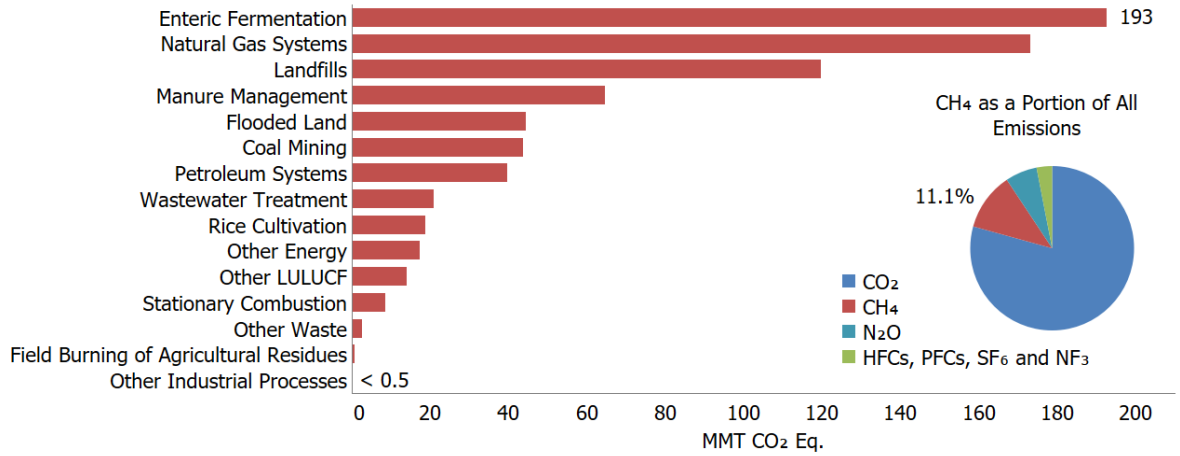
Electric Power. The United States relies on electricity to meet a significant portion of its energy demands. Electricity generators used 30.5 percent of U.S. energy from fossil fuels and emitted 32.6 percent of the CO_2 from fossil fuel combustion in 2022. The type of energy source used to generate electricity, and the mix of electric generation resources used to meet demand, are the main factors influencing emissions.[14] Coal-fired electric generation (in kilowatt-hours [kWh]) decreased from 54.1 percent of generation in 1990 to 20.3 percent in 2022.[15] This corresponded with an increase in natural gas generation and non-fossil fuel renewable energy generation, largely from wind and solar energy. Natural gas generation (in kWh) represented 10.7 percent of electric power generation in 1990 and increased over the 33-year period to represent 38.8 percent of electric power generation in 2022. Wind and solar generation (in kWh) represented 0.1 percent of electric power generation in 1990 and increased over the 33-year period to represent 14.2 percent of electric power generation in 2022. Between 2021 and 2022, coal electricity generation decreased by 10.2 percent, natural gas generation increased by 4.0 percent, and renewable energy generation increased by 7.6 percent.

Across the time series, changes in electricity generation and the carbon intensity of fuels used for electric power have a significant impact on CO_2 emissions. While CO_2 emissions from fossil fuel combustion in the electric power sector have decreased by 15.8 percent since 1990, the carbon intensity of the electric power sector, in terms of CO_2 Eq. per QBtu input, decreased by 27.6 percent during that same timeframe. This decoupling of the level of electric power generation and the resulting CO_2 emissions is shown in Figure ES-7.

[14] In line with the reporting requirements for inventories submitted under the UNFCCC, CO_2 emissions from biomass combustion have been estimated separately from fossil fuel CO_2 emissions and are not included in the electricity sector totals and trends discussed in this section. Net carbon fluxes from changes in biogenic carbon reservoirs are accounted for in the estimates for Land Use, Land-Use Change, and Forestry.

[15] Values represent electricity *net* generation from the electric power sector. See Table 7.2b Electricity Net Generation: Electric Power Sector of EIA (2024).

Figure ES-7: Electric Power Generation and Emissions



Other significant CO_2 trends included the following:

- Carbon dioxide emissions from natural gas and petroleum systems combined accounted for 1.2 percent of CO_2 emissions and 0.9 percent of total gross emissions in 2022. These emissions increased by 39.1 percent (16.4 MMT CO_2 Eq.) from 1990 to 2022. This increase is due primarily to increases in the production segment, where flaring emissions from associated gas flaring, tanks, and miscellaneous production flaring have increased over time.
- Carbon dioxide emissions from iron and steel production and metallurgical coke production accounted for 0.8 percent of CO_2 and 0.6 percent of total gross emissions. Emissions decreased by 61.2 percent (64.1 MMT CO_2 Eq.) from 1990 through 2022. This decrease was primarily due to restructuring of the industry, technological improvements, and increased scrap steel utilization.
- Total carbon stock change (i.e., net CO_2 removals) in the LULUCF sector decreased by 10.9 percent between 1990 and 2022. This decrease was primarily due to a decrease in the rate of net carbon accumulation in forest carbon stocks and cropland remaining cropland, as well as an increase in emissions from land converted to settlements.

Methane Emissions

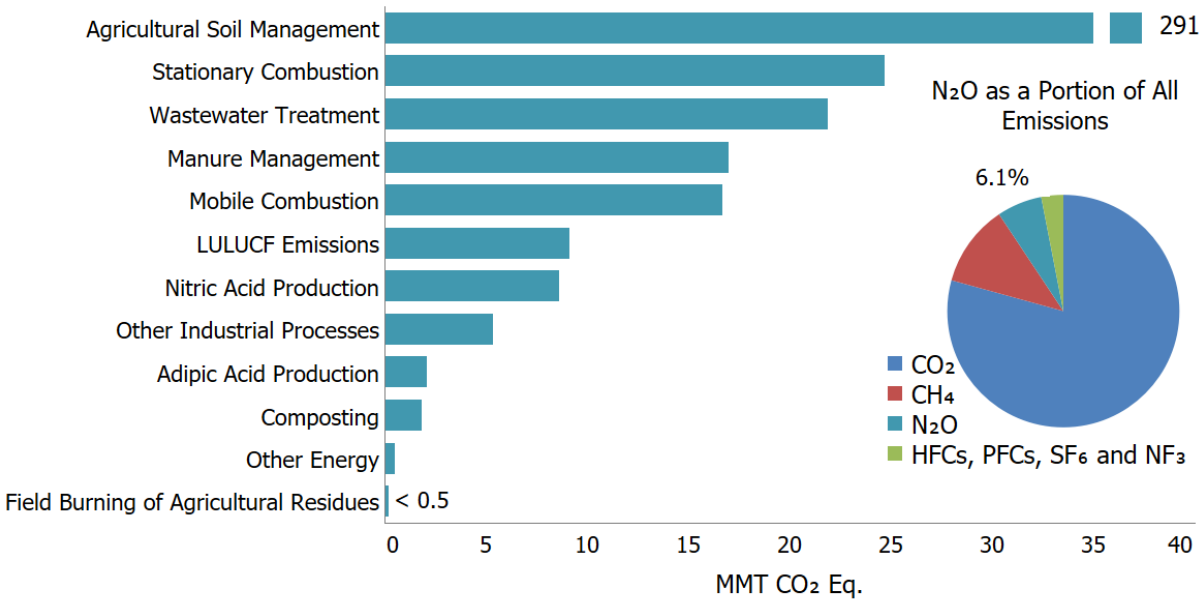
Methane (CH_4) is significantly more effective than CO_2 at trapping heat in the atmosphere: by a factor of 28 over a 100-year time frame based on the IPCC *Fifth Assessment Report* estimate (IPCC 2013). Over the last 250 years, the concentration of CH_4 in the atmosphere increased by 161.9 percent (IPCC 2013; NOAA/ESRL 2024b). Within the United States, the main anthropogenic sources of CH_4 include enteric fermentation from domestic livestock, natural gas systems, landfills, domestic livestock manure management, flooded land, coal mining, and petroleum systems (see Figure ES-8).

Figure ES-8: 2022 Sources of CH_4 Emissions

Note: "Other Energy" includes CH_4 emissions from abandoned oil and gas wells, abandoned underground coal mines, incineration of waste, and mobile combustion. "Other Waste" includes CH_4 emissions from anaerobic digestion at biogas facilities and composting. "Other Industrial Processes" includes CH_4 emissions from carbide production and consumption, ferroalloy production, iron and steel production and metallurgical coke production, and petrochemical production. "Other LULUCF" includes the CH_4 reported for peatlands remaining peatlands, forest fires, drained organic soils, grassland fires, coastal wetlands remaining coastal wetlands, and land converted to coastal wetlands.

Overall, CH_4 emissions in the United States in 2022, including LULUCF CH_4 emissions, accounted for 760.8 MMT CO_2 Eq., representing a decrease of 17.7 percent (164.0 MMT CO_2 Eq.) since 1990 and 2.8 percent decrease (21.8 MMT CO_2 Eq.) since 2021. Significant trends for the largest sources of anthropogenic CH_4 emissions include the following:

- Enteric fermentation was the largest anthropogenic source of CH_4 emissions in the United States in 2022, accounting for 27.4 percent of total CH_4 emissions and 3.0 percent of total gross emissions. Emissions have increased by 5.2 percent (9.5 MMT CO_2 Eq.) since 1990. This increase in emissions from 1990 to 2022 generally follows the increasing trends in cattle populations.
- Natural gas systems were the second largest anthropogenic source category of CH_4 emissions in the United States in 2022, accounting for 24.6 percent of total CH_4 emissions and 2.7 percent of total gross emissions. Emissions have decreased by 20.9 percent (45.7 MMT CO_2 Eq.) since 1990, largely due to decreases in emissions from distribution, transmission, and storage.
- Landfills were the third largest anthropogenic source of CH_4 emissions in the United States in 2022, accounting for 17.1 percent of total CH_4 emissions and 1.9 percent of total gross emissions and representing a decrease of 39.4 percent (78.0 MMT CO_2 Eq.) since 1990, with small year-to-year increases. This downward trend in emissions coincided with increased landfill gas collection and control systems, and a reduction of decomposable materials (i.e., paper and paperboard, food scraps, and yard trimmings) discarded in MSW landfills over the time series.[16]



Nitrous Oxide Emissions

Nitrous oxide (N_2O) is produced by biological processes that occur in soil and water and by a variety of anthropogenic activities in the agricultural, energy, industrial, and waste management fields. While total N_2O emissions are much lower than CO_2 emissions, N_2O is 265 times more powerful than CO_2 at trapping heat in the atmosphere over a 100-year time frame (IPCC 2013). Since 1750, the global atmospheric concentration of N_2O has

[16] Carbon dioxide emissions from landfills are not included specifically in summing waste sector totals. Net carbon fluxes from changes in biogenic carbon reservoirs and decay of disposed wood products are accounted for in the estimates for LULUCF.

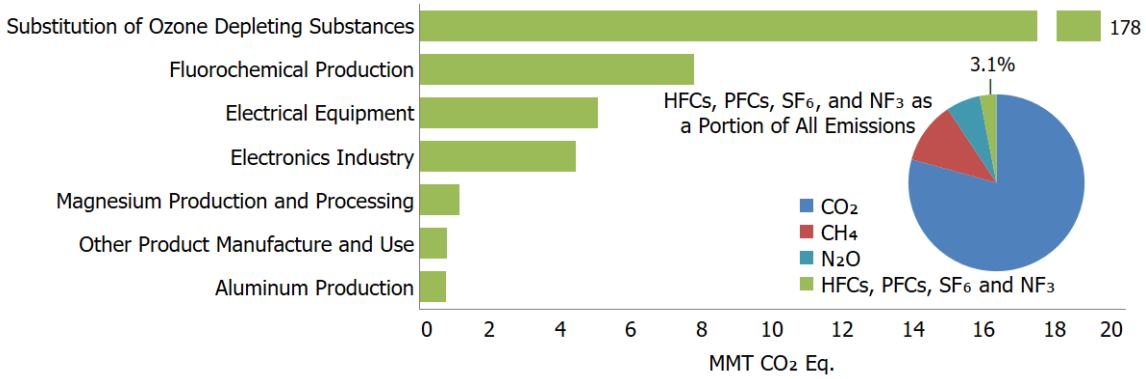
risen by 24.3 percent (IPCC 2013; NOAA/ESRL 2024c). The main anthropogenic activities producing N_2O in the United States are agricultural soil management, wastewater treatment, stationary fuel combustion, manure management, fuel combustion in motor vehicles, and nitric acid production (see Figure ES-9).

Figure ES-9: 2022 Sources of N_2O Emissions

Note: "Other Industrial Processes" includes N_2O emissions from caprolactam, glyoxal, and glyoxylic acid production; the electronics industry; and product uses. "Other Energy" includes N_2O emissions from petroleum systems, natural gas systems, and incineration of waste. LULUCF emissions include N_2O emissions reported for peatlands remaining peatlands, forest fires, drained organic soils, grassland fires, coastal wetlands remaining coastal wetlands, forest soils, and settlement soils.

Overall, N_2O emissions in the United States in 2022, including LULUCF N_2O emissions, accounted for 398.8 MMT CO_2 Eq., representing a decrease of 3.4 percent (14.2 MMT CO_2 Eq.) since 1990 and a decrease of 2.5 percent (10.1 MMT CO_2 Eq.) since 2021. Significant trends for the largest sources of anthropogenic N_2O emissions include the following:

- Agricultural soils were the largest anthropogenic source of N_2O emissions in 2022, accounting for 74.6 percent of N_2O emissions and 4.6 percent of total gross greenhouse gas emissions in the United States. These emissions increased by 0.7 percent (2.0 MMT CO_2 Eq.) from 1990 to 2022 but fluctuated during that period due to annual variations in weather patterns, fertilizer use, and crop production.
- Stationary combustion was the second largest source of anthropogenic N_2O emissions in 2022, accounting for 6.3 percent of N_2O emissions and 0.4 percent of total gross U.S. greenhouse gas emissions in 2022. Stationary combustion emissions peaked in 2007 and steadily decreased until 2020. Emissions increased in 2021 and 2022. Stationary combustion emissions have increased by 10.6 percent (2.4 MMT CO_2 Eq.) since 1990.
- Wastewater treatment, both domestic and industrial, was the third largest anthropogenic source of N_2O emissions in 2022, accounting for 5.6 percent of N_2O emissions and 0.3 percent of total gross greenhouse gas emissions in the United States in 2022. Emissions from wastewater treatment increased by 48.2 percent (7.1 MMT CO_2 Eq.) since 1990 as a result of growing U.S. population and protein consumption.



HFC, PFC, SF_6, and NF_3 Emissions

Hydrofluorocarbons (HFCs) are synthetic chemicals that are used as alternatives to ozone depleting substances (ODS), which are being phased out under the Montreal Protocol and Clean Air Act Amendments of 1990. Hydrofluorocarbons do not deplete the stratospheric ozone layer and therefore have been used as alternatives under the Montreal Protocol.

Perfluorocarbons (PFCs) are emitted from the production of electronics and aluminum and also (in smaller quantities) from their use as alternatives to ODS. Sulfur hexafluoride (SF_6) is emitted from the manufacturing and use of electrical equipment as well as the production of electronics and magnesium. NF_3 is emitted from electronics production. HFCs are also emitted during production of HCFC-22 and electronics (see Figure ES-10).

HFCs, PFCs, SF_6, and NF_3 are potent greenhouse gases. In addition to having very high GWPs, SF_6, NF_3, and PFCs have extremely long atmospheric lifetimes, resulting in their essentially irreversible accumulation in the atmosphere once emitted. Sulfur hexafluoride is the most potent greenhouse gas the IPCC has evaluated (IPCC 2021).

Figure ES-10: 2022 Sources of HFCs, PFCs, SF_6, and NF_3 Emissions

Some significant trends for the largest sources of U.S. HFC, PFC, SF_6, and NF_3 emissions include the following:

- Hydrofluorocarbon and perfluorocarbon emissions resulting from their use as substitutes for ODS (e.g., chlorofluorocarbons [CFCs]) are the largest share of fluorinated emissions (89.9 percent) in 2022 and have been consistently increasing, from small amounts since 1990. This increase over the time series was largely the result of efforts to phase out CFCs and other ODS in the United States.
- Sulfur hexafluoride emissions from electrical equipment decreased by 79.4 percent (19.6 MMT CO_2 Eq.) from 1990 to 2022. There are two factors contributing to this decrease: (1) a sharp increase in the price of SF_6 during the 1990s and (2) a growing awareness of the environmental impact of SF_6 emissions through programs such as EPA's SF_6 Emission Reduction Partnership for Electric Power Systems.
- HFC, PFC, SF_6, and NF_3 emissions from fluorochemical production decreased by 89.0 percent (63.2 MMT CO_2 Eq.) from 1990 to 2022 due to a reduction in the HFC-23 emission rate from HCFC-22 production (kg HFC-23 emitted/kg HCFC-22 produced), the imposition of emissions controls at production facilities, and a decrease in SF_6 production (due to the cessation of production at the major SF_6 production facility in 2010).
- PFC emissions from aluminum production decreased by 96.1 percent (18.5 MMT CO_2 Eq.) from 1990 to 2022, due to both industry emission reduction efforts and lower domestic aluminum production.

ES.3 Overview of Sector Emissions and Trends

Figure ES-11 and Table ES-3 aggregate emissions and sinks by the sectors defined by the UNFCCC and Paris Agreement reporting guidelines and methodological framework in the IPCC guidelines to promote comparability across countries. Over the 33-year period of 1990 to 2022, total emissions from the Energy and Waste sectors decreased by 3.4 percent (181.2 MMT CO_2 Eq.) and 29.3 percent (69.1 MMT CO_2 Eq.) respectively. Emissions from the Industrial Processes and Product Use and Agriculture sectors grew by 3.9 percent (14.4 MMT CO_2 Eq.), and 7.7 percent (42.2 MMT CO_2 Eq.), respectively. Over the same period, the overall net flux from LULUCF (i.e., the net sum of all CH_4 and N_2O emissions to the atmosphere plus LULUCF net carbon stock changes in units of MMT CO_2 Eq.) decreased by 12.5 percent (122.5 MMT CO_2 Eq.) and resulted in a removal of 854.2 MMT CO_2 Eq. in 2022.

Figure ES-11: U.S. Greenhouse Gas Emissions and Sinks by UNFCCC/IPCC Sector

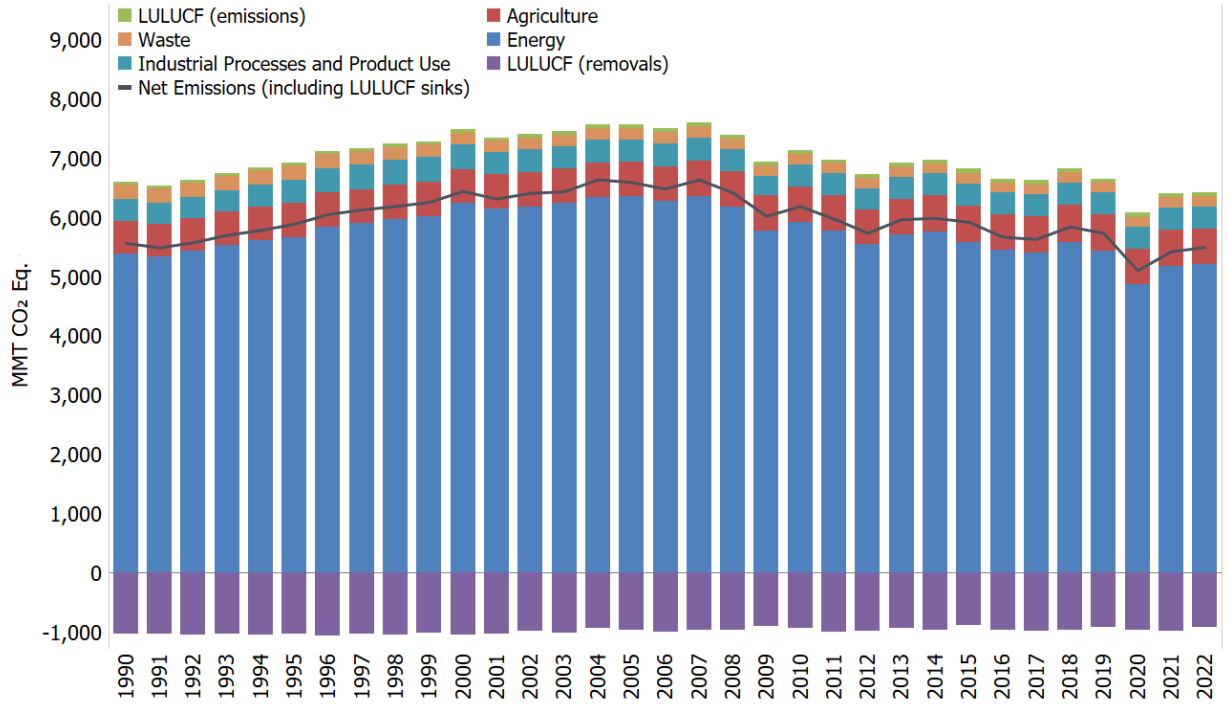


Table ES-3: Recent Trends in U.S. Greenhouse Gas Emissions and Sinks by UNFCCC/IPCC Sector (MMT CO_2 Eq.)

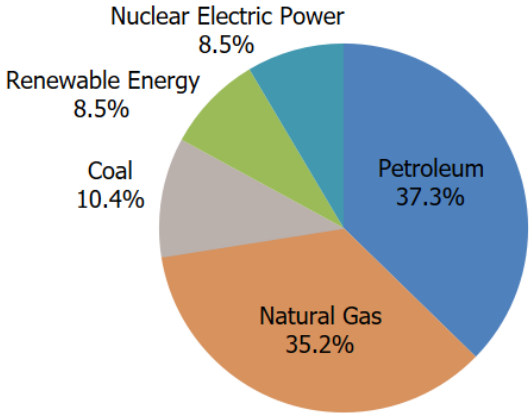
UNFCCC/IPCC Sector	1990	2005	2018	2019	2020	2021	2022	Percent Change Since 1990
Energy	5,381.0	6,349.5	5,570.0	5,422.4	4,862.6	5,173.3	5,199.8	-3.4%
Industrial Processes and Product Use	368.8	371.3	367.2	371.9	367.9	381.6	383.2	3.9%
Agriculture	551.1	581.8	642.4	620.1	599.7	604.8	593.4	7.7%
Waste	235.9	192.0	173.2	175.8	171.7	169.2	166.9	-29.3%
Total Gross Emissions[a] (Sources)	**6,536.9**	**7,494.6**	**6,752.7**	**6,590.1**	**6,001.8**	**6,328.8**	**6,343.2**	**-3.0%**
LULUCF Sector Net Total[b]	(976.7)	(907.7)	(915.5)	(863.6)	(904.4)	(910.6)	(854.2)	-12.5%
Net Emissions (Sources and Sinks)[c]	**5,560.2**	**6,586.9**	**5,837.3**	**5,726.6**	**5,097.4**	**5,418.2**	**5,489.0**	**-1.3%**

[a] Total emissions without LULUCF.

[b] The LULUCF sector net total is the sum of all LULUCF CH_4 and N_2O emissions to the atmosphere plus LULUCF net carbon stock changes in units of MMT CO_2 Eq.

[c] Net emissions with LULUCF.



Notes: Totals may not sum due to independent rounding. Parentheses indicate negative values or sequestration.

Energy

The Energy chapter contains emissions of all greenhouse gases resulting from stationary and mobile energy activities including fuel combustion and fugitive fuel emissions, and the use of fossil fuels for non-energy purposes. Energy-related activities, primarily fossil fuel combustion, accounted for the vast majority of U.S. CO_2 emissions for the period of 1990 through 2022. Energy-related activities are also responsible for CH_4 and N_2O emissions (40.2 percent and 10.8 percent of total U.S. emissions of each gas, respectively).[17] Overall, emission sources in the Energy chapter account for a combined 82.0 percent of total gross U.S. greenhouse gas emissions in 2022. Emissions from energy increased by 0.5 percent (26.5 MMT CO_2 Eq.) since 2021, but they have decreased by 3.4 percent (181.2 MMT CO_2 Eq.) since 1990.

In 2022, 83.0 percent of the energy used in the United States (on a Btu basis) was produced through the combustion of fossil fuels. The remaining 17.0 percent came from other energy sources, such as hydropower, biomass, nuclear, wind, and solar energy (see Figure ES-12).

Figure ES-12: 2022 U.S. Energy Consumption by Energy Source (Percent)

Industrial Processes and Product Use

The Industrial Processes and Product Use (IPPU) chapter contains greenhouse gas emissions generated and emitted as the byproducts of non-energy-related industrial processes, which involve the chemical or physical transformation of raw materials and can release waste gases such as CO_2, CH_4, N_2O, and fluorinated gases (e.g., HFC-23). These processes include iron and steel production and metallurgical coke production, cement production, petrochemical production, ammonia production, lime production, other process uses of carbonates (e.g., other uses of carbonates, other uses of soda ash not associated with glass manufacturing, ceramics production, and non-metallurgical magnesia production), nitric acid production, adipic acid production, urea consumption for non-agricultural purposes, aluminum production, HCFC-22 production, other fluorochemical production, glass production, soda ash production, ferroalloy production, titanium dioxide production, caprolactam production, zinc production, phosphoric acid production, lead production, and silicon carbide production and consumption. Most of these industries also emit CO_2 from fossil fuel combustion which, in line with UNFCCC/IPCC sectoral definitions, is included in the Energy sector.

[17] The contribution of energy non-CO_2 emissions is based on gross totals and excludes LULUCF methane (CH_4) and nitrous oxide (N_2O) emissions. The contribution of energy-related CH_4 and N_2O including LULUCF non-CO_2 emissions is 37.1 percent and 9.8 percent respectively.

This chapter also contains emissions resulting from the release of HFCs, PFCs, SF_6, and NF_3 and other man-made compounds used in industrial manufacturing processes and by end-consumers (e.g., residential and mobile air conditioning). These industries include electronics manufacturing, electric power transmission and distribution, and magnesium metal production and processing. In addition, N_2O is used in and emitted by electronics industry and anesthetic and aerosol applications, PFCs and SF_6 are emitted in other product use, and CO_2 is consumed and emitted through various end-use applications. In 2022, emissions resulting from use of the substitution of ODS (e.g., chlorofluorocarbons [CFCs]) by end-consumers was the largest source of IPPU emissions and accounted for 46.5 percent of total IPPU emissions.

IPPU activities are responsible for 3.3, less than 0.5, and 4.1 percent of total U.S. CO_2, CH_4, and N_2O emissions respectively as well as for all U.S. emissions of fluorinated gases including HFCs, PFCs, SF_6 and NF_3. Overall, emission sources in the IPPU chapter accounted for 6.0 percent of U.S. greenhouse gas emissions in 2022. IPPU emissions have increased by 0.4percent (1.6 MMT CO_2 Eq.) since 2021 and by 3.9 percent (14.4 MMT CO_2 Eq.) since 1990, mostly due to increased use of ODS substitutes (e.g., HFCs).

Agriculture

The Agriculture chapter contains information on anthropogenic emissions from agricultural activities (except fuel combustion, which is addressed in the Energy chapter, and some agricultural CO_2, CH_4, and N_2O fluxes, which are addressed in the Land Use, Land-Use Change, and Forestry chapter).

Several agricultural activities contribute directly to emissions of greenhouse gases including the following sources: agricultural soil management, enteric fermentation in domestic livestock, livestock manure management, rice cultivation, urea fertilization, liming, and field burning of agricultural residues.

In 2022, agricultural activities were responsible for 9.4 percent of total gross U.S. greenhouse gas emissions. Agriculture sector emissions decreased by 11.4 MMT CO_2 Eq. (1.9 percent) since 2021 and have increased by 42.2 MMT CO_2 Eq. (7.7 percent) since 1990, mostly from trends in enteric fermentation and manure management. Methane, N_2O, and CO_2 are greenhouse gases emitted by agricultural activities. Methane emissions from enteric fermentation and manure management represented 36.6 percent of total CH_4 emissions from anthropogenic activities in 2022. Agricultural soil management activities, such as application of synthetic and organic fertilizers, deposition of livestock manure, and growing N-fixing plants, were the largest contributors to U.S. N_2O emissions in 2022, accounting for 74.6 percent of total N_2O emissions. Carbon dioxide emissions from the application of crushed limestone and dolomite (i.e., soil liming) and urea fertilization represented 0.2 percent of total CO_2 emissions from anthropogenic activities.

Land Use, Land-Use Change, and Forestry

The LULUCF chapter contains emissions and removals of CO_2 and emissions of CH_4 and N_2O from managed lands in the United States. Consistent with the *2006 IPCC Guidelines*, emissions and removals from managed lands are considered to be anthropogenic, while emissions and removals from unmanaged lands are considered to be natural.[18] The share of managed land in the United States is approximately 95 percent of total land included in the Inventory.[19] More information on the definition of managed land used in the *Inventory* is provided in Chapter 6.

Overall, the *Inventory* results show that managed land is a net sink for CO_2 (C sequestration). The primary drivers of fluxes on managed lands include forest management practices, tree planting in urban areas, the management of agricultural soils, lands remaining and lands converted to reservoirs and other constructed waterbodies, landfilling

[18] See http://www.ipcc-nggip.iges.or.jp/public/2006gl/pdf/4_Volume4/V4_01_Ch1_Introduction.pdf.

[19] The current land representation does not include land in U.S. Territories, but there are planned improvements to include these regions in future *Inventories*. U.S. Territories represent approximately 0.1 percent of the total land base for the United States. See Box 6-2 in Chapter 6 of this report.

of yard trimmings and food scraps, and activities that cause changes in carbon stocks in coastal wetlands. The main drivers for forest carbon sequestration include forest growth and increasing forest area (i.e., afforestation), as well as a net accumulation of carbon stocks in harvested wood pools. The net sequestration in settlements remaining settlements, which occurs predominantly from urban forests (i.e., settlement trees) and landfilled yard trimmings and food scraps, is a result of net tree growth and increased urban forest area, as well as long-term accumulation of carbon from yard trimmings and food scraps in landfills.

The LULUCF sector in 2022 resulted in a net increase in carbon stocks (i.e., net CO_2 removals) of 921.8 CO_2 Eq.[20] The removals of carbon offset 14.5 percent of total gross greenhouse gas emissions in 2022. Emissions of CH_4 and N_2O from LULUCF activities in 2022 represented 1.2 percent of net greenhouse gas emissions.[21] Carbon dioxide removals from carbon stock changes are presented in Table ES-4 along with CH_4 and N_2O emissions for LULUCF source categories.

Between 1990 and 2022, total carbon sequestration in the LULUCF sector decreased by 10.9 percent, primarily due to a decrease in the rate of net carbon accumulation in forests and in cropland remaining cropland, as well as an increase in CO_2 emissions from land converted to settlements. The overall net flux from LULUCF (i.e., net sum of all CH_4 and N_2O emissions to the atmosphere plus LULUCF net carbon stock changes in units of MMT CO_2 Eq.) resulted in a removal of 854.2 MMT CO_2 Eq. in 2022.

Flooded lands were the largest source of CH_4 emissions from the LULUCF sector and the fifth largest source overall net CH_4 emissions in 2022. Forest fires were the second largest source of CH_4 emissions, followed by coastal wetlands remaining coastal wetlands. Forest fires were the largest source of N_2O emissions from the LULUCF sector in 2022.

Table ES-4: U.S. Greenhouse Gas Emissions and Removals (Net Flux) from Land Use, Land-Use Change, and Forestry (MMT CO_2 Eq.)

Land-Use Category	1990	2005	2018	2019	2020	2021	2022
Forest Land Remaining Forest Land[a]	(968.8)	(860.1)	(863.4)	(807.0)	(846.3)	(823.9)	(771.7)
Land Converted to Forest Land[b]	(100.2)	(100.2)	(100.4)	(100.3)	(100.3)	(100.3)	(100.3)
Cropland Remaining Cropland	(5.0)	(31.6)	(17.8)	(19.4)	(8.8)	(32.0)	(31.7)
Land Converted to Cropland[c]	45.4	34.5	31.9	31.4	29.3	34.9	35.1
Grassland Remaining Grassland[d]	24.6	24.9	29.7	28.9	17.1	11.5	14.0
Land Converted to Grassland[c]	35.3	21.8	25.2	25.4	28.7	24.5	25.6
Wetlands Remaining Wetlands[e]	36.8	39.4	38.2	38.1	38.1	38.1	38.1
Land Converted to Wetlands[e]	7.2	1.8	0.7	0.7	0.7	0.7	0.7
Settlements Remaining Settlements[f]	(109.1)	(115.2)	(131.0)	(131.5)	(131.8)	(132.3)	(132.3)
Land Converted to Settlements[c]	57.2	77.1	71.4	70.2	68.8	68.2	68.2
LULUCF Carbon Stock Change[g]	**(1,034.7)**	**(976.6)**	**(978.3)**	**(921.6)**	**(972.8)**	**(983.4)**	**(921.8)**
LULUCF Emissions[h]	**58.0**	**68.9**	**62.8**	**58.0**	**68.4**	**72.9**	**67.6**
CH_4	53.1	58.5	55.5	52.5	59.3	62.1	58.4
N_2O	4.8	10.3	7.3	5.5	9.1	10.7	9.1
LULUCF Sector Net Total[i]	**(976.7)**	**(907.7)**	**(915.5)**	**(863.6)**	**(904.4)**	**(910.6)**	**(854.2)**

[a] Includes the net changes to carbon stocks stored in all forest ecosystem pools and harvested wood products, emissions from fires on both forest land remaining forest land and land converted to forest land, emissions from N fertilizer additions on both forest land remaining forest land and land converted to forest land, and CH_4 and N_2O emissions from drained organic soils on both forest land remaining forest land and land converted to forest land.

[20] LULUCF carbon stock change is the net C stock change from the following categories: forest land remaining forest land, land converted to forest land, cropland remaining cropland, land converted to cropland, grassland remaining grassland, land converted to grassland, wetlands remaining wetlands, land converted to wetlands, settlements remaining settlements, and land converted to settlements.

[21] LULUCF emissions include the CH_4 and N_2O emissions reported for peatlands remaining peatlands, forest fires, drained organic soils, grassland fires, and coastal wetlands remaining coastal wetlands; CH_4 emissions from land converted to coastal wetlands; and N_2O emissions from forest soils and settlement soils.

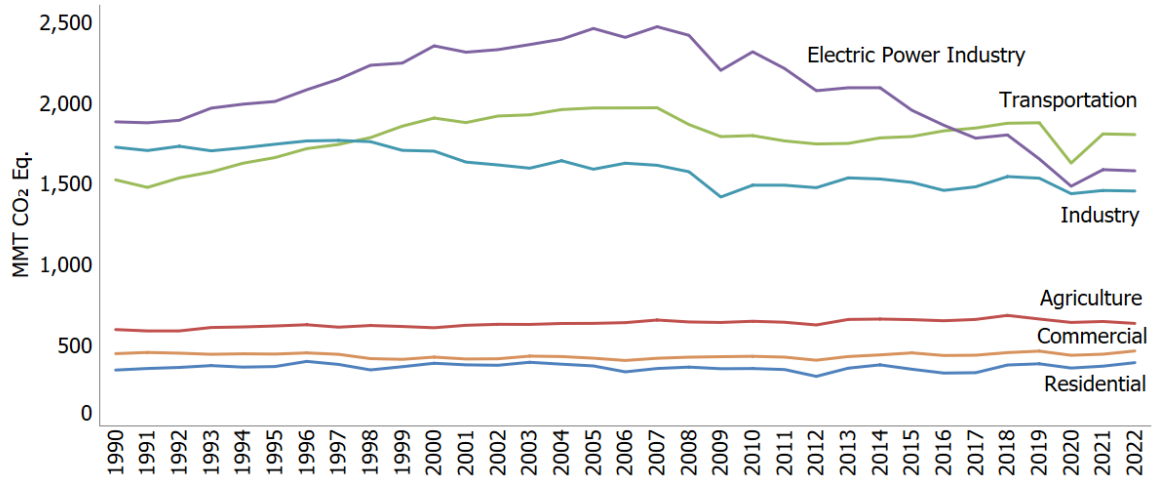
[b] Includes the net changes to carbon stocks stored in all forest ecosystem pools.
[c] Includes changes in mineral and organic soil carbon stocks for all land use conversions to cropland, grassland, and settlements, respectively. Also includes aboveground/belowground biomass, dead wood, and litter carbon stock changes for conversion of forest land to cropland, grassland, and settlements, respectively.
[d] Estimates include CH_4 and N_2O emissions from fires on both grassland remaining grassland and land converted to grassland.
[e] Estimates include CH_4 emissions from flooded land remaining flooded land and land converted to flooded land.
[f] Estimates include N_2O emissions from N fertilizer additions on both settlements remaining settlements and land converted to settlements because it is not possible to separate the activity data at this time.
[g] LULUCF carbon stock change includes any carbon stock gains and losses from all land use and land use conversion categories.
[h] LULUCF emissions subtotal includes the CH_4 and N_2O emissions reported for peatlands remaining peatlands, forest fires, drained organic soils, grassland fires, and coastal wetlands remaining coastal wetlands; CH_4 emissions from land converted to coastal wetlands, flooded land remaining flooded land, and land converted to flooded land; and N_2O emissions from forest soils and settlement soils. Emissions values are included in land-use category rows.
[i] The LULUCF sector net total is the net sum of all LULUCF CH_4 and N_2O emissions to the atmosphere plus LULUCF net carbon stock changes in units of MMT CO_2 Eq.
Notes: Totals may not sum due to independent rounding. Parentheses indicate net sequestration.

Waste

The Waste chapter contains emissions from waste management activities (except the incineration of waste, which is addressed in the Energy chapter). Landfills were the largest source of anthropogenic greenhouse gas emissions from waste management activities, accounting for 71.8 percent of total greenhouse gas emissions from waste management activities, and 17.1 percent of total U.S. CH_4 emissions.[22] Additionally, wastewater treatment accounted for 25.6 percent of total Waste sector greenhouse gas emissions, 3.0 percent of U.S. CH_4 emissions, and 5.6 percent of U.S. N_2O emissions in 2022. Emissions of CH_4 and N_2O from commercial composting are also included in this chapter, accounting for 1.5 percent (2.6 MMT CO_2 Eq.) and 1.1 percent (1.8 MMT CO_2 Eq.) of overall waste sector emissions, respectively. Anaerobic digestion at biogas facilities generated CH_4 emissions, accounting for less than 0.05 percent of emissions from the Waste sector. Overall, emission sources in the Waste chapter accounted for 2.6 percent of total gross U.S. greenhouse gas emissions in 2022. Waste sector emissions decreased by 1.4 percent (2.3 MMT CO_2 Eq.) since 2021 and by 29.3 percent (69.1 MMT CO_2 Eq.) since 1990.

ES.4 Other Information

Emissions and Sinks by Economic Sector



In addition to the Paris Agreement and UNFCCC sectors and methods defined by the IPCC, this report also characterizes emissions according to commonly used economic sector categories: residential, commercial, industry, transportation, electric power, and agriculture.[23] Emissions from U.S. Territories are reported as their own end-use sector due to a lack of specific consumption data for the individual end-use sectors within U.S. Territories. For more information on trends in the Land Use, Land-Use Change, and Forestry sector, see Section ES.2 Recent Trends in U.S. Greenhouse Gas Emissions and Sinks.

[22] Landfills also store carbon, due to incomplete degradation of organic materials such as harvest wood products, yard trimmings, and food scraps, as described in the Land Use, Land-Use Change, and Forestry chapter of the Inventory report. Also, the estimated total methane emissions used to estimate contribution excludes methane emissions from the LULUCF sector.

[23] The agriculture economic sector includes emissions from fossil fuel combustion and electricity use within the agricultural sector.

Figure ES-13 shows the trend in emissions by economic sector from 1990 to 2022, and Table ES-5 summarizes emissions from each of these economic sectors.

Figure ES-13: U.S. Greenhouse Gas Emissions Allocated to Economic Sectors

Note: Emissions and removals from Land Use, Land-Use Change, and Forestry are excluded from figure above. Excludes U.S. Territories.

Table ES-5: U.S. Greenhouse Gas Emissions Allocated to Economic Sectors (MMT CO_2 Eq.)

Economic Sectors	1990	2005	2018	2019	2020	2021	2022	Percent Change Since 1990
Transportation	1,521.4	1,965.9	1,871.6	1,874.6	1,625.3	1,805.5	1,801.5	18.4%

Total Gross Emissions (Sources)	**6,536.9**	**7,494.6**	**6,752.7**	**6,590.1**	**6,001.8**	**6,328.8**	**6,343.2**	**-3.0%**
LULUCF Sector Net Total[a]	(976.7)	(907.7)	(915.5)	(863.6)	(904.4)	(910.6)	(854.2)	-12.5%
Net Emissions (Sources and Sinks)	**5,560.2**	**6,586.9**	**5,837.3**	**5,726.6**	**5,097.4**	**5,418.2**	**5,489.0**	**-1.3%**

[a] The LULUCF sector net total is the net sum of all LULUCF CH_4 and N_2O emissions to the atmosphere plus LULUCF net carbon stock changes.

Notes: Total (gross) emissions are presented without LULUCF. Total net emissions are presented with LULUCF. Totals may not sum due to independent rounding. Parentheses indicate negative values or sequestration.

Using this categorization, emissions from transportation activities accounted for the largest portion (28.4 percent) of total gross U.S. greenhouse gas emissions in 2022. Electric power accounted for the second largest portion (24.9 percent) of U.S. greenhouse gas emissions in 2022, while emissions from industry accounted for the third largest portion (22.9 percent). Emissions from industry have in general declined over the past decade, due to a number of factors, including structural changes in the U.S. economy (i.e., shifts from a manufacturing-based to a service-based economy), fuel switching, and energy efficiency improvements.

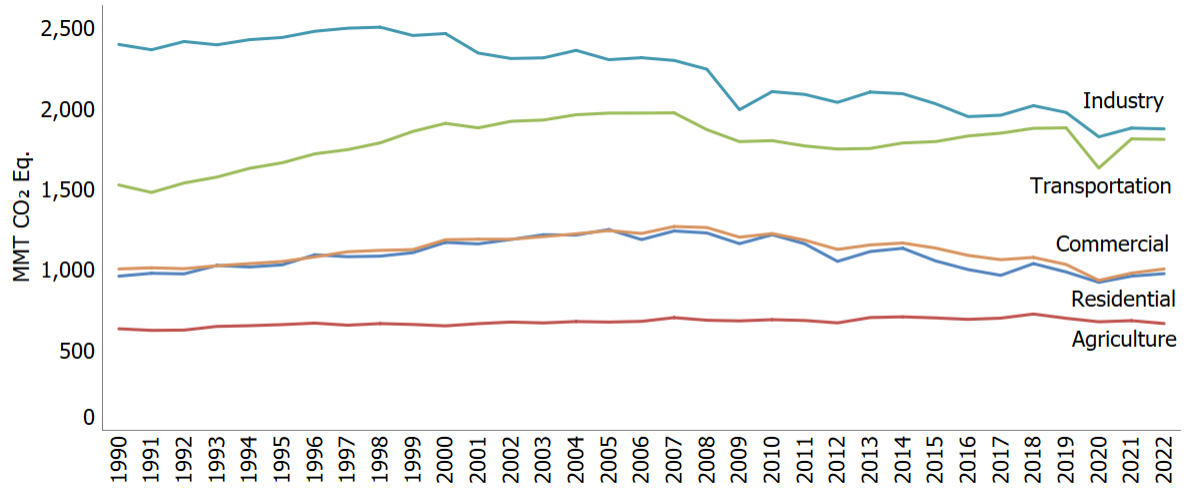
The remaining 23.8 percent of U.S. greenhouse gas emissions were contributed by, in order of magnitude, the agriculture, commercial, and residential sectors, plus emissions from U.S. Territories. Activities related to agriculture accounted for 10.0 percent of U.S. emissions; unlike other economic sectors, agricultural sector

emissions were dominated by N_2O emissions from agricultural soil management and CH_4 emissions from enteric fermentation. An increasing amount of carbon is stored in agricultural soils each year, but this CO_2 sequestration is assigned to the LULUCF sector rather than the agriculture economic sector. The commercial and residential sectors accounted for 7.3 percent and 6.2 percent of emissions, respectively, and U.S. Territories accounted for 0.4 percent of emissions; emissions from these sectors primarily consisted of CO_2 emissions from fossil fuel combustion. Carbon dioxide was also emitted and sequestered by a variety of activities related to forest management practices, tree planting in urban areas, the management of agricultural soils, landfilling of yard trimmings, and changes in carbon stocks in coastal wetlands.

Electricity is ultimately used in the economic sectors described above. Table ES-6 presents greenhouse gas emissions from economic sectors with emissions related to electric power distributed into end-use categories (i.e., emissions from electric power generation are allocated to the economic sectors in which the electricity is used). To distribute electricity emissions among end-use sectors, emissions from the source categories assigned to electric power were allocated to the residential, commercial, industry, transportation, and agriculture economic sectors according to retail sales of electricity for each end-use sector (EIA 2024).[24] These source categories include CO_2 from fossil fuel combustion and the use of limestone and dolomite for flue gas desulfurization, CO_2 and N_2O from incineration of waste, CH_4 and N_2O from stationary sources, and SF_6 from electrical equipment systems.

When emissions from electricity use are distributed among these end-use sectors, industrial activities and transportation account for the largest shares of U.S. greenhouse gas emissions (29.5 percent and 28.5 percent, respectively) in 2022. The commercial and residential sectors contributed the next largest shares of total gross U.S. greenhouse gas emissions in 2022 (15.8and 15.3 percent, respectively). Emissions from the commercial and residential sectors increase substantially when emissions from electricity use are included, due to their relatively large share of electricity use for energy (e.g., lighting, cooling, appliances). Figure ES-14 shows the trends in these emissions by sector from 1990 to 2022.

Table ES-6: U.S. Greenhouse Gas Emissions with Electricity-Related Emissions Distributed by Economic Sector (MMT CO_2 Eq.)



Economic Sectors	1990	2005	2018	2019	2020	2021	2022	Percent Change Since 1990
Industry	2,397.3	2,302.9	2,017.1	1,974.8	1,823.5	1,877.8	1,872.9	-21.9%
Transportation	1,524.6	1,970.8	1,876.5	1,879.5	1,629.5	1,810.6	1,807.8	18.6%
Commercial	1,002.5	1,241.1	1,074.3	1,030.5	931.5	976.8	1,002.6	0.0%
Residential	958.0	1,247.7	1,035.9	984.0	919.5	958.0	973.5	1.6%
Agriculture	631.1	672.6	722.7	696.3	674.4	681.6	663.6	5.2%
U.S. Territories	23.4	59.7	26.3	25.1	23.4	23.9	22.7	-3.1%
Total Gross Emissions (Sources)	**6,536.9**	**7,494.6**	**6,752.7**	**6,590.1**	**6,001.8**	**6,328.8**	**6,343.2**	**-3.0%**
LULUCF Sector Net Total[a]	(976.7)	(907.7)	(915.5)	(863.6)	(904.4)	(910.6)	(854.2)	-12.5%
Net Emissions (Sources and Sinks)	**5,560.2**	**6,586.9**	**5,837.3**	**5,726.6**	**5,097.4**	**5,418.2**	**5,489.0**	**-1.3%**

[a] The LULUCF sector net total is the net sum of all LULUCF CH_4 and N_2O emissions to the atmosphere plus LULUCF net carbon stock changes.

Notes: Emissions from electric power are allocated based on aggregate electricity use in each end-use sector. Totals may not sum due to independent rounding. Parentheses indicate negative values or sequestration.

[24] U.S. Territories consumption data that are obtained from EIA are only available at the aggregate level and cannot be broken out by end-use sector. The distribution of emissions to each end-use sector for the 50 states does not apply to Territories data.

Figure ES-14: U.S. Greenhouse Gas Emissions with Electricity-Related Emissions Distributed to Economic Sectors

Note: Emissions and removals from Land Use, Land-Use Change, and Forestry are excluded from figure above. Excludes U.S. Territories.

Box ES-2: Trends in Various U.S. Greenhouse Gas Emissions-Related Data

Total (gross) greenhouse gas emissions can be compared to other economic and social indices to highlight changes over time. These comparisons include: (1) aggregate energy use, because energy-related activities are the largest sources of emissions; (2) energy use per capita as a measure of efficiency; (3) emissions per unit of total gross domestic product as a measure of national economic activity; and (4) emissions per capita.

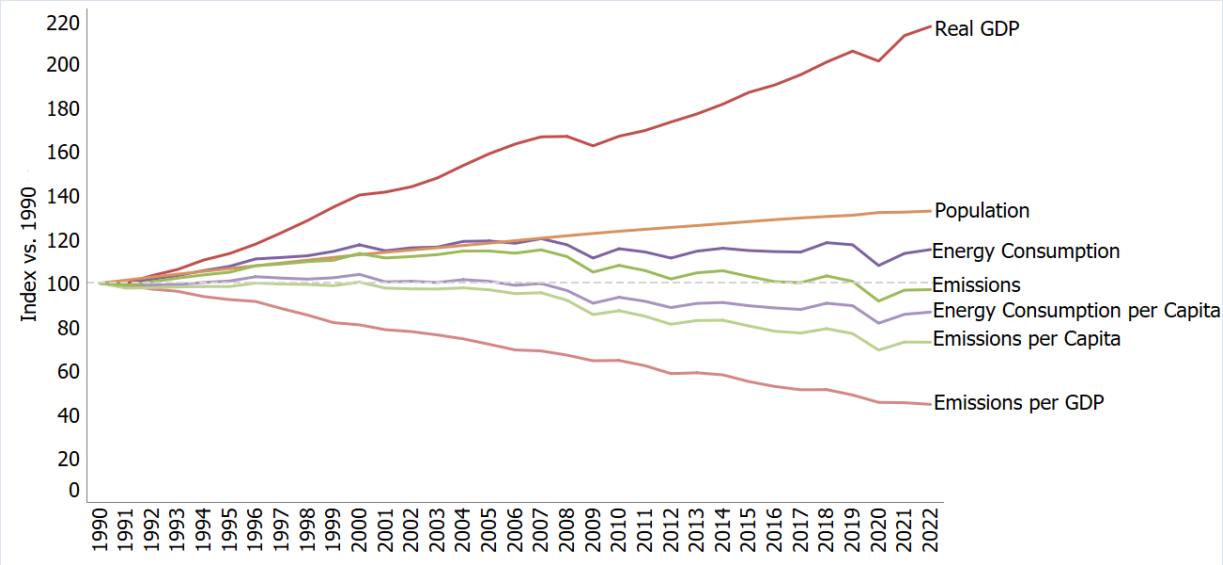


Table ES-7 provides data on various statistics related to U.S. greenhouse gas emissions normalized to 1990 as a baseline year. These values represent the relative change in each statistic since 1990. Greenhouse gas emissions in the United States have declined at an average annual rate of 0.01 percent since 1990, although changes from year to year have been significantly larger. This growth rate is slightly slower than that for total energy use and fossil fuel consumption, and overall gross domestic product (GDP), and national population (see Figure ES-15). The direction of these trends started to change after 2005, when greenhouse gas emissions, total energy use, and fossil fuel consumption began to peak. Greenhouse gas emissions in the United States have decreased at an average annual rate of 0.9 percent since 2005. Since 2005, GDP and national population, generally, continued to increase while energy has decreased slightly—noting 2020 was impacted by the COVID-19 pandemic.

Table ES-7: Recent Trends in Various U.S. Data (Index 1990 = 100)

Variable	1990	2005	2018	2019	2020	2021	2022	Avg. Annual Growth Rate Since 1990[a]	Avg. Annual Growth Rate Since 2005[a]
Greenhouse Gas Emissions[b]	100	115	103	101	92	97	97	-0.1%	-0.9%
Energy Use[c]	100	119	118	117	107	113	115	0.5%	-0.2%
GDP[d]	100	159	201	206	201	213	217	2.5%	1.9%

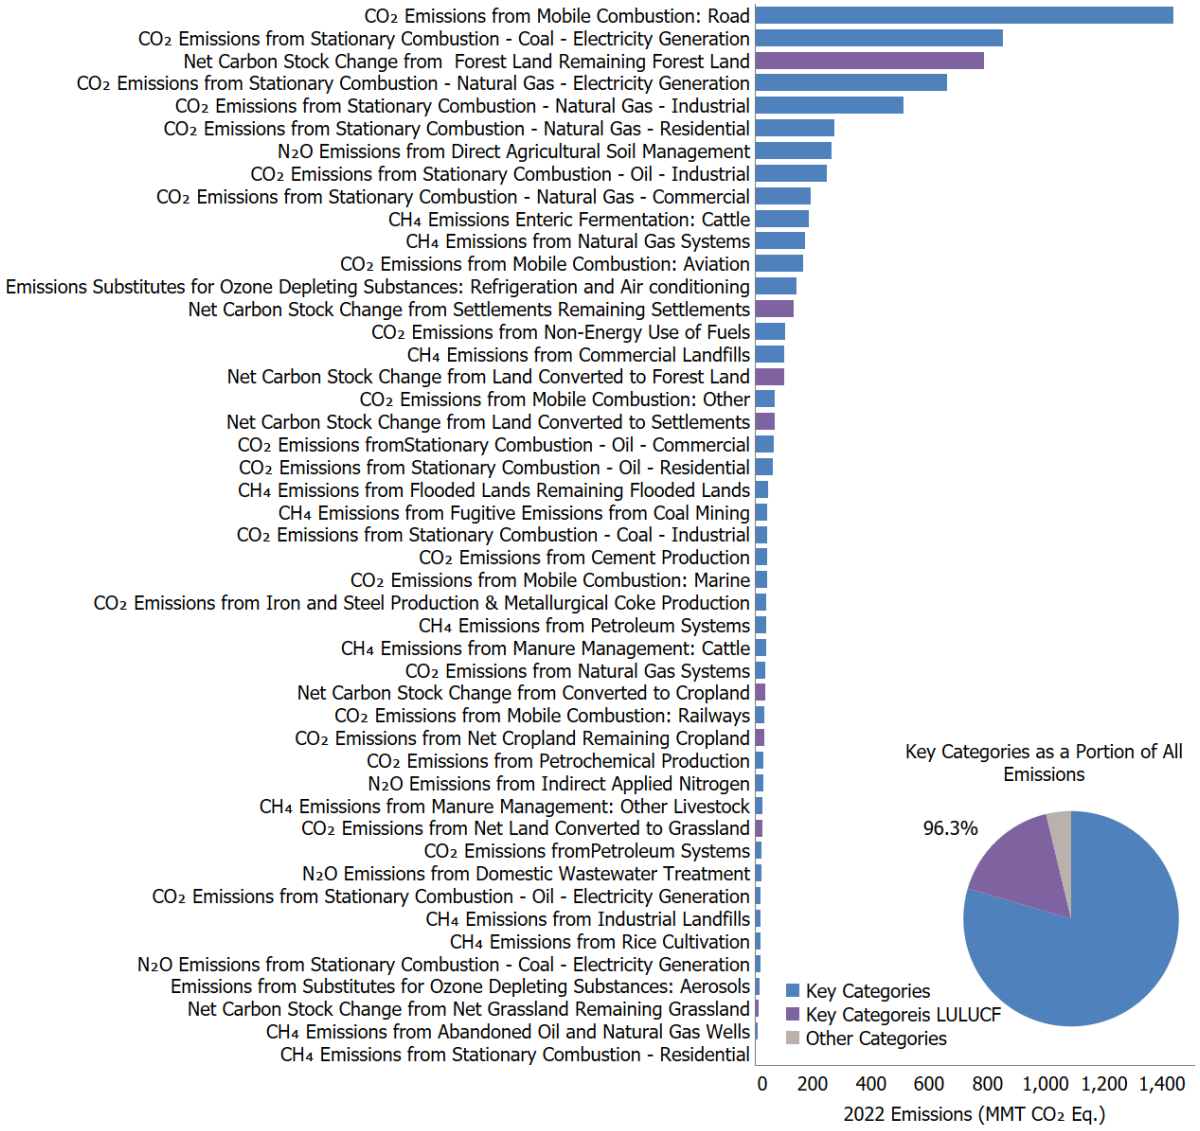
Key Categories

The *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (IPCC 2006) and *2019 Refinement to the 2006 IPCC Guidelines for National Greenhouse Gas Inventories* (IPCC 2019) defines key categories as "inventory categories which individually, or as a group of categories (for which a common method, emission factor and activity data are applied) are prioritized within the national inventory system because their estimates have a significant influence on a country's total inventory of greenhouse gases in terms of the absolute level, the trend, or



the level of uncertainty in emissions or removals."[25] A key category analysis identifies priority source or sink categories for focusing efforts to improve overall Inventory quality. In addition, a qualitative review of key categories and non-key categories can also help identify additional source and sink categories to consider for improvement efforts, including reducing uncertainty.

Figure ES-16 presents the 2022 key categories identified by the Approach 1 level assessment, including the LULUCF sector. A level assessment using Approach 1 identifies all source and sink categories that cumulatively account for 95 percent of total (i.e., gross) emissions in a given year when assessed in descending order of absolute magnitude.

For a complete list of key categories and more information regarding the overall key category analysis, including approaches accounting for uncertainty and the influence of trends of individual source and sink categories, see the Introduction chapter, Section 1.5, and Annex 1.

[25] See Chapter 4 "Methodological Choice and Identification of Key Categories" in IPCC (2006) and IPCC (2019). See http://www.ipcc-nggip.iges.or.jp/public/2006gl/vol1.html and https://www.ipcc-nggip.iges.or.jp/public/2019rf/pdf/1_Volume1/19R_V1_Ch04_MethodChoice.pdf.

Figure ES-16: 2022 Key Categories (Approach 1 including LULUCF)[a]

Note: For a complete list of key categories and detailed discussion of the underlying key category analysis, see Annex 1. Bars indicate key categories identified using Approach 1 level assessment including the LULUCF sector. The absolute values of net CO_2 emissions from LULUCF are presented in this figure but reported separately from gross emissions totals. Refer to Table ES-4 for a breakout of emissions and removals for LULUCF by source/sink category.

Quality Assurance and Quality Control (QA/QC)

The United States seeks continuous improvements to the quality, transparency, and usability of the *Inventory of U.S. Greenhouse Gas Emissions and Sinks*. To assist in these efforts, the United States implemented a systematic approach to QA/QC. The procedures followed for the Inventory have been formalized in accordance with the U.S. Inventory QA/QC plan, and the UNFCCC reporting guidelines and *2006 IPCC Guidelines for National Greenhouse Gas Inventories*. The QA process includes expert and public reviews for the Inventory estimates and this report.

Box ES-3: Use of Ambient Measurements Systems for Validation of Emission Inventories

In following Article 13.7(a) of the Paris Agreement and Article 4.1(a) of the UNFCCC, as well as relevant decisions under those agreements to develop and submit national greenhouse gas emission inventories, the emissions and sinks presented in this report are organized by source and sink categories and calculated using internationally accepted methods in the 2006 IPCC Guidelines for National Greenhouse Gas Inventories (2006 IPCC Guidelines) and, where appropriate, its supplements and refinements.[26] Several recent studies have estimated emissions at the national or regional level with estimated results that sometimes differ from EPA's estimate of emissions. EPA has engaged with researchers on how remote sensing, ambient measurement, and inverse modeling techniques for estimating greenhouse gas emissions could assist in improving the understanding of inventory estimates. In working with the research community to improve national greenhouse gas inventories, EPA follows guidance from the IPCC on the use of measurements and modeling to validate emission inventories.[27] An area of particular interest in EPA's outreach efforts is how ambient measurement data can be used to assess estimates or potentially be incorporated into the Inventory in a manner consistent with this *Inventory* report's transparency of its calculation methodologies, and the ability of inverse modeling techniques to attribute emissions and removals from remote sensing to anthropogenic sources, as defined by the IPCC for this report, versus natural sources and sinks.

The *2019 Refinement to the IPCC 2006 Guidelines for National Greenhouse Gas Inventories* (IPCC 2019) Volume 1 General Guidance and Reporting, Chapter 6: Quality Assurance, Quality Control and Verification notes that emission estimates derived from atmospheric concentration measurements can provide independent data sets as a basis for comparison with inventory estimates. The *2019 Refinement* provides guidance on conducting such comparisons (as summarized in Table 6.2 of IPCC [2019] Volume 1, Chapter 6) and provides guidance on using such comparisons to identify areas of improvement in national inventories (as summarized in Box 6.5 of IPCC [2019] Volume 1, Chapter 6). Further, it identified fluorinated gases as particularly suitable for such comparisons due their limited natural sources, their generally long atmospheric lifetimes, and well-understood loss mechanisms, which makes it relatively more straightforward to model their emission fluxes from observed mass quantities. Unlike emissions of CO_2, CH_4, and N_2O, emissions of fluorinated greenhouse gases are almost exclusively anthropogenic, meaning that the fluorinated greenhouse gas emission sources included in this Inventory account for the majority of the total U.S. emissions of these gases detectable in the atmosphere. This evaluation approach is also useful for gases and sources with larger uncertainties in available bottom-up inventory methods and data, such as emissions of CH_4, which are primarily from uncertain biological (e.g., enteric fermentation) and fugitive (e.g., natural gas production) activities.

In this *Inventory*, EPA includes the results from current and previous comparisons between fluorinated gas emissions inferred from atmospheric measurements and fluorinated gas emissions estimated based on bottom-up measurements and modeling. These comparisons, performed for HFCs and SF_6 respectively, are described under the QA/QC and Verification discussions in Chapter 4, Sections 4.25 Substitution of Ozone Depleting Substances and 4.26 Electrical Equipment, in the IPPU chapter of this report.

Consistent with the *2019 Refinement*, a key element to facilitate such comparisons is a spatially-explicit (or gridded inventory as an input to inverse modeling. To improve the ability to compare methane emissions from the national-level greenhouse gas inventory with observation-based estimates , a team of researchers from U.S. EPA, SRON Netherlands Institute for Space Research, Harvard University, and Lawrence Berkely National Laboratory and other coauthors developed a time series of anthropogenic methane emissions maps with 0.1° x 0.1° (10 km x 10 km) spatial resolution and monthly temporal resolution for the contiguous United States.[28] The gridded methane inventory is designed to be consistent with the U.S. EPA *Inventory of U.S. Greenhouse Gas*

[26] See http://www.ipcc-nggip.iges.or.jp/public/index.html.

[27] See http://www.ipcc-nggip.iges.or.jp/meeting/pdfiles/1003_Uncertainty%20meeting_report.pdf.

[28] See https://www.epa.gov/ghgemissions/us-gridded-methane-emissions.

Emissions and Sinks estimates, which presents national totals for different source types.[29] The development of this gridded inventory is consistent with the recommendations contained in two National Academies of Science reports examining greenhouse gas emissions data (National Research Council 2010; National Academies of Sciences, Engineering, and Medicine 2018).

Finally, in addition to the use of atmospheric concentration measurement data for comparison with Inventory data, information from top-down studies is directly incorporated in the natural gas systems calculations to quantify emissions from certain well blowout events.

Uncertainty Analysis of Emission and Sink Estimates

Uncertainty assessment is an essential element of a complete inventory of greenhouse gas emissions and removals because it helps to inform and prioritize inventory improvements. Recognizing the benefit of conducting an uncertainty analysis, the UNFCCC reporting guidelines follow the recommendations of the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (IPCC 2006), Volume 1, Chapter 3 and require that countries provide single estimates of uncertainty for source and sink categories. In addition to quantitative uncertainty assessments, a qualitative discussion of uncertainty is presented for each source and sink category identifying specific factors affecting the uncertainty surrounding the estimates provided in accordance with UNFCCC reporting guidelines. Some of the current estimates, such as those for CO_2 emissions from energy-related combustion activities, are considered to have low uncertainties. This is because the amount of CO_2 emitted from energy-related combustion activities is directly related to the amount of fuel consumed, the fraction of the fuel that is oxidized, and the carbon content of the fuel, and for the United States, the uncertainties associated with estimating those factors are relatively small. For some other categories of emissions and sinks, however, inherent variability or a lack of data increases the uncertainty or systematic error associated with the estimates presented. Finally, an analysis is conducted to assess uncertainties associated with the overall emissions, sinks, and trends estimates. The overall uncertainty surrounding total net greenhouse gas emissions is estimated to be -6 to +6 percent in 1990 and -5 to +6 percent in 2022. When the LULUCF sector is excluded from the analysis the uncertainty is estimated to be -3 to +4 percent in 1990 and -2 to +4 percent in 2022.

[29] See https://www.epa.gov/ghgemissions/inventory-us-greenhouse-gas-emissions-and-sinks.

1. Introduction

This report presents an inventory of U.S. anthropogenic greenhouse gas emissions and sinks for the years 1990 through 2022 compiled by the United States government. A summary of source and sink category estimates is provided in Table 2-1, Table 2-2, andTable 2-4 by gas and IPCC sector in the Trends in Greenhouse Gas Emissions and Sinks chapter. The emission and sink estimates in these tables are presented throughout the main report in both CO_2 equivalents (CO_2 Eq.[30] and unweighted units). This report also discusses the methods and data used to calculate the emission and sink estimates.

The United States is party to both the 1992 UNFCCC and the 2015 Paris Agreement. The Paris Agreement set a global temperature goal–holding the increase in the global average temperature to well below 2°C above pre-industrial levels and pursuing efforts to limit the increase to 1.5°C–that articulates with greater precision States' views on what is necessary to meet the UNFCCC's objective of "stabiliz[ing] … greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system.[31]

The United States is committed to submitting a national inventory of anthropogenic emissions sources and removals by sinks of greenhouse gases by April 15 of each year. The United States has prepared this report, in conjunction with Common Reporting Tables (CRTs) that accompany this report, consistent with its obligations under those agreements.

In 1988, preceding the creation of the UNFCCC, the World Meteorological Organization (WMO) and the United Nations Environment Programme (UNEP) jointly established the Intergovernmental Panel on Climate Change (IPCC). The role of the IPCC is to assess on a comprehensive, objective, open and transparent basis the scientific, technical and socio-economic information relevant to understanding the scientific basis of risk of human-induced climate change, its potential impacts and options for adaptation and mitigation (IPCC 2021). The Paris Agreement and the UNFCCC require use of methods from the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* and encourages Parties to use the *2013 Supplement to the 2006 IPCC Guidelines for National Greenhouse Gas Inventories: Wetlands* and *the 2019 Refinement to the 2006 IPCC Guidelines for National Greenhouse Gas Inventories*. The recently released *2019 Refinement* clarify and elaborate on the existing guidance in the *2006 IPCC Guidelines*, along with providing updates to default values of emission factors and other parameters based on updated science. This report applies both the *2013 Supplement* and updated guidance in the *2019 Refinement* to improve accuracy and completeness of the *Inventory*. For more information on specific uses, see Section 1.4 of this chapter on Methodology and Data Sources.

[30] More information is provided in the Global Warming Potentials section of this chapter on the use of IPCC *Fifth Assessment Report* (AR5) GWP values.

[31] See Paris Agreement, Article 2.1(a); UNFCCC, Article 2.

Box 1-1: Methodological Approach for Estimating and Reporting U.S. Emissions and Removals, including Relationship to EPA's Greenhouse Gas Reporting Program

Consistent with Article 13.7(a) of the Paris Agreement and Article 4.1(a) of the UNFCCC, as well as relevant decisions under those agreements, the emissions and removals presented in this report and this chapter are organized by source and sink categories and calculated using internationally accepted methods in the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (*2006 IPCC Guidelines*) and, where appropriate, its supplements and refinements. Additionally, the calculated emissions and removals in a given year for the United States are presented in a common manner in line with the reporting guidelines for the reporting of inventories under the Paris Agreement and the UNFCCC. The Parties' use of consistent methods to calculate emissions and removals for their inventories helps to ensure that these reports are comparable. The presentation of emissions and removals provided in this *Inventory* does not preclude alternative examinations (e.g., economic sectors). Rather, this *Inventory* presents emissions and removals in a common format consistent with how Parties are to report their national inventories under the Paris Agreement and the UNFCCC. The report itself, and this chapter, follows this common format, and provides an explanation of the application of methods used to calculate emissions and removals.

EPA also collects greenhouse gas emissions data from individual facilities and suppliers of certain fossil fuels and industrial gases through its Greenhouse Gas Reporting Program (GHGRP), which is complementary to the U.S. *Inventory*.[32] The GHGRP applies to direct greenhouse gas emitters, fossil fuel suppliers, industrial greenhouse gas suppliers, and facilities that inject carbon dioxide (CO_2) underground for sequestration or other reasons and requires reporting by over 8,000 sources or suppliers in 41 industrial categories.[33] Annual reporting is at the facility level, except for certain suppliers of fossil fuels and industrial greenhouse gases. In general, the threshold for reporting is 25,000 metric tons or more of CO_2 Eq. per year. Facilities in most source categories[34] subject to GHGRP began reporting for the 2010 reporting year while additional types of industrial operations began reporting for the 2011 reporting year. Methodologies used in EPA's GHGRP are consistent with the *2006 IPCC Guidelines*. While the GHGRP does not provide full coverage of total annual U.S. greenhouse gas emissions and removals (e.g., the GHGRP excludes emissions from the Agriculture and Land Use, Land-Use Change, and Forestry sectors), it is an important input to the calculations of national-level emissions in this *Inventory*.

Data presented in this *Inventory* report and EPA's GHGRP are complementary. The GHGRP dataset continues to be an important resource for the *Inventory*, providing not only annual emissions information, but also other annual information such as activity data and emission factors that can improve and refine national emission estimates and trends over time. Methodologies used in EPA's GHGRP are consistent with the *2006 IPCC Guidelines* (e.g., higher tier methods). GHGRP data also allow EPA to disaggregate national inventory estimates in new ways that can highlight differences across regions and sub-categories of emissions, along with enhancing the application of QA/QC procedures and assessment of uncertainties. EPA uses annual GHGRP data in several categories to improve the national estimates presented in this *Inventory*, consistent with IPCC methodological guidance. See Annex 9 for more information on specific uses of GHGRP data in the *Inventory* (e.g., natural gas systems).

1.1 Background Information

Science

For over the past 200 years, the burning of fossil fuels such as coal, oil, and natural gas, along with deforestation, land-use changes, and other activities have caused the concentrations of heat-trapping "greenhouse gases" to increase significantly in our atmosphere (IPCC 2021). These gases in the atmosphere absorb some of the energy

being radiated from the surface of the Earth that would otherwise be lost to space, essentially acting like a blanket that makes the Earth's surface warmer than it would be otherwise.

Greenhouse gases are necessary to life as we know it. Without greenhouse gases to create the natural heat-trapping properties of the atmosphere, the planet's surface would be about 60 degrees Fahrenheit cooler than present (USGCRP 2017). Carbon dioxide is also necessary for plant growth. With emissions from biological and geological sources, there is a natural level of greenhouse gases that is maintained in the atmosphere. Human emissions of greenhouse gases and subsequent changes in atmospheric concentrations alter the balance of energy transfers between space and the earth system (IPCC 2021). A gauge of these changes is called radiative forcing, which is a measure of a substance's total net effect on the global energy balance for which a positive number represents a warming effect, and a negative number represents a cooling effect (IPCC 2021). IPCC concluded in its most recent scientific assessment report that it is "unequivocal that human influence has warmed the atmosphere, ocean and land" (IPCC 2021).

As concentrations of greenhouse gases continue to increase from man-made sources, the Earth's temperature is climbing above past levels. The Earth's average land and ocean surface temperature has increased by about 2.0 degrees Fahrenheit from the 1850 to 1900 period to the decade of 2011 to 2020 (IPCC 2021). The last four decades have each been the warmest decade successively at the Earth's surface since at least 1850 (IPCC 2021). Other aspects of the climate are also changing, such as rainfall patterns, snow and ice cover, and sea level. If greenhouse gas concentrations continue to increase, climate models predict that the average temperature at the Earth's surface is likely to increase between 0.27 to 9.99 degrees Fahrenheit (0.15 to 5.55 degrees Celsius) relative to 1995 to 2014 levels by the end of this century, depending on the emissions scenario and the responsiveness of the climate system (IPCC 2021).

For further information on greenhouse gases, radiative forcing, and implications for climate change, see the recent scientific assessment reports from the IPCC,[35] the U.S. Global Change Research Program (USGCRP),[36] and the National Academies of Sciences, Engineering, and Medicine (NAS).[37]

Greenhouse Gases

Although the Earth's atmosphere consists mainly of oxygen and nitrogen, neither plays a significant role in enhancing the greenhouse effect because both are essentially transparent to terrestrial radiation. The greenhouse effect is primarily a function of the concentration of water vapor, carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), and other trace gases in the atmosphere that absorb the terrestrial radiation leaving the surface of the Earth (IPCC 2021).

Naturally occurring greenhouse gases include water vapor, CO_2, CH_4, N_2O, and ozone (O_3). Several classes of halogenated substances that contain fluorine, chlorine, or bromine are also greenhouse gases, but they are, for the most part, solely a product of industrial activities. Chlorofluorocarbons (CFCs) and hydrochlorofluorocarbons (HCFCs) are halocarbons that contain chlorine, while halocarbons that contain bromine are referred to as bromofluorocarbons (i.e., halons). As stratospheric ozone depleting substances, CFCs, HCFCs, and halons are covered under the Montreal Protocol on Substances that Deplete the Ozone Layer. The UNFCCC defers to this earlier international treaty. Consequently, Parties to the UNFCCC are not required to include these gases in

---

[32] On October 30, 2009, EPA promulgated a rule requiring annual reporting of greenhouse gas data from large greenhouse gas emissions sources in the United States. Implementation of the rule, codified at 40 CFR Part 98, is referred to as EPA's Greenhouse Gas Reporting Program (GHGRP).

national greenhouse gas inventories.[38] Some other fluorine-containing halogenated substances—hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), sulfur hexafluoride (SF_6), and nitrogen trifluoride (NF_3)—do not deplete stratospheric ozone but are potent greenhouse gases. These latter substances are addressed by the UNFCCC and accounted for in national greenhouse gas inventories.

There are also several other substances that influence the global radiation budget but are short-lived and therefore not well-mixed, leading to spatially variable radiative forcing effects. These substances include carbon monoxide (CO), nitrogen dioxide (NO_2), sulfur dioxide (SO_2), and tropospheric (ground level) ozone (O_3). Tropospheric ozone is formed from chemical reactions in the atmosphere of precursor pollutants, which include volatile organic compounds (VOCs), CH_4, and nitrogen oxides (NO_x), in the presence of ultraviolet light (sunlight).

Aerosols are extremely small particles or liquid droplets suspended in the Earth's atmosphere that are often composed of sulfur compounds, carbonaceous combustion products (e.g., black carbon), crustal materials (e.g., dust) and other human-induced pollutants. They can affect the absorptive characteristics of the atmosphere (e.g., scattering incoming sunlight away from the Earth's surface, or, in the case of black carbon, absorbing sunlight) and can play a role in affecting cloud formation and lifetime, as well as the radiative forcing of clouds and precipitation patterns.

CO_2, CH_4, and N_2O are continuously emitted to and removed from the atmosphere by natural processes on Earth. Anthropogenic activities (such as fossil fuel combustion, cement production, land-use, land-use change, and forestry, agriculture, or waste management), however, can cause additional quantities of these and other greenhouse gases to be emitted or sequestered, thereby changing their global average atmospheric concentrations. Natural activities such as respiration by plants or animals and seasonal cycles of plant growth and decay are examples of processes that only cycle carbon or nitrogen between the atmosphere and organic biomass. Such processes, except when directly or indirectly perturbed out of equilibrium by anthropogenic activities, generally do not alter average atmospheric greenhouse gas concentrations over decadal timeframes. Climatic changes resulting from anthropogenic activities, however, could have positive or negative feedback effects on these natural systems. Atmospheric concentrations of these gases, along with their rates of growth and atmospheric lifetimes, are presented in Table 1-1.

Table 1-1: Global Atmospheric Concentration, Rate of Concentration Change, and Atmospheric Lifetime of Selected Greenhouse Gases

Atmospheric Variable	CO_2	CH_4	N_2O	SF_6	CF_4
Pre-industrial atmospheric concentration	280 ppm	0.730 ppm	0.270 ppm	0.01 ppt	34.1 ppt
Atmospheric concentration	419 ppm[a]	1.912 ppm[b]	0.336 ppm[c]	11.02 ppt[d]	85.5 ppt[e]
Rate of concentration change	2.28 ppm/yr[f]	8.83 ppb/yr[f,g]	1.01 ppb/yr[f]	0.32 ppt/yr[f]	0.81 ppt/yr[f]
Atmospheric lifetime (years)	See footnote[h]	11.8	109[i]	About 1,000[j]	50,000

[a] The atmospheric CO_2 concentration is the 2022 annual average at the Mauna Loa, HI station (NOAA/ESRL 2024a). The global atmospheric CO_2 concentration, computed using an average of sampling sites across the world, was 417 ppm in 2022.

[b] The values presented are global 2022 annual average mole fractions (NOAA/ESRL 2024b).

[c] The values presented are global 2022 annual average mole fractions (NOAA/ESRL 2024c).

[d] The values presented are global 2022 annual average mole fractions (NOAA/ESRL 2024d).

[e] The 2019 CF_4 global mean atmospheric concentration is from the Advanced Global Atmospheric Gases Experiment (IPCC 2021).

[f] The rate of concentration change for CO_2 is an average of the rates from 2007 through 2022 and has fluctuated between 1.5 to 3.0 ppm per year over this period (NOAA/ESRL 2024a). The rate of concentration change for CH_4, N_2O, and SF_6, is the average rate of change between 2007 and 2022 (NOAA/ESRL 2024b; NOAA/ESRL 2024c; NOAA/ESRL 2024d). The rate of concentration change for CF_4 is the average rate of change between 2011 and 2019 (IPCC 2021).

[g] The growth rate for atmospheric CH_4 decreased from over 10 ppb/year in the 1980s to nearly zero in the early 2000s; recently, the growth rate has been about 13.22 ppb/year (NOAA/ESRL 2024b).

[38] Emissions estimates of CFCs, HCFCs, halons and other ozone-depleting substances are included in this document for informational purposes.

[h] For a given amount of CO_2 emitted, some fraction of the atmospheric increase in concentration is quickly absorbed by the oceans and terrestrial vegetation, some fraction of the atmospheric increase will only slowly decrease over a number of years, and a small portion of the increase will remain for many centuries or more.

[i] This table reports the "perturbation lifetime" for both CH_4 and N_2O, which takes into account the interactions between emissions of the gas and its own atmospheric residence time.

[j] The lifetime for SF_6 was revised from 3,200 years to about 1,000 years based on recent studies (IPCC 2021).

Source: Pre-industrial atmospheric concentrations and atmospheric lifetimes for CH_4, and N_2O, are from IPCC (2021), pre-industrial atmospheric concentration for SF_6, is from Rigby (2010), and pre-industrial atmospheric concentration for CF_4 is from Meinhausen (2017).

A brief description of each greenhouse gas, its sources, and its role in the atmosphere is given below. The following section then explains the concept of global warming potentials (GWPs), which are assigned to individual gases as a measure of their relative average global radiative forcing effect.

Water Vapor (H_2O). Water vapor is the largest contributor to the natural greenhouse effect. Water vapor is fundamentally different from other greenhouse gases in that it can condense and rain out when it reaches high concentrations, and the total amount of water vapor in the atmosphere is in part a function of the Earth's temperature. While some human activities such as evaporation from irrigated crops or power plant cooling release water vapor into the air, these activities have been determined to have a negligible effect on global climate (IPCC 2021). The lifetime of water vapor in the troposphere is on the order of 10 days. Water vapor can also contribute to cloud formation, and clouds can have both warming and cooling effects by either trapping or reflecting heat. Because of the relationship between water vapor levels and temperature, water vapor and clouds serve as a feedback to climate change, such that for any given change in other greenhouse gas concentrations, the total temperature change is greater than would happen in the absence of water vapor. Aircraft emissions can create contrails, which may also develop into contrail-induced cirrus clouds, with complex regional and temporal net radiative forcing effects that currently have a low level of scientific certainty (IPCC 2021).

Carbon Dioxide (CO_2). In nature, carbon is cycled between various atmospheric, oceanic, land biotic, marine biotic, and mineral reservoirs. The largest fluxes occur between the atmosphere and terrestrial biota, and between the atmosphere and surface water of the oceans. In the atmosphere, carbon predominantly exists in its oxidized form as CO_2. Atmospheric CO_2 is part of this global carbon cycle, and therefore its fate is a complex function of geochemical and biological processes. Carbon dioxide concentrations in the atmosphere increased from approximately 280 parts per million by volume (ppmv) in pre-industrial times to 419 ppmv in 2022, a 50 percent increase (IPCC 2021; NOAA/ESRL 2024a).[39, 40] The IPCC states that "Observed increases in well-mixed greenhouse gas (GHG) concentrations since around 1750 are unequivocally caused by human activities" (IPCC 2021). The predominant source of anthropogenic CO_2 emissions is the combustion of fossil fuels. Forest clearing, other biomass burning, and some non-energy production processes (e.g., cement production) also emit notable quantities of CO_2. In its *Sixth Assessment Report*, the IPCC determined that of the 2.0 degrees of observed warming, the best estimate is that 1.9 degrees of that are due to human influence, with elevated CO_2 concentrations being the most important contributor to that warming (IPCC 2021).

Methane (CH_4). Methane is primarily produced through anaerobic decomposition of organic matter in biological systems. Agricultural processes such as wetland rice cultivation, enteric fermentation in animals, and the decomposition of animal wastes emit CH_4, as does the decomposition of municipal solid wastes and treatment of wastewater. Methane is also emitted during the production and distribution of natural gas and petroleum, and is released as a byproduct of coal mining and incomplete fossil fuel combustion. Atmospheric concentrations of CH_4 have increased by about 162 percent since 1750, from a pre-industrial value of about 730 ppb to 1,912 ppb in 2022[41] although the rate of increase decreased to near zero in the early 2000s, and has recently increased again to

[39] The pre-industrial period is considered as the time preceding the year 1750 (IPCC 2021).

[40] Carbon dioxide concentrations during the last 1,000 years of the pre-industrial period (i.e., 750 to 1750), a time of relative climate stability, fluctuated by about ±10 ppmv around 280 ppmv (IPCC 2021).

[41] This value is the global 2022 annual average mole fraction (NOAA/ESRL 2024b).

about 8.83 ppb/year. The IPCC has estimated that about half of the current CH_4 flux to the atmosphere (and the entirety of the increase in concentration) is anthropogenic, from human activities such as agriculture, fossil fuel production and use, and waste disposal (IPCC 2021).

Methane is primarily removed from the atmosphere through a reaction with the hydroxyl radical (OH) and is ultimately converted to CO_2. Minor removal processes also include reaction with chlorine in the marine boundary layer, a soil sink, and stratospheric reactions. Increasing emissions of CH_4 reduce the concentration of OH, creating a feedback that increases the atmospheric lifetime of CH_4 (IPCC 2021). Methane's reactions in the atmosphere also lead to production of tropospheric ozone and stratospheric water vapor, both of which also contribute to climate change. Tropospheric ozone also has negative effects on human health and plant productivity.

Nitrous Oxide (N_2O). Anthropogenic sources of N_2O emissions include agricultural soils, especially production of nitrogen-fixing crops and forages, the use of synthetic and manure fertilizers, and manure deposition by livestock; fossil fuel combustion, especially from mobile combustion; adipic (nylon) and nitric acid production; wastewater treatment and waste incineration; and biomass burning. The atmospheric concentration of N_2O has increased by 24 percent since 1750, from a pre-industrial value of about 270 ppb to 336 ppb in 2022,[42] a concentration that has not been exceeded during at least the last 800 thousand years. Nitrous oxide is primarily removed from the atmosphere by the photolytic action of sunlight in the stratosphere (IPCC 2021).

Ozone (O_3). Ozone is present in both the upper stratosphere,[43] where it shields the Earth from harmful levels of ultraviolet radiation, and at lower concentrations in the troposphere,[44] where it is the main component of anthropogenic photochemical "smog." During the last two decades, emissions of anthropogenic chlorine and bromine-containing halocarbons, such as CFCs, have depleted stratospheric ozone concentrations. This loss of ozone in the stratosphere has resulted in negative radiative forcing, representing an indirect effect of anthropogenic emissions of chlorine and bromine compounds (IPCC 2021). The depletion of stratospheric ozone and its radiative forcing remained relatively unchanged since 2000 for the last two decades and is starting to decline; recovery is expected to occur shortly after the middle of the twenty-first century (WMO/UNEP 2018).

The past increase in tropospheric ozone, which is also a greenhouse gas, is estimated to provide the third largest increase in direct radiative forcing since the pre-industrial era, behind CO_2 and CH_4. Tropospheric ozone is produced from complex chemical reactions of volatile organic compounds and CH_4 mixing with NO_x in the presence of sunlight. The tropospheric concentrations of ozone and these other pollutants are short-lived and, therefore, spatially variable (IPCC 2021).

Halocarbons, Sulfur Hexafluoride (SF_6), and Nitrogen Trifluoride (NF_3). Halocarbons are, for the most part, man-made chemicals that have direct radiative forcing effects and could also have an indirect effect. Halocarbons that contain chlorine (CFCs, HCFCs, methyl chloroform, and carbon tetrachloride) and bromine (halons, methyl bromide, and hydrobromofluorocarbons) result in stratospheric ozone depletion and are therefore controlled under the Montreal Protocol on Substances that Deplete the Ozone Layer. Although most CFCs and HCFCs are potent global warming gases, their net radiative forcing effect on the atmosphere is reduced because they cause stratospheric ozone depletion, which itself is a greenhouse gas but which also shields the Earth from harmful levels of ultraviolet radiation. Under the Montreal Protocol, the United States phased out the production and importation of halons by 1994 and of CFCs by 1996. Under the Copenhagen Amendments to the Protocol, a cap

[42] This value is the global 2022 annual average (NOAA/ESRL 2024c).

[43] The stratosphere is the layer from the troposphere up to roughly 50 kilometers. In the lower regions the temperature is nearly constant but in the upper layer the temperature increases rapidly because of sunlight absorption by the ozone layer. The ozone-layer is the part of the stratosphere from 19 kilometers up to 48 kilometers where the concentration of ozone reaches up to 10 parts per million.

[44] The troposphere is the layer from the ground up to 11 kilometers near the poles and up to 16 kilometers in equatorial regions (i.e., the lowest layer of the atmosphere where people live). It contains roughly 80 percent of the mass of all gases in the atmosphere and is the site for most weather processes, including most of the water vapor and clouds.

was placed on the production and importation of HCFCs by non-Article 5 countries, including the United States,[45] beginning in 1996, and then followed by intermediate requirements and a complete phase-out by the year 2030. While ozone depleting gases covered under the Montreal Protocol and its Amendments are not covered by the UNFCCC, they are reported in this Inventory under Annex 6.2 for informational purposes.

HFCs, PFCs, SF_6, and NF_3 are not ozone depleting substances. The most common HFCs are, however, powerful greenhouse gases. Hydrofluorocarbons are primarily used as replacements for ozone depleting substances but are also emitted as a byproduct of the HCFC-22 (chlorodifluoromethane) manufacturing process. Other contributing sources to HFC emissions include the electronics industry and magnesium production and processing. Currently, these emissions have a small aggregate radiative forcing impact, but it was anticipated that without further controls their contribution to overall radiative forcing would increase, the ERF (effective radiative forcing) of halogenated gases increased by 3.5 percent between 2011 and 2019 primarily due to a decrease in atmospheric mixing-ratios of CFCs and an increase in their replacements (IPCC 2021). On December 27, 2020, the American Innovation and Manufacturing (AIM) Act was enacted by Congress and which gives EPA authority to phase down HFC production and consumption (i.e., production plus import, minus export), through an allowance allocation program, promulgate certain regulations for purposes of maximizing reclamation and minimizing releases of HFCs and their substitutes from equipment, and facilitate the transition to next-generation technologies through sector-based restrictions, which will lead to lower HFC emissions over time. On October 31, 2022, the United States also ratified the Kigali Amendment to the Montreal Protocol, committing to continued phase down of HFCs. Perfluorocarbons, SF_6, and NF_3 are predominantly emitted from various industrial processes including aluminum smelting, semiconductor manufacturing, electric power transmission and distribution, and magnesium casting. Currently, the radiative forcing impact of PFCs, SF_6, and NF_3 is also small, but they have a significant growth rate, extremely long atmospheric lifetimes, and are strong absorbers of infrared radiation, and therefore have the potential to influence climate far into the future (IPCC 2021).

Carbon Monoxide (CO). Carbon monoxide has an indirect radiative forcing effect by elevating concentrations of CH_4 and tropospheric ozone through chemical reactions with other atmospheric constituents (e.g., the hydroxyl radical, OH) that would otherwise assist in destroying CH_4 and tropospheric ozone. Carbon monoxide is created when carbon-containing fuels are burned incompletely. Through natural processes in the atmosphere, it is eventually oxidized to CO_2. Carbon monoxide concentrations are both short-lived in the atmosphere and spatially variable.

Nitrogen Oxides (NO_x). The primary climate change effects of nitrogen oxides (i.e., NO and NO_2) are indirect. Warming effects can occur due to reactions leading to the formation of ozone in the troposphere, but cooling effects can occur due to the role of NO_x as a precursor to nitrate particles (i.e., aerosols) and due to destruction of stratospheric ozone when emitted from very high-altitude aircraft.[46] Additionally, NO_x emissions are also likely to decrease CH_4 concentrations, thus having a negative radiative forcing effect (IPCC 2021). Nitrogen oxides are created from lightning, soil microbial activity, biomass burning (both natural and anthropogenic fires) fuel combustion, and, in the stratosphere, from the photo-degradation of N_2O. Concentrations of NO_x are both relatively short-lived in the atmosphere and spatially variable.

Non-methane Volatile Organic Compounds (NMVOCs). Non-methane volatile organic compounds include substances such as propane, butane, and ethane. These compounds participate, along with NO_x, in the formation of tropospheric ozone and other photochemical oxidants. NMVOCs are emitted primarily from transportation and industrial processes, as well as biomass burning and non-industrial consumption of organic solvents. Concentrations of NMVOCs tend to be both short-lived in the atmosphere and spatially variable.

[45] Article 5 of the Montreal Protocol covers several groups of countries, especially developing countries, with low consumption rates of ozone depleting substances. Developing countries with per capita consumption of less than 0.3 kg of certain ozone depleting substances (weighted by their ozone depleting potential) receive financial assistance and a grace period of ten additional years in the phase-out of ozone depleting substances.

[46] NO_x emissions injected higher in the stratosphere, primarily from fuel combustion emissions from high altitude supersonic aircraft, can lead to stratospheric ozone depletion.

Aerosols. Aerosols are extremely small particles or liquid droplets found in the atmosphere that are either directly emitted into or are created through chemical reactions in the Earth's atmosphere. Aerosols or their chemical precursors can be emitted by natural events such as dust storms, biogenic or volcanic activity, or by anthropogenic processes such as transportation, coal combustion, cement manufacturing, waste incineration, or biomass burning. Various categories of aerosols exist from both natural and anthropogenic sources, such as soil dust, sea salt, biogenic aerosols, sulfates, nitrates, volcanic aerosols, industrial dust, and carbonaceous[47] aerosols (e.g., black carbon, organic carbon). Aerosols can be removed from the atmosphere relatively rapidly by precipitation or through more complex processes under dry conditions.

Aerosols affect radiative forcing differently than greenhouse gases. Their radiative effects occur through direct and indirect mechanisms: directly by scattering and absorbing solar radiation (and to a lesser extent scattering, absorption, and emission of terrestrial radiation); and indirectly by increasing cloud droplets and ice crystals that modify the formation, precipitation efficiency, and radiative properties of clouds (IPCC 2021). Despite advances in understanding of cloud-aerosol interactions, the contribution of aerosols to radiative forcing are difficult to quantify because aerosols generally have short atmospheric lifetimes, and have number concentrations, size distributions, and compositions that vary regionally, spatially, and temporally (IPCC 2021).

The net effect of aerosols on the Earth's radiative forcing is believed to be negative (i.e., net cooling effect on the climate). In fact, aerosols contributed a cooling influence of up to 1.4 degrees, offsetting a substantial portion of greenhouse gas warming (IPCC 2021). Because aerosols remain in the atmosphere for only days to weeks, their concentrations respond rapidly to changes in emissions.[48] Not all aerosols have a cooling effect. Current research suggests that another constituent of aerosols, black carbon, has a positive radiative forcing by heating the Earth's atmosphere and causing surface warming when deposited on ice and snow (IPCC 2021). Black carbon also influences cloud development, but the direction and magnitude of this forcing is an area of active research.

Global Warming Potentials

A GWP is a quantified measure of the relative globally averaged radiative forcing impacts of emissions of a particular greenhouse gas over time (see Table 1-2). It is defined as the accumulated radiative forcing within a specific time horizon caused by emitting 1 kilogram (kg) of the gas, relative to that of the reference gas CO_2 (IPCC 2021). Direct radiative effects occur when the gas itself absorbs radiation. Indirect radiative forcing occurs when chemical transformations involving the original gas produce a gas or gases that are greenhouse gases, or when a gas influences other radiatively important processes such as the atmospheric lifetimes of other gases. The reference gas used is CO_2, and therefore GWP-weighted emissions are measured in CO_2 equivalent (CO_2 Eq.).[49] For example, the relationship between a kg of emissions of a gas and a kg of CO_2 Eq. emissions can be expressed as follows and also adapted to other units (e.g. metric tons, etc.):

[47] Carbonaceous aerosols are aerosols that are comprised mainly of carbon and hydrogen. Those carbonaceous aerosols with more hydrogen are classified as "organic carbon", and are generally reflective, while the aerosols that are nearly pure carbon are classified as "black carbon" (also referred to as "soot") and can absorb light (IPCC 2021).

[48] Volcanic activity can inject significant quantities of aerosol producing sulfur dioxide and other sulfur compounds into the stratosphere, which can result in a longer lasting negative forcing effect (i.e., a few years) (IPCC 2021).

[49] Carbon comprises 12/44^{ths} of carbon dioxide by weight.

Equation 1-1: Calculating CO_2 Equivalent Emissions

$$\text{kg } CO_2 \text{ Eq.} = (\text{kg emission of gas}) \times (\text{GWP})$$

where,

kg CO_2 Eq.	= kilograms of CO_2 equivalent
kt	= kilograms (equivalent to a thousand metric grams)
GWP	= Global warming potential

GWP values allow for a comparison of the impacts of emissions and reductions of different gases. According to the IPCC, GWPs typically have an uncertainty of ±40 percent.

All estimates are provided throughout the report in both MMT CO_2 equivalents and unweighted units. Recent decisions under the UNFCCC require Parties to use 100-year GWP values from the IPCC *Fifth Assessment Report* (AR5) for calculating CO_2-equivalent emissions in their national reporting by the end of 2024.

> *…Decides that, until it adopts a further decision on the matter, the global warming potential values used by Parties in their reporting under the Convention to calculate the carbon dioxide equivalence of anthropogenic greenhouse gas emissions by sources and removals by sinks shall be based on the effects of greenhouse gases over a 100-year time horizon as listed in table 8.A.1 in appendix 8.A to the contribution of Working Group I to the Fifth Assessment Report of the Intergovernmental Panel on Climate Change,[50] excluding the value for fossil methane.*[51]

This reflects updated science and ensures that national greenhouse gas inventories reported by all nations are comparable. In preparation for upcoming UNFCCC requirement,[52] this report reflects CO_2-equivalent greenhouse gas totals using 100-year AR5 GWP values. A comparison of emission values with the previously used 100-year GWP values from IPCC *Fourth Assessment Report* (AR4) (IPCC 2007), and the IPCC *Sixth Assessment Report* (AR6) (IPCC 2021) values can be found in Annex 6.1 of this report. The 100-year GWP values used in this report are listed below in Table 1-2.

Greenhouse gases with relatively long atmospheric lifetimes (e.g., CO_2, CH_4, N_2O, HFCs, PFCs, SF_6, NF_3) tend to be evenly distributed throughout the atmosphere, and consequently global average concentrations can be determined. The short-lived gases such as water vapor, carbon monoxide, tropospheric ozone, ozone precursors (e.g., NO_x, and NMVOCs), and tropospheric aerosols (e.g., SO_2 products and carbonaceous particles), however, vary regionally, and consequently it is difficult to quantify their global radiative forcing impacts. Parties to the UNFCCC have not agreed upon GWP values for these gases that are short-lived and spatially inhomogeneous in the atmosphere.

Box 1-2: The IPCC Sixth Assessment Report and Global Warming Potentials

In 2021, the IPCC published its *Sixth Assessment Report* (AR6), which updated its comprehensive scientific assessment of climate change. Within the AR6 report, the GWP values of gases were revised relative to previous IPCC assessment reports, e.g., the IPCC *Fifth Assessment Report* (AR5) (IPCC 2014). Although the AR5 GWP values are used throughout this report, consistent with UNFCCC reporting requirements, it is straight-forward to review the changes to the GWP values and their impact on estimates of the total GWP-weighted emissions of the United States. In the AR6, the IPCC used more recent estimates of the atmospheric lifetimes and radiative efficiencies of some gases and updated background concentrations. The AR6 now includes climate-carbon feedback effects for non-CO_2 gases, improving the consistency between treatment of CO_2 and non-CO_2 gases. Indirect effects of gases on other atmospheric constituents (such as the effect of methane on ozone) have also been updated to match more recent science.

Table 1-3 presents the new GWP values, relative to those presented in the AR5, using the 100-year time horizon common to Paris Agreement and UNFCCC reporting.[53] Updated reporting guidelines under the Paris Agreement require the United States and other countries to shift to use of the IPCC *Fifth Assessment Report* (AR5) (IPCC 2013) 100-year GWP values (without feedbacks) for national inventory reporting.[54] All estimates provided throughout this report are also presented in unweighted units. For informational purposes, emission estimates that use 100-year GWPs from other recent IPCC Assessment Reports are presented in detail in Annex 6.1 of this report.

NC (No Change)

[a] The GWP values in this column reflect values used in this report from AR5 excluding climate-carbon feedbacks and the value for fossil methane.

[b] The GWP values in this column are from the AR5 report but include climate-carbon feedbacks for the non-CO_2 gases in order to be consistent with the approach used in calculating the CO_2 lifetime.

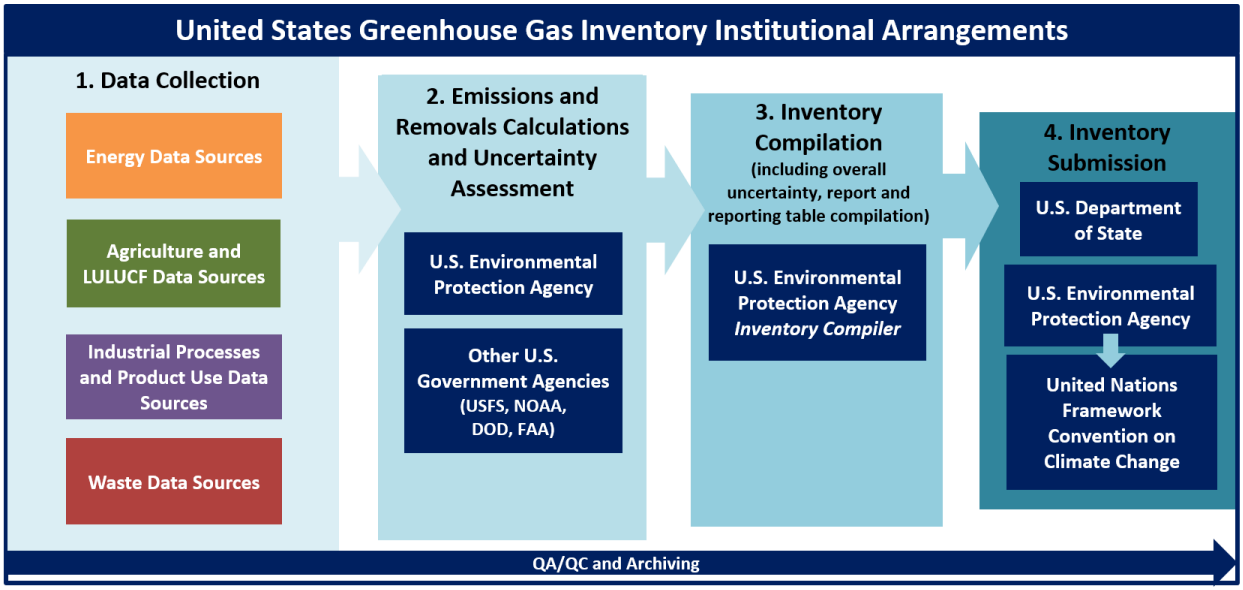
[c] The GWP values in this column are from the AR6 report.

[d] The GWP of CH_4 includes the direct effects and those indirect effects due to the production of tropospheric ozone and stratospheric water vapor. Including the indirect effect due to the production of CO_2 resulting from methane oxidation would lead to an increase in AR5 methane GWP values by 2 for fossil methane and is not shown in this table.

Note: Parentheses indicate negative values.

Sources: IPCC (2021), IPCC (2013), IPCC (2007), IPCC (2001), IPCC (1996).

1.2 National Inventory Arrangements



The U.S. Environmental Protection Agency (EPA), in cooperation with other U.S. government agencies, prepares the *Inventory of U.S. Greenhouse Gas Emissions and Sinks*. A wide range of agencies and individuals are involved in supplying data to, planning methodological approaches and improvements, reviewing, or preparing portions of the Inventory—including federal and state government authorities, research and academic institutions, industry associations, and private consultants.

Within EPA, the Office of Atmospheric Protection (OAP) is the lead office responsible for the emission and removal calculations provided in the Inventory, as well as the completion of the National Inventory Report including the Common Reporting Tables (CRTs). EPA's Office of Transportation and Air Quality (OTAQ) and Office of Research and Development (ORD) are also involved in calculating emissions and removals for the Inventory. The U.S. Department of State (DOS) serves as the overall national focal point to the Paris Agreement and the UNFCCC, and EPA's OAP serves as the National Inventory Focal Point for this report, including responding to technical questions and comments on the U.S. Inventory. EPA staff coordinate the annual methodological choice, activity data collection, emission and removal calculations, uncertainty assessment, QA/QC processes, and improvement

planning at the individual source and sink category level. EPA's inventory coordinator manages overall compilation of the entire *Inventory* into the proper reporting format for submission under the Paris Agreement and the UNFCCC and is responsible for the synthesis of information along with the consistent application of cross-cutting IPCC good practice across the *Inventory*.

Several other government agencies contribute to the collection and analysis of the necessary underlying activity data used in the Inventory calculations via formal (e.g., interagency agreements) and informal relationships, in addition to the calculation of estimates integrated in the report (e.g., U.S. Department of Agriculture's U.S. Forest Service and Agricultural Service, National Oceanic and Atmospheric Administration, Federal Aviation Administration, and Department of Defense). Other U.S. agencies provide official data for use in the *Inventory*. The U.S. Department of Energy's Energy Information Administration provides national fuel consumption data and the U.S. Department of Defense provides data on military fuel consumption and use of bunker fuels. Other U.S. agencies providing activity data for use in EPA's emission calculations include: the U.S. Department of Agriculture, National Oceanic and Atmospheric Administration, the U.S. Geological Survey, the Federal Highway Administration, the Department of Transportation, the Bureau of Transportation Statistics, the Department of Commerce, and the Federal Aviation Administration. Academic and research centers also provide activity data and calculations to EPA, as well as individual companies participating in voluntary outreach efforts with EPA. EPA engages with agencies regularly on data needs and improvements to ensure sufficient activity collection for annual compilation of estimates. Finally, EPA as the National Inventory Focal Point, in coordination with the U.S. Department of State, officially submits the *Inventory* under the Paris Agreement and the UNFCCC each April by the reporting deadline.

Figure 1-1: National Inventory Arrangements and Process Diagram

Overview of Inventory Data Sources by Source and Sink Category

Energy	Agriculture and LULUCF	IPPU	Waste
U.S. Energy Information Administration	USDA U.S. Forest Service Forest Inventory and Analysis Program (FIA)	EPA Greenhouse Gas Reporting Program (GHGRP)	EPA Greenhouse Gas Reporting Program (GHGRP)
U.S. Department of Commerce – Bureau of the Census	USDA Natural Resource Conservation Service (NRCS)	U.S. Geological Survey (USGS) National Minerals Information Center	EPA Office of Land and Emergency Management (OLEM)
U.S. Department of Defense – Defense Logistics Agency	USDA National Agricultural Statistics Service (NASS) and Agricultural Research Service (ARS)	American Chemistry Council (ACC)	EPA Clean Watershed Needs Survey (CWNS)
U.S. Department of Homeland Security	EPA Office of Research and Development (ORD)	American Iron and Steel Institute (AISI)	American Housing Survey
U.S. Department of Transportation - Federal Highway Administration	U.S. Fish and Wildlife Service	U.S. International Trade Commission (USITC)	Data from research studies, trade publications, and industry associations
U.S. Department of Transportation - Federal Aviation Administration	U.S. Department of Agriculture (USDA) Animal and Plant Health Inspection Service (APHIS)	Air-Conditioning, Heating, and Refrigeration Institute	
U.S. Department of Transportation & Bureau of Transportation Statistics	Association of American Plant Food Control Officials (AAPFCO)	Data from other U.S. government agencies, research studies, trade publications, and industry association	
U.S. Department of Labor – Mine Safety and Health Administration	National Oceanic and Atmospheric Administration (NOAA)	UNEP Technology and Economic Assessment Panel (TEAP)	
U.S. Department of Energy and its National Laboratories	EPA Office of Land and Emergency Management (OLEM)		
EPA Acid Rain Program	USDA Farm Service Agency

Federal Energy Regulatory Commission			
Data from research studies, trade publications, and industry associations			

Note: This table is not an exhaustive list of all data sources.

1.3 Inventory Preparation Process

This section describes EPA's approach to preparing the annual U.S. *Inventory*, which includes both the National Inventory Document (NID) and Common Reporting Tables (CRTs). The inventory coordinator at EPA, with support from the cross-cutting compilation staff, is responsible for coordinating aggregation of all emission and removal estimates, conducting the overall uncertainty analysis of *Inventory* emissions and trends over time, and ensuring consistency and quality throughout the NID and CRTs. Emission and removal calculations, including associated uncertainty analysis for individual sources and/or sink categories are the responsibility of individual source and sink category leads, who are most familiar with each category, underlying data, and the unique national circumstances relevant to its emissions or removals profile. Using IPCC methodological decision trees and suggested good practice guidance, the individual leads determine the most appropriate methodology and collect the relevant activity data to use in the emission and removal calculations, based upon their expertise in the source or sink category, as well as coordinating with researchers and expert consultants familiar with the sources and sinks. Each year, the coordinator oversees a multi-stage process for collecting information from each individual source and sink category lead to compile all information and data for the *Inventory*.

Methodology Development, Data Collection, and Emissions and Sinks Estimation

Source and sink category leads at EPA coordinate the collection of input data (e.g., activity data and other information) and, as necessary, evaluate or develop the estimation methodology for the individual source and/or sink categories. Because EPA has been leading preparation of the *Inventory* for many years, for most source and sink categories, the methodology for the previous year is applied to the new "current" year of the *Inventory*, and inventory analysts collect any new data or update data that have changed from the previous year. If estimates for a new source or sink category are being developed for the first time, or if the methodology is changing for an existing category (e.g., the United States is implementing improvement efforts to apply a higher tiered approach for that category), then the source and/or sink category lead will develop and implement the new or refined methodology, gather the appropriate activity data and other information (e.g., emission factors or in some cases direct emission measurements) for the entire time series, and conduct any further category-specific review with involvement of relevant experts from industry, government, and universities (see Chapter 9 and Box ES-3 on EPA's approach to recalculations).

Once the methodology is in place and the data are collected, the individual source and sink category leads calculate emission and removal estimates. The individual leads then update or create the relevant national inventory document text and accompanying annexes for the *Inventory*. Source and sink category leads are also responsible for completing the relevant sectoral background tables of the CRTs, conducting quality control (QC) checks, preparing relevant category materials for QA, or expert reviews, category-level uncertainty assessments, and reviewing data for publication in EPA's GHG Data Explorer.[55]

The treatment of confidential business information (CBI) in the *Inventory* is based on EPA internal guidelines, as well as regulations[56] applicable to the data used. EPA has specific procedures in place to safeguard CBI during the inventory compilation process. When information derived from CBI data is used for development of inventory calculations, EPA procedures ensure that these confidential data are sufficiently aggregated to protect confidentiality while still providing useful information for analysis. For example, within the Energy and Industrial

[55] See https://cfpub.epa.gov/ghgdata/inventoryexplorer/.

[56] 40 CFR Part 2, Subpart B titled "Confidentiality of Business Information" which is the regulation establishing rules governing handling of data entitled to confidentiality treatment. See https://www.ecfr.gov/cgi-bin/text-idx?SID=a764235c9eadf9afe05fe04c07a28939&mc=true&node=sp40.1.2.b&rgn=div6.

Processes and Product Use (IPPU) sectors, EPA has used aggregated facility-level data from the Greenhouse Gas Reporting Program (GHGRP) to develop, inform, and/or quality-assure U.S. emission estimates. In 2014, EPA's GHGRP, with industry engagement, compiled criteria that would be used for aggregating its confidential data to shield the underlying CBI from public disclosure.[57] In the *Inventory*, EPA is publishing only data values that meet the GHGRP aggregation criteria.[58] Specific uses of aggregated facility-level data are described in the respective methodological sections within those chapters. In addition, EPA uses historical data reported voluntarily to EPA via various voluntary initiatives with U.S. industry (e.g., EPA Voluntary Aluminum Industrial Partnership (VAIP)) and follows guidelines established under the voluntary programs for managing CBI.

Data Compilation and Archiving

The inventory coordinator at EPA with support from the data/document manager collects the source and sink categories' descriptive text and annexes, and also aggregates the emission and removal estimates into a summary data file that links the individual source and sink category data files together. This summary data file contains all of the essential data in one central location, in formats commonly used in the *Inventory* document. In addition to the data from each source and sink category, other national trend and related data are also gathered in the summary sheet for use in the Executive Summary, Introduction, and Trends chapters of the *Inventory* report (e.g., GDP, population, energy use). Similarly, the recalculation analysis and key category analysis are completed in a separate data file based on output from the summary data file. The uncertainty estimates for each source and sink category are also aggregated into uncertainty summary data files that are used to conduct the overall *Inventory* uncertainty analysis (see Section 1.7). A Microsoft SharePoint work site, maintained within EPA's IT infrastructure by the inventory coordinator, provides a platform for facilitating collaboration on the national inventory report preparation during each compilation phase, but also the efficient storage and archiving of electronic document and data files each annual cycle. Previous final published inventories are also maintained on a report archive page on EPA's Greenhouse Gas Emissions website.[59]

National Inventory Document (NID) Preparation

The NID is compiled from the sections developed by each individual source or sink category lead. In addition, the inventory coordinator prepares a brief overview of each chapter that summarizes the emissions and removals from all sources and sinks discussed in the chapters. Also at this time, the Executive Summary, Introduction, Trends in Greenhouse Gas Emissions and Removals, and Recalculations and Improvements chapters are drafted, to reflect the trends and impact from improvements for the time series of the current *Inventory*. The analysis of trends necessitates gathering supplemental data, including annual climate, economic activity and gross domestic product, population, atmospheric conditions, and the annual use of electricity, energy, fossil and non-fossil fuels. Changes in these data are used to explain the trends observed in greenhouse gas emissions in the United States. Furthermore, specific factors that affect individual sectors are researched and discussed. Many of the factors that affect emissions are included in the *Inventory* document as separate analyses or side discussions in boxes within the text. Finally, the uncertainty analysis and key category analysis are compiled and updated in the report as part of final analysis steps. Throughout the report text boxes are also created to provide additional documentation (e.g., definitions) and/or examine the data aggregated in different ways than in the remainder of the document, such as a focus on transportation activities or emissions from electricity generation. The document is prepared to align with the Paris Agreement and UNFCCC reporting guidelines for National Inventory Reports while also reflecting national circumstances.

[59] See https://www.epa.gov/ghgemissions/us-greenhouse-gas-inventory-report-archive.

Common Reporting Tables (CRTs) Compilation

The CRTs are compiled from individual time series input data sheets completed by each individual source or sink category lead, which contain emissions and/or removals and activity data, estimates, methodological and completeness notations and associated explanations. The inventory coordinator and cross-cutting compilation staff import the U.S. category and subcategory background data into the UNFCCC's Enhanced Transparency Framework Reporting Tools to export CRTs, assuring consistency and completeness across all sectoral tables. The summary reports for emissions and removals, methods, and emission factors used, the summary tables indicating completeness of estimates (i.e., notation key NE/IE tables), the recalculation tables, and the emission and removal trends tables are automatically compiled by the online reporting software and reviewed by the inventory coordinator with support from the cross-cutting compilation staff. Internal automated quality checks within the software, as well as checks by the cross-cutting and category leads, are completed for the entire time series of CRTs before submission.

QA/QC and Uncertainty

Quality assurance and quality control (QA/QC) and uncertainty analyses are guided by the QA/QC and inventory coordinators, who help maintain the QA/QC plan and the overall uncertainty analysis procedures (see sections on QA/QC and Uncertainty, below) in collaboration with the broader inventory compilation team. The QA/QC coordinator works closely with the Inventory coordinator and source and sink category leads to ensure that a consistent QA/QC plan is implemented across all inventory categories. Similarly, the inventory coordinator ensures the uncertainty analysis is implemented consistently across all categories. The inventory QA/QC plan, outlined in Section 1.6 and Annex 8, is consistent with the quality assurance procedures outlined by EPA and IPCC good practices. The QA/QC and uncertainty findings also inform overall improvement planning, and specific improvements are noted in the Planned Improvements sections of respective categories. QA processes are outlined below.

Expert, Public, and UNFCCC/Paris Reviews

The compilation of the *Inventory* includes a two-stage review or QA process, in addition to international technical expert review following submission of the report under the UNFCCC and Paris Agreement. EPA publishes responses to comments received during both expert and public reviews with the publication of the final report on its website.[60] Responses to UNFCCC and Paris reviews are included in Annex 8 of this document.

During the first stage of review, i.e., the 30-day expert review period, a first draft of updated sectoral chapters are sent to technical experts who are not directly involved in preparing estimates. The purpose of the expert review is to provide an objective review of the methodological approaches and data sources used in the current *Inventory*, especially for sources and sinks which have experienced any changes since the previous *Inventory*. Expert review follows good practices from EPA's Peer Review handbook, i.e., the review is organized by sector, and reviewers are provided a guidance memo and charge questions to facilitate their review.[61] Expert reviewers include other federal agency staff, researchers, industry experts, and others who have technical knowledge of the data, industry, and methods. EPA reviews and updates expert participation and outreach on an annual basis prior to each expert review cycle. Experts are identified in various ways; for example, many reach out to EPA with technical feedback and are added to the expert reviewer list. Reviewers are also identified through direct outreach by inventory staff based on expertise. Currently, EPA's expert list includes nearly 300 experts across all sectors. Once comments are received, they are reviewed by the source or sink lead and addressed in several ways. For example, comments suggesting methodological clarifications may be incorporated into methodological discussions prior to the next

[60] See https://www.epa.gov/ghgemissions/draft-inventory-us-greenhouse-gas-emissions-and-sinks-1990-2022.

[61] See https://www.epa.gov/osa/peer-review-handbook-4th-edition-2015.

review phase, while comments citing new literature or data will be noted for review as part of planned improvements.

Following expert review, a second draft of the document, including cross-cutting synthesis chapters, is released for a 30-day public review through a notice in the U.S. Federal Register. The entire draft *Inventory* document is published on the EPA website. The public review period is open to the entire U.S. public. Comments are submitted and tracked using an online electronic docket that is accessible to the general public as well. Similar to expert review, some comments received may require further discussion with commenters, other experts and/or additional research. Specific *Inventory* improvements requiring further analysis as a result of comments are noted in the relevant category's Planned Improvement section.

As mentioned above, following completion and submission of the report under the UNFCCC and the Paris Agreement, the report also undergoes review by an international team of independent experts for adherence to UNFCCC/Paris reporting guidelines and consistency with IPCC methodological guidance.[62] Feedback from all review processes that contribute to improving inventory quality over time are described within each planned improvement section and further in Annex 8. See also the Improvement Planning process discussed below.

Final Submittal and Publication under the Paris Agreement and the UNFCCC

After the final revisions to incorporate any comments from the Expert Review and Public Review periods, EPA prepares the final NIR, which includes the NID and the accompanying CRTs for electronic reporting. Prior to submission, EPA's Office of Atmospheric Protection briefs senior leadership on reporting findings and improvements since the previous report, along with an overview of feedback from the expert and public review processes.

EPA, as the National Inventory Focal Point, sends the official submission of the U.S. *Inventory* under the Paris Agreement and the UNFCCC using the UN's reporting software, coordinating with the U.S. Department of State, the overall UNFCCC focal point. Concurrently, the report is also published on EPA's website.[63] On EPA's website, users can also visualize and download the current time-series estimates from the GHG Inventory Data Explorer Tool,[64] and also download more detailed data presented in tables within the report and report annex in CSV format.

Improvement Planning

Each year, several emission and sink estimates in the *Inventory of U.S. Greenhouse Gas Emissions and Sinks* are recalculated and revised, through the use of better methods and/or data with the goal of improving inventory quality and reducing uncertainties, including the transparency, completeness, consistency, and overall usefulness of the report. In this effort, the United States follows the *2006 IPCC Guidelines* (IPCC 2006) and its *2019 Refinement*, which state, "Both methodological changes and refinements over time are an essential part of improving inventory quality. It is *good practice* to change or refine methods when available data have changed; the previously used method is not consistent with the IPCC guidelines for that category; a category has become key; the previously used method is insufficient to reflect mitigation activities in a transparent manner; the capacity for inventory preparation has increased; improved inventory methods become available; and/or for correction of errors." The EPA's OAP coordinates improvement planning across all sectors and also cross-cutting analyses based on annual review and input from the technical teams leading compilation of each sector's estimates, including

[62] See https://unfccc.int/process-and-meetings/transparency-and-reporting/reporting-and-review-under-the-convention/greenhouse-gas-inventories-annex-i-parties/review-process.

[64] See https://cfpub.epa.gov/ghgdata/inventoryexplorer/.

continuous improvements to the overall data and document compilation and QA/QC processes. Planned improvements are identified through QA/QC processes (including completeness checks), the key category analysis, and the uncertainty analysis. The inventory coordinator, with input from EPA source and sink category leads, maintains a log of all planned improvements, by sector and cross-cutting, tracking the category significance, specific category improvement, prioritization, anticipated time frame for implementation of each proposed improvement, and status of progress in implementing improvement. Improvements for significant or key categories are usually prioritized across all improvements unless effort would require disproportionate levels of effort and resources relative to improvements for other key categories to address.

1.4 Methodology and Data Sources

Emissions and removals of greenhouse gases from various source and sink categories have been estimated using methodologies that are consistent with the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (IPCC 2006) and its supplements and refinements. To a great extent, this report makes use of published official economic and physical statistics for activity data, emission factors and other key parameters as inputs to the methods applied. Depending on the category, activity data can include fuel consumption or deliveries, vehicle-miles traveled, raw material processed, or commodity produced, etc. Emission factors are factors that relate quantities of emissions to an activity. For more information on data sources see Section 1.2 above, Box 1-1 on use of GHGRP data, and categories' methodology sections for more information on other data sources. In addition to official statistics, the report utilizes findings from academic studies, trade association surveys and statistical reports, along with expert judgment, consistent with the *2006 IPCC Guidelines*.

The methodologies provided in the *2006 IPCC Guidelines* represent foundational methodologies for a variety of source and sink categories, and many of these methodologies continue to be improved and refined as new research and data become available. This report uses those IPCC methodologies when applicable, and supplements them with refined guidance, other available country-specific methodologies and data where possible (e.g., EPA's GHGRP). For example, as noted earlier in this chapter, this report does apply recent supplements and refinements to *2006 IPCC Guidelines* in estimating emissions and removals from coal mining, wastewater treatment and discharge, low voltage anode effects (LVAE) during aluminum production, drained organic soils, and management of wetlands, including flooded lands. Choices made regarding the methodologies and data sources used are provided in the Methodology and Time-Series Consistency discussion of each category within each sectoral chapter of the report, applying higher tiered methods when feasible, especially for key categories consistent with methodological decision trees. Where additional detail is helpful and necessary to explain methodologies and data sources used to estimate emissions, complete documentation is provided in the annexes as indicated in the methodology sections of those respective source categories (e.g., Annex 3.13 for forest land remaining forest land and land converted to forest land). Methods used for key categories (discussed below) are summarized in Annex 1.

1.5 Key Categories

The *2006 IPCC Guidelines* (IPCC 2006) and *2019 Refinement to the 2006 IPCC Guidelines* (IPCC 2019) define key categories as "inventory categories which individually, or as a group of categories (for which a common method, emission factor and activity data are applied) are prioritized within the national inventory system because their estimates have a significant influence on a country's total inventory of greenhouse gases in terms of the absolute level, the trend, or the level of uncertainty in emissions or removals. Whenever the term *key category* is used, it

includes both source and sink categories."[65] A key category analysis identifies source or sink categories for focusing efforts to improve overall Inventory quality, including additional review when feasible.

The *2006 IPCC Guidelines* (IPCC 2006) and its *2019 Refinement* (2019) define several approaches, both quantitative and qualitative, to conduct a key category analysis and identify key categories both in terms of absolute level and trend, along with consideration of uncertainty. This report employs all approaches to identify key categories for the United States. The first approach, Approach 1, identifies significant or key categories without considering uncertainty in its calculations. An Approach 1 level assessment identifies all source and sink categories that cumulatively account for 95 percent of total level, i.e., total emissions (gross) in a given year when assessed in descending order of absolute magnitude. The level analysis was performed twice, including and excluding sources and sinks from the land use, land-use change, and forestry (LULUCF) sector categories. Similarly, an Approach 1 trend analysis can identify categories with trends that significantly influence overall trends by identifying all source and sink categories that cumulatively account for 95 percent of the sum all the trend assessments (e.g., percent change relative to national trend) when sorted in descending order of absolute magnitude.

The next method, Approach 2, was then implemented to identify any additional key categories not already identified from the Approach 1 level and trend assessments by considering uncertainty. The Approach 2 analysis differs from Approach 1 by incorporating each category's uncertainty assessments in its calculations and was also performed twice, including and excluding LULUCF categories. An Approach 2 level assessment identifies all sources and sink categories that cumulatively account for 90 percent of the sum of all level assessments when sorted in descending order of magnitude. Similarly, an Approach 2 trend analysis can identify categories whose trends contribute significantly to overall trends weighing the relative trend difference with the category's relative uncertainty assessment for 2022.

For 2022, based on the key category analysis, excluding the LULUCF sector and uncertainty, 34 categories accounted for 95 percent of emissions. Four categories account for 55 percent of emissions: CO_2 from road transport-related fuel combustion, CO_2 from coal-fired electricity generation, CO_2 from gas fired electricity generation, and CO_2 from gas-fired industrial processes. When considering uncertainties, additional categories such as emissions from substitutes for ozone depleting substances in aerosols were also identified as a key category. In the trend analysis, 32 categories were identified as key categories, and when considering uncertainties, 7 additional categories were identified as key. The trend analysis shows that CO_2 emissions from coal-fired electricity generation, in addition to CO_2 from gas fired electricity generation, CO_2 from road transport related combustion, and HFC and PFC emissions from substitutes for ozone depleting substances in the refrigeration and air conditioning sector are also significant with respect to trends over the time series.

When considering the contribution of the LULUCF sector to 2022 emissions and removals, 42 categories accounted for 95 percent of emissions and sinks, with the most significant category from LULUCF being net CO_2 emission from forest land remaining forest land. When considering uncertainties and the contribution of the LULUCF sector, additional categories such as net CO_2 emissions from grassland remaining grassland were also identified as a key category. In the trend analysis, 40 categories were identified as key, and when considering uncertainties, 2 additional categories were identified as key.

Finally, in addition to conducting Approach 1 and 2 level and trend assessments as described above, a qualitative assessment of the source and sinks categories was conducted to capture any additional key categories that were not identified using the previously described quantitative approaches. For this *Inventory*, no additional categories were identified using qualitative criteria recommend by IPCC, but EPA continues to review its qualitative assessment on an annual basis. Find more information on the key category analysis, including the approach to disaggregation of inventory estimates, see Annex 1 to this report.

[65] See Chapter 4 Volume 1, "Methodological Choice and Identification of Key Categories" in IPCC (2006) and IPCC (2019). See http://www.ipcc-nggip.iges.or.jp/public/2006gl/index.html.

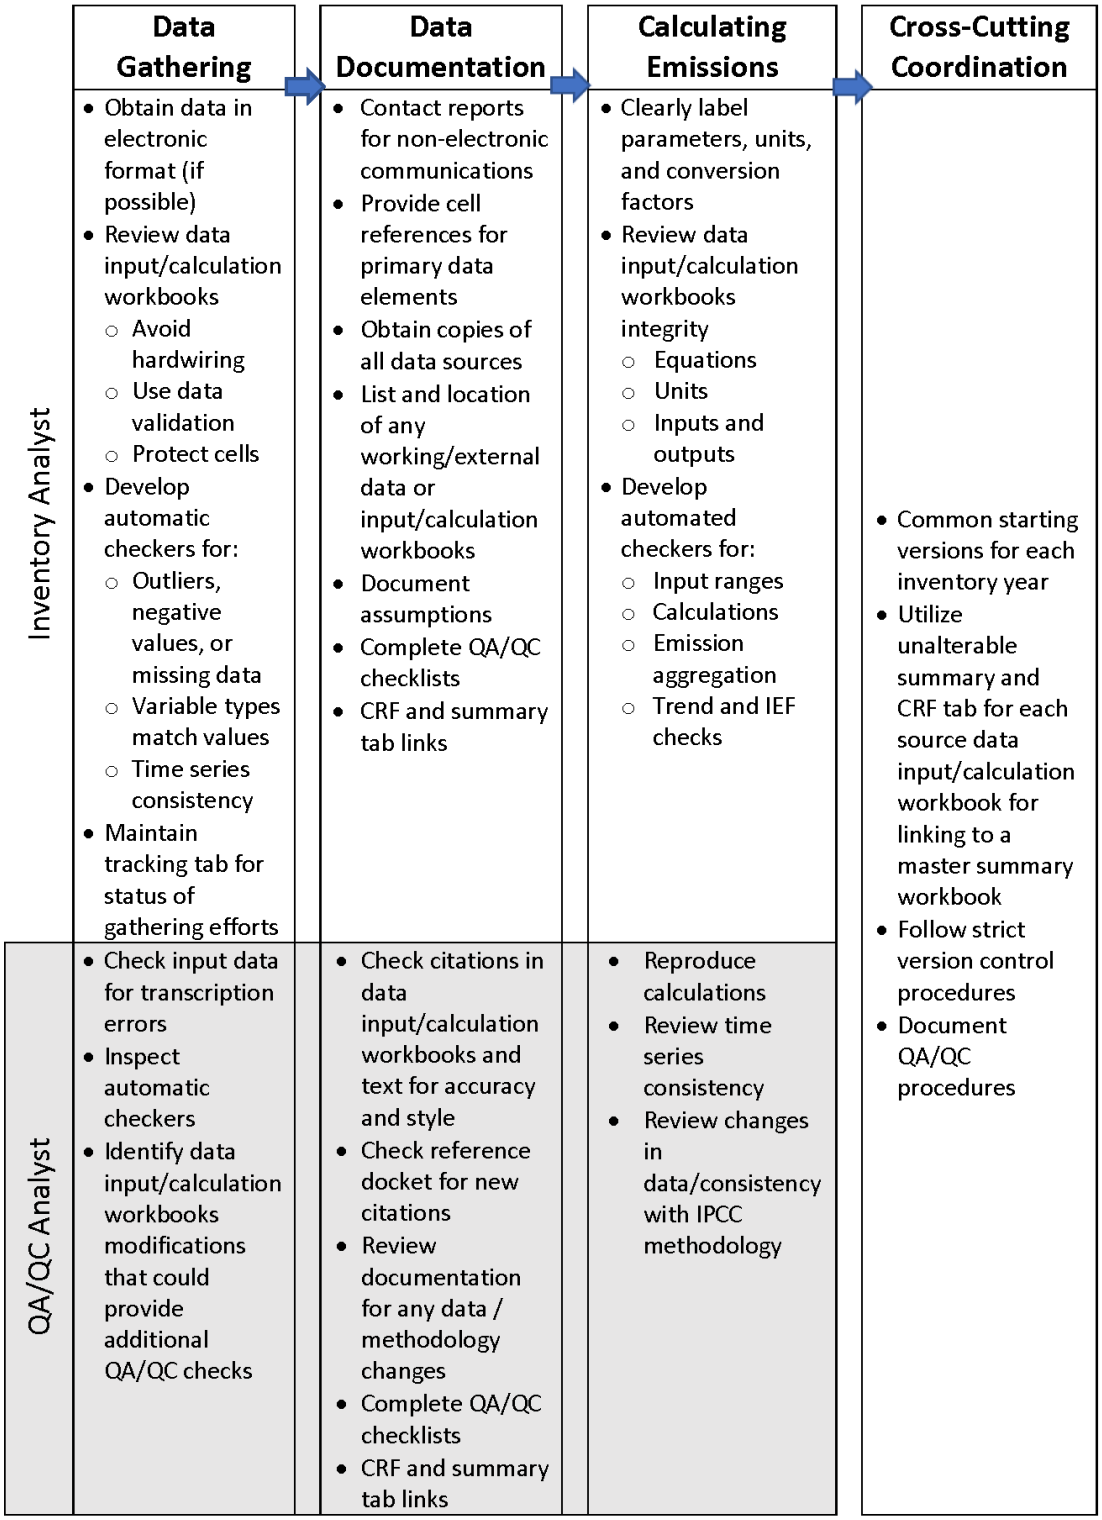
Note: Parentheses indicate negative values (or sequestration).



1.6 Quality Assurance and Quality Control (QA/QC)

As part of efforts to achieve its stated goals for inventory quality, transparency, and credibility, the United States has developed a quality assurance and quality control plan designed to check, document, and improve the quality of its inventory over time. QA/QC activities on the *Inventory* are undertaken within the framework of the U.S. *Quality Assurance/Quality Control and Uncertainty Management Plan* (QA/QC plan) *for the U.S. Greenhouse Gas Inventory: Procedures Manual for QA/QC and Uncertainty Analysis*.

Key attributes of the QA/QC plan are summarized in Figure 1-2. These attributes include:

- *Procedures and Forms:* detailed and specific systems that serve to standardize the process of documenting and archiving QA/QC implementation and related information, as well as to guide the implementation of QA/QC and the analysis of uncertainty
- *Implementation of Procedures:* guidance on application of QA/QC procedures throughout the whole Inventory development process from initial data collection, through preparation of the emission and removal estimates, to publication of the *Inventory,* consistent with the *2006 IPCC Guidelines*.
- *Quality Assurance (QA):* process for implementing expert and public reviews for both the inventory estimates and the Inventory report (which is the primary vehicle for disseminating the results of the inventory development process). The expert technical review conducted by the UNFCCC supplements these QA processes, consistent with the QA good practice and the *2006 IPCC Guidelines* (IPCC 2006). See Section 1.3 for more details on these QA processes.
- *Quality Control (QC)*: application of *General (Tier 1) and Category-specific (Tier 2)* quality controls and checks, as recommended by *2006 IPCC Guidelines* (IPCC 2006), along with consideration of secondary data and category-specific checks (additional Tier 2 QC) in parallel and coordination with the uncertainty assessment; the development of protocols and templates, which provides for more structured communication and integration with the suppliers of secondary information
- *General (Tier 1) and Category-specific (Tier 2) Checks:* quality controls and checks, as recommended by *IPCC Good Practice Guidance* and *2006 IPCC Guidelines* (IPCC 2006)
- *Record Keeping:* provisions to track which procedures have been followed, the results of the QA/QC, uncertainty analysis, and feedback mechanisms for corrective action based on the results of the investigations which provide for continual data quality improvement and guided research efforts moving forward.
- *Multi-Year Implementation*: tracking the application of more involved QA/QC procedures which may take more than one cycle to fully implement, especially for category-specific QC, prioritizing key categories in conjunction with improvement planning (see Section 1.3).
- *Interaction and Coordination:* promoting communication within the EPA, across federal agencies and departments, state government programs, and research institutions and consulting firms involved in supplying data or preparing estimates for the *Inventory*. The QA/QC Management Plan itself is intended to be revised and reflect new information that becomes available as the program develops, methods are improved, or additional supporting documents become necessary.

Figure 1-2: Summary of Key QC Processes from U.S. QA/QC Plan

Box 1-3: Examples of Verification Activities

Consistent with IPCC guidance for national greenhouse gas inventories, verification activities include comparisons with emission or removal estimates prepared by other bodies and comparisons with estimates derived from fully independent assessments, e.g., atmospheric concentration measurements. Verification activities provide information to improve inventories and are part of the overall QA/QC system.

Use of Lower Tier Methods. The Paris Agreement/UNFCCC reporting guidelines require countries to complete a "top-down" reference approach for estimating CO_2 emissions from fossil fuel combustion in addition to their "bottom-up" sectoral methodology for purposes of verification. This estimation method uses alternative methodologies and different data sources than those contained in that section of the Energy chapter. The reference approach estimates fossil fuel consumption by adjusting national aggregate fuel production data for imports, exports, and stock changes rather than relying on end-user consumption surveys (see Annex 4 of this report). The reference approach assumes that once carbon-based fuels are brought into a national economy, they are either saved in some way (e.g., stored in products, kept in fuel stocks, or left unoxidized in ash) or combusted, and therefore the carbon in them is oxidized and released into the atmosphere. Accounting for actual consumption of fuels at the sectoral or sub-national level is not required.

Use of Ambient Measurements Systems for Validation of Emission Inventories. In following the Paris Agreement and UNFCCC reporting requirements to develop and submit national greenhouse gas emission inventories, the emissions and sinks presented in this report are organized by source and sink categories and calculated using internationally accepted methods provided by the IPCC.[66] Several recent studies have estimated emissions at the national or regional level with estimated results that sometimes differ from EPA's estimate of emissions. EPA has engaged with researchers on how remote sensing, ambient measurement, and inverse modeling techniques for estimating greenhouse gas emissions could assist in improving the understanding of inventory estimates. In working with the research community to improve national greenhouse gas inventories, EPA follows guidance from the IPCC on the use of measurements and modeling to validate emission inventories.[67] An area of particular interest in EPA's outreach efforts is how ambient measurement data can be used to assess estimates or potentially be incorporated into the *Inventory* in a manner consistent with this *Inventory* report's transparency of its calculation methodologies, and the ability of inverse modeling to attribute emissions and removals from remote sensing to anthropogenic sources, as defined by the IPCC for this report, versus natural sources and sinks.

The *2019 Refinement to the IPCC 2006 Guidelines for National Greenhouse Gas Inventories* (IPCC 2019) Volume 1 General Guidance and Reporting, Chapter 6: Quality Assurance, Quality Control and Verification notes that emission estimates derived from atmospheric concentration measurements can provide independent data sets as a basis for comparison with inventory estimates. The *2019 Refinement* provides guidance on conducting such comparisons (as summarized in Table 6.2 of IPCC [2019] Volume 1, Chapter 6) and provides guidance on using such comparisons to identify areas of improvement in national inventories (as summarized in Box 6.5 of IPCC [2019] Volume 1, Chapter 6). Further, it identified fluorinated gases as particularly suitable for such comparisons due their limited natural sources, their generally long atmospheric lifetimes, and well-understood loss mechanisms, which makes it relatively more straightforward to model their emission fluxes from observed mass quantities. Unlike emissions of CO_2, CH_4, and N_2O, emissions of fluorinated greenhouse gases are almost exclusively anthropogenic, meaning that the fluorinated greenhouse gas emission sources included in this Inventory account for the majority of the total U.S. emissions of these gases detectable in the atmosphere. This evaluation approach is also useful for gases and sources with larger uncertainties in available bottom-up inventory methods and data, such as emissions of CH_4, which are primarily from uncertain biological (e.g., enteric fermentation) and fugitive (e.g., natural gas production) activities.

In this *Inventory*, EPA includes the results from current and previous comparisons between fluorinated gas

[66] See http://www.ipcc-nggip.iges.or.jp/public/index.html.

[67] See http://www.ipcc-nggip.iges.or.jp/meeting/pdfiles/1003_Uncertainty%20meeting_report.pdf.

emissions inferred from atmospheric measurements and fluorinated gas emissions estimated based on bottom-up measurements and modeling. These comparisons, performed for HFCs and SF_6 respectively, are described under the QA/QC and Verification discussions in Chapter 4, Sections 4.25 Substitution of Ozone Depleting Substances and 4.26 Electrical Equipment in the IPPU chapter of this report.

Consistent with the *2019 Refinement*, a key element to facilitate such comparisons is a spatially-explicit (or gridded) emissions inventory as an input to inverse modeling. To improve the ability to compare methane emissions from the national-level greenhouse gas inventory with observation-based emission estimates, a team of researchers from U.S. EPA, SRON Netherlands Institute for Space Research, Harvard University, and Lawrence Berkely National Laboratory developed a time series of annual anthropogenic methane emissions maps with 0.1° x 0.1° (~10km x 10km) spatial resolution and monthly temporal resolution for the contiguous United States.[68] The gridded methane inventory is designed to be consistent with the *U.S. EPA Inventory of U.S. Greenhouse Gas Emissions and Sinks* estimates, which presents national totals for different source types.[69] The development of this gridded inventory is consistent with the recommendations contained in two National Academies of Science reports examining greenhouse gas emissions data (National Research Council 2010; National Academies of Sciences, Engineering, and Medicine 2018).

Finally, in addition to use of atmospheric concentration measurement data for comparison with Inventory data, information from top-down studies is directly incorporated in the Natural Gas Systems calculations to quantify emissions from certain well blowout events.

In addition, based on the national QA/QC plan for the *Inventory*, some sector, subsector and category-specific QA/QC and verification checks have been applied. These checks follow the procedures outlined in the national QA/QC plan, tailoring the procedures to the specific documentation and data files associated with individual sources. For each greenhouse gas emissions source or sink category included in this *Inventory*, a minimum of general or Tier 1 QC analysis has been undertaken. Where QC activities for a particular category go beyond the minimum general checks and include category-specific checks (Tier 2) or include verification, further explanation is provided within the respective source or sink category text. Similarly, responses or updates based on comments from the expert, public and the international technical expert reviews (e.g., UNFCCC) are also addressed within the respective source or sink category sections in each sectoral chapter and Annex 8.

The quality control activities described in the U.S. QA/QC plan occur throughout the inventory process; QA/QC is not separate from, but is an integral part of, preparing the *Inventory*. Quality control—in the form of both good practices (such as documentation procedures) and checks on whether good practices and procedures are being followed—is applied at every stage of inventory development and document preparation. In addition, quality assurance occurs during the expert review and the public review, in addition to the UNFCCC expert technical review. While all phases significantly contribute to improving inventory quality, the public review phase is also essential for promoting the openness of the inventory development process and the transparency of the inventory methods and underlying input data sources.

The QA/QC plan guides the process of ensuring inventory quality by describing data and methodology checks, developing processes governing peer review and public comments, and developing guidance on conducting an analysis of the uncertainty surrounding the emission and removal estimates. The QA/QC procedures also include feedback loops and provide for corrective actions that are designed to improve the inventory estimates over time.

1.7 Uncertainty Analysis

Emissions and removals calculated for the U.S. Inventory reflect best estimates for greenhouse gas source and sink categories in the United States and are continuously revised and improved as new information becomes available. Uncertainty assessment is an essential element of a complete and transparent emissions inventory because it helps inform and prioritize Inventory improvements. For the U.S. Inventory, uncertainty analyses are conducted for each source and sink category as well as for the uncertainties associated with the overall emission (current and base year) and trends estimates. These analyses reflect the quantitative uncertainty in the emission (and removal) estimates associated with uncertainties in their input parameters (e.g., activity data and EFs) and serve to evaluate the relative contribution of individual input parameter uncertainties to the overall Inventory, its trends, and each source and sink category.

The overall level and trend uncertainty estimates for total U.S. greenhouse gas emissions was developed using the IPCC Approach 2 uncertainty estimation methodology (assuming a Normal distribution for Approach 1 estimates), which employs a Monte Carlo stochastic simulation technique. The IPCC provides good practice guidance on two approaches—Approach 1 and Approach 2—to estimating uncertainty for both individual and combined source categories. Approach 2 quantifies uncertainties based on a distribution of emissions (or removals), built-up from repeated calculations of emission estimation models and the underlying input parameters, randomly selected according to their known distributions. Approach 2 methodology is applied to each individual source and sink category wherever data and resources are permitted and is also used to quantify the uncertainty in the overall Inventory and its Trends. Source and sink chapters in this report provide additional details on the uncertainty analysis conducted for each source and sink category. See Annex 7 of this report for further details on the U.S. process for estimating uncertainty associated with the overall emission (base and current year) and trends estimates. Consistent with IPCC (IPCC 2006), the United States has ongoing efforts to continue to improve the overall Inventory uncertainty estimates presented in this report.

The United States has also implemented many improvements over the last several years to reduce uncertainties across the source and sink categories and improve Inventory estimates. These improvements largely result from new data sources that provide more accurate data and/or increased data coverage, as well as methodological improvements. Following IPCC good practice, additional efforts to reduce Inventory uncertainties can occur through efforts to incorporate excluded emission and sink categories (see Annex 5), improve estimation methods, and collect more detailed, measured, and representative data. Individual category chapters and Annex 7 both describe current ongoing and planned Inventory and uncertainty analysis improvements. Consistent with IPCC (2006), the United States has ongoing efforts to continue to improve the category-specific uncertainty estimates presented in this report, largely prioritized by considering improvements categories identified as significant by the Key Category Analysis.

Estimates of quantitative uncertainty for the total U.S. greenhouse gas emissions in 1990 (base year) and 2022 are shown below in Table 1-5 and Table 1-6, respectively. The overall uncertainty surrounding the Total Net Emissions is estimated to be -6 to +6 percent in 1990 and -5 to +6 percent in 2022. When the LULUCF sector is excluded from the analysis the uncertainty is estimated to be -3 to +4 percent in 1990 and -2 to +4 percent in 2022.

Table 1-5: Estimated Overall Inventory Quantitative Uncertainty for 1990 (MMT CO_2 Eq. and Percent)

Gas	1990 Emission Estimate (MMT CO_2 Eq.)	Uncertainty Range Relative to Greenhouse Gas Estimate[a] (MMT CO_2 Eq.)		Uncertainty Range Relative to Greenhouse Gas Estimate[a] (%)		Mean[b] (MMT CO_2 Eq.)	Standard Deviation[b] (MMT CO_2 Eq.)
		Lower Bound[c]	Upper Bound[c]	Lower Bound	Upper Bound		
CO_2	5,131.6	5,008.2	5,348.2	-2%	4%	5,098.2	88.0
CH_4[d]	871.7	731.3	948.4	-16%	9%	701.5	56.3
N_2O[d]	408.2	349.7	513.0	-14%	26%	434.8	41.6
PFC, HFC, SF_6, and NF_3[d]	125.5	108.6	152.9	-13%	22%	207.3	11.6
Total Gross Emissions	**6,536.9**	**6,354.3**	**6,792.8**	**-3%**	**4%**	**6,441.8**	**113.3**
LULUCF Emissions[e]	57.9	55.2	61.9	-5%	7%	68.7	1.7
LULUCF Carbon Stock Change Flux[f]	(1,034.7)	(1,296.1)	(845.3)	25%	-18%	(957.3)	116.7
LULUCF Sector Net Total[g]	**(976.7)**	**(1,237.7)**	**(787.8)**	**27%**	**-19%**	**(888.6)**	**116.7**
Net Emissions (Sources and Sinks)	**5,560.2**	**5,247.0**	**5,882.2**	**-6%**	**6%**	**5,553.3**	**161.4**

[a] The lower and upper bounds for emission estimates correspond to a 95 percent confidence interval, with the lower bound corresponding to 2.5th percentile and the upper bound corresponding to 97.5th percentile.

[b] Mean value indicates the arithmetic average of the simulated emission estimates; standard deviation indicates the extent of deviation of the simulated values from the mean.

[c] The lower and upper bound emission estimates for the sub-source categories do not sum to total emissions because the low and high estimates for total emissions were calculated separately through simulations.

[d] The overall uncertainty estimates did not take into account the uncertainty in the GWP values for CH_4, N_2O and high GWP gases used in the Inventory emission calculations for 1990.

[e] LULUCF emissions include the CH_4 and N_2O emissions reported for peatlands remaining peatlands, forest fires, drained organic soils, grassland fires, and coastal wetlands remaining coastal wetlands; CH_4 emissions from land converted to coastal wetlands, land converted to flooded land, and flooded land remaining flooded land; and N_2O emissions from forest soils and settlement soils.

[f] LULUCF carbon stock change is the net C stock change from the following categories: forest land remaining forest land, land converted to forest land, cropland remaining cropland, land converted to cropland, grassland remaining grassland, land converted to grassland, wetlands remaining wetlands, land converted to wetlands, settlements remaining settlements, and land converted to settlements. Since the resulting flux is negative the signs of the resulting lower and upper bounds are reversed.

[g] The LULUCF sector net total is the net sum of all CH_4 and N_2O emissions to the atmosphere plus net carbon stock changes.

Notes: Total emissions (excluding emissions for which uncertainty was not quantified) are presented without LULUCF. Net emissions are presented with LULUCF. Totals may not sum due to independent rounding. Parentheses indicate net sequestration.

Table 1-6: Estimated Overall Inventory Quantitative Uncertainty for 2022 (MMT CO_2 Eq. and Percent)

Gas	2022 Emission Estimate (MMT CO_2 Eq.)	Uncertainty Range Relative to Greenhouse Gas Estimate[a] (MMT CO_2 Eq.)		Uncertainty Range Relative to Greenhouse Gas Estimate[a] (%)		Mean[b] (MMT CO_2 Eq.)	Standard Deviation[b] (MMT CO_2 Eq.)
		Lower Bound[c]	Upper Bound[c]	Lower Bound	Upper Bound		
CO_2	5,053.0	4,937.3	5,257.7	-2%	4%	5,095.2	81.9
CH_4[d]	702.4	604.3	803.1	-14%	14%	703.8	52.0
N_2O[d]	389.7	324.6	490.2	-17%	26%	399.5	42.3
PFC, HFC, SF_6, and NF_3[d]	198.1	182.8	217.5	-8%	10%	199.5	9.0

Total Gross Emissions	**6,343.2**	**6,190.3**	**6,604.8**	**-2%**	**4%**	**6,397.9**	**106.3**
LULUCF Emissions[e]	67.5	64.3	73.2	-5%	8%	68.6	2.3
LULUCF Carbon Stock Change Flux[f]	(921.8)	(1,158.6)	(748.7)	26%	-19%	(957.5)	105.3
LULUCF Sector Net Total[g]	**(854.3)**	**(1,090.3)**	**(680.5)**	**28%**	**-20%**	**(888.8)**	**105.3**
Net Emissions (Sources and Sinks)	**5,488.9**	**5,216.2**	**5,801.9**	**-5%**	**6%**	**5,509.0**	**150.6**

[a] The lower and upper bounds for emission estimates correspond to a 95 percent confidence interval, with the lower bound corresponding to 2.5th percentile and the upper bound corresponding to 97.5th percentile.

[b] Mean value indicates the arithmetic average of the simulated emission estimates; standard deviation indicates the extent of deviation of the simulated values from the mean.

[c] The lower and upper bound emission estimates for the sub-source categories do not sum to total emissions because the low and high estimates for total emissions were calculated separately through simulations.

[d] The overall uncertainty estimates did not take into account the uncertainty in the GWP values for CH_4, N_2O and high GWP gases used in the Inventory emission calculations for 2022.

[e] LULUCF emissions include the CH_4 and N_2O emissions reported for peatlands remaining peatlands, forest fires, drained organic soils, grassland fires, and coastal wetlands remaining coastal wetlands; CH_4 emissions from land converted to coastal wetlands, land converted to flooded land, and flooded land remaining flooded land; and N_2O emissions from forest soils and settlement soils.

[f] LULUCF carbon stock change is the net C stock change from the following categories: forest land remaining forest land, land converted to forest land, cropland remaining cropland, land converted to cropland, grassland remaining grassland, land converted to grassland, wetlands remaining wetlands, land converted to wetlands, settlements remaining settlements, and land converted to settlements. Since the resulting flux is negative the signs of the resulting lower and upper bounds are reversed.

[g] The LULUCF sector net total is the net sum of all CH_4 and N_2O emissions to the atmosphere plus net carbon stock changes.

Notes: Total emissions (excluding emissions for which uncertainty was not quantified) are presented without LULUCF. Net emissions are presented with LULUCF. Totals may not sum due to independent rounding. Parentheses indicate net sequestration.

The uncertainty for 2022 is similar to the uncertainty for 1990, though slightly lower. There have been some improvements in significant categories which do not necessarily reduce uncertainties as also acknowledged in the IPCC 2006 IPCC GL, p. 3.13 (e.g., improvements to estimates for Agricultural Soil Management over time, implications of methodological choice). For example, the 95 percent uncertainty bounds for nitrous oxide emissions from Agricultural Soil Management were increased from –25 percent to 29 percent in 1990 to –30 percent to 72 percent in 2022. Methodological and data quality improvements were also made for HFCs, PFCs, SF_6 and NF_3 this year but the uncertainties for these sources also slightly increased, better representing the limitations of existing emissions estimates. The methods and data for fossil fuel combustion categories, the most significant source, has not changed significantly and neither have uncertainties. It is also worth noting that some of the improvements to shift to use of GHGRP have been in less significant categories within the inventory (e.g., for IPPU). So, the overall uncertainty for latest year reflects these offsetting effects and trends within the uncertainty assessment.

In addition to the estimates of uncertainty associated with the current and base year estimates, Table 1-7 presents the estimates of inventory trend uncertainty. The *2006 IPCC Guidelines* defines trend as the difference in emissions between the base year (i.e., 1990) and the current year (i.e., 2022) *Inventory* estimates. However, for purposes of understanding the concept of trend uncertainty, the trend is defined in this Inventory as the percentage change in the gross emissions (or net emissions) estimated for the current year, relative to the gross emission (or net emissions) estimated for the base year. The uncertainty associated with this trend is referred to as trend uncertainty and is reported as between -8 and 8 percent at the 95 percent confidence level between 1990 and 2022. This indicates a range of approximately -8 percent below and 8 percent above the trend estimate of -1.3 percent. See Annex 7 for trend uncertainty estimates for individual source and sink categories by gas.

Table 1-7: Quantitative Assessment of Trend Uncertainty (MMT CO_2 Eq. and Percent)

Gas	Base Year Emissions[a]	2022 Emissions	Emissions Trend	Trend Range[b]	
	(MMT CO_2 Eq.)		(%)	(%)	
				Lower Bound	Upper Bound
CO_2	5,131.6	5,053.0	-2%	-6%	3%
CH_4	871.7	702.4	-19%	-32%	2%
N_2O	408.2	389.7	-5%	-30%	51%
HFCs, PFCs, SF_6, and NF_3	125.5	198.1	58%	32%	95%
Total Gross Emissions[c]	**6,536.9**	**6,343.2**	**-3%**	**-7%**	**3%**
LULUCF Emissions[d]	57.9	67.5	17%	6%	30%
LULUCF Carbon Stock Change Flux[e]	(1,034.7)	(921.8)	-11%	-35%	21%
LULUCF Sector Net Total[f]	**(976.7)**	**(854.3)**	**-13%**	**-37%**	**21%**
Net Emissions (Sources and Sinks)[c]	**5,560.2**	**5,488.9**	**-1.3%**	**-8%**	**8%**

[a] Base Year is 1990 for all sources.

[b] The trend range represents a 95 percent confidence interval for the emission trend, with the lower bound corresponding to 2.5th percentile value and the upper bound corresponding to 97.5th percentile value.

[c] Totals exclude emissions for which uncertainty was not quantified.

[d] LULUCF emissions include the CH_4 and N_2O emissions reported for peatlands remaining peatlands, forest fires, drained organic soils, grassland fires, and coastal wetlands remaining coastal wetlands; CH_4 emissions from land converted to coastal wetlands, land converted to flooded land, and flooded land remaining flooded land; and N_2O emissions from forest soils and settlement soils.

[e] LULUCF carbon stock change is the net C stock change from the following categories: forest land remaining forest land, land converted to forest land, cropland remaining cropland, land converted to cropland, grassland remaining grassland, land converted to grassland, wetlands remaining wetlands, land converted to wetlands, settlements remaining settlements, and land converted to settlements.

[f] The LULUCF sector net total is the net sum of all CH_4 and N_2O emissions to the atmosphere plus net carbon stock changes.

Notes: Totals may not sum due to independent rounding. Parentheses indicate net sequestration. Total emissions (excluding emissions for which uncertainty was not quantified) are presented without LULUCF. Net emissions are presented with LULUCF.

1.8 Completeness

This report, along with its accompanying CRTs, serves as a thorough assessment of the anthropogenic sources and sinks of greenhouse gas emissions for the United States for the time series 1990 through 2022. This report is intended to be comprehensive and includes the vast majority of emissions and removals identified as anthropogenic, consistent with IPCC methods and the Paris Agreement and UNFCCC reporting guidelines. In general, sources or sink categories not accounted for in this *Inventory* are excluded because they are not occurring in the United States and its territories, or because data are unavailable to develop an estimate and/or the categories were determined to be insignificant[70] in terms of overall national emissions per the Paris Agreement and UNFCCC reporting guidelines.

The United States is continually working to improve upon the understanding of such sources and sinks currently not included and seeking to find the data required to estimate related emissions and removals, focusing on categories that are anticipated to be significant. See Chapter 9 on Improvements and Recalculations for more

[70] See paragraph 32 in the Annex to Decision18/CMA.1 of the Paris Agreement reporting guidelines on national inventories that state "…emissions from a category should only be considered insignificant if the likely level of emissions is below 0.05 per cent of the national total GHG emissions, excluding LULUCF, or 500 kilotonnes of carbon dioxide equivalent (kt CO_2 eq), whichever is lower. The total national aggregate of estimated emissions for all gases from categories considered insignificant shall remain below 0.1 per cent of the national total GHG emissions, excluding LULUCF. Parties should use approximated activity data and default IPCC emission factors to derive a likely level of emissions for the respective category."

information on completeness and improvements implemented this cycle. As such improvements are implemented, new emission and removal estimates are quantified and included in the *Inventory*, improving completeness of national estimates. For a list of sources and sink categories not included and more information on significance of these categories, see Annex 5 and the respective category sections in each sectoral chapter of this report.

1.9 Organization of Report

In accordance with the Paris Agreement and UNFCCC reporting guidelines, this *Inventory* is grouped into five sector-specific chapters consistent with the Paris Agreement Common Reporting Tables (CRT),[71] listed below in Table 1-8. In addition, the U.S. *Inventory* submission includes chapters on Trends in Greenhouse Gas Emissions, Other information, and Recalculations and Improvements to be considered consistent with the suggested outline or national inventory documents submitted under the Paris Agreement and UNFCCC.

Table 1-8: CRT/IPCC Sector Descriptions

Chapter (CRT and UNFCCC/IPCC Sector)	Activities Included
Energy	Emissions of all greenhouse gases resulting from stationary and mobile energy activities including fuel combustion and fugitive fuel emissions, and non-energy use of fossil fuels.
Industrial Processes and Product Use	Emissions resulting from industrial processes and product use of greenhouse gases.
Agriculture	Emissions from agricultural activities except fuel combustion, which is addressed under Energy.
Land Use, Land-Use Change, and Forestry	Emissions and removals of CO_2, and emissions of CH_4, and N_2O from land use, land-use change, and forestry.
Waste	Emissions from waste management activities.

Within each chapter, emissions are identified by the anthropogenic activity that is the source or sink of the greenhouse gas emissions being estimated (e.g., coal mining). Overall, the following organizational structure is consistently applied throughout this report:

Chapter/CRT/IPCC Sector: Overview of emissions and trends for each CRT/IPCC defined sector.

CRT Source or Sink Category: Description of category pathway and emission/removal trends based on IPCC methodologies, consistent with the Paris Agreement and UNFCCC reporting guidelines.

Methodology and Time-Series Consistency: Description of analytical methods (e.g., from *2006 IPCC Guidelines,* or country-specific methods) employed to produce emission estimates and identification of data references, primarily for activity data and emission factors, and a discussion of time-series consistency.

Uncertainty: A discussion and quantification of the uncertainty in emission estimates.

QA/QC and Verification: A discussion on steps taken to QA/QC and verify the emission estimates, consistent with the U.S. QA/QC plan, and any key QC findings.

Recalculations Discussion: A discussion of any data or methodological changes that necessitate a recalculation of previous years' emission estimates, and the impact of the recalculation on the emission estimates, if applicable.

Planned Improvements: A discussion on any category-specific planned improvements, if applicable.

[71] See paragraph 50 in the Annex to Decision 18/CMA.1

Special attention is given to CO_2 from fossil fuel combustion relative to other sources because of its share of emissions and its dominant influence on emission trends. For example, each energy consuming end-use sector (i.e., residential, commercial, industrial, and transportation), as well as the electricity generation sector, is described individually. Additional information for certain source categories and other topics is also provided in several Annexes listed in Table 1-9.

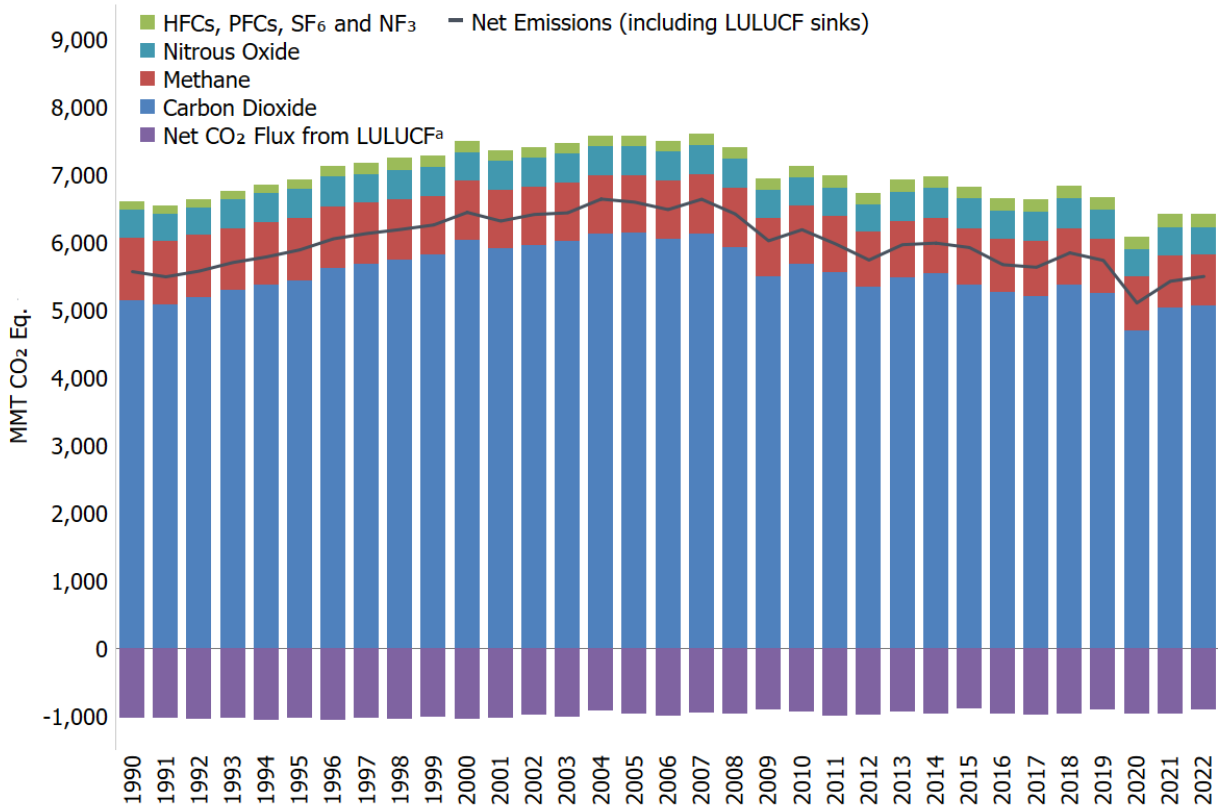
ANNEX 1 Key Category Analysis	
ANNEX 2 Methodology and Data for Estimating CO_2 Emissions from Fossil Fuel Combustion	
2.1.	Methodology for Estimating Emissions of CO_2 from Fossil Fuel Combustion
2.2.	Methodology for Estimating the Carbon Content of Fossil Fuels
2.3.	Methodology for Estimating Carbon Emitted from Non-Energy Uses of Fossil Fuels
ANNEX 3 Methodological Descriptions for Additional Source or Sink Categories	
3.1.	Methodology for Estimating Emissions of CH_4, N_2O, and Indirect Greenhouse Gases from Stationary Combustion
3.2.	Methodology for Estimating Emissions of CH_4, N_2O, and Indirect Greenhouse Gases from Mobile Combustion and Methodology for and Supplemental Information on Transportation-Related Greenhouse Gas Emissions
3.3.	Methodology for Estimating Emissions from Commercial Aircraft Jet Fuel Consumption
3.4.	Methodology for Estimating CH_4 Emissions from Coal Mining
3.5.	Methodology for Estimating CH_4 and CO_2 Emissions from Petroleum Systems
3.6.	Methodology for Estimating CH_4 Emissions from Natural Gas Systems
3.7.	Methodology for Estimating CO_2 and N_2O Emissions from Incineration of Waste
3.8.	Methodology for Estimating Emissions from International Bunker Fuels used by the U.S. Military
3.9.	Methodology for Estimating HFC and PFC Emissions from Substitution of Ozone Depleting Substances
3.10.	Methodology for Estimating CH_4 Emissions from Enteric Fermentation
3.11.	Methodology for Estimating CH_4 and N_2O Emissions from Manure Management
3.12.	Methodology for Estimating N_2O Emissions, CH_4 Emissions and Soil Organic C Stock Changes from Agricultural Lands (Cropland and Grassland)
3.13.	Methodology for Estimating Net Carbon Stock Changes in Forest Land Remaining Forest Land and Land Converted to Forest Land
3.14.	Methodology for Estimating CH_4 Emissions from Landfills
ANNEX 4 IPCC Reference Approach for Estimating CO_2 Emissions from Fossil Fuel Combustion	
ANNEX 5 Assessment of the Sources and Sinks of Greenhouse Gas Emissions Not Included	
ANNEX 6 Additional Information	
6.1.	Global Warming Potential Values
6.2.	Ozone Depleting Substance Emissions
6.3.	Greenhouse Gas Precursors: Mapping of NEI categories to the Inventory
6.4.	Constants, Units, and Conversions
6.5.	Chemical Formulas
ANNEX 7 Uncertainty	
7.1.	Overview
7.2.	Methodology and Results
7.3.	Reducing Uncertainty
7.4.	Planned Improvements
7.5.	Additional Information on Uncertainty Analyses by Source
ANNEX 8 QA/QC Procedures	
8.1.	Background
8.2.	Purpose
8.3.	Assessment Factors
8.4.	Responses During the Review Process
ANNEX 9 Use of Greenhouse Gas Reporting Program (GHGRP) in Inventory	

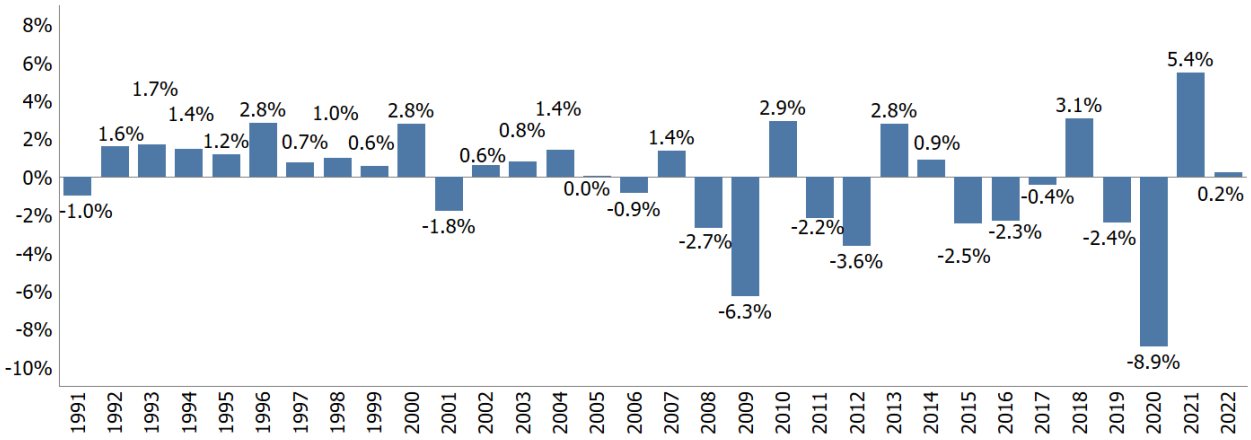
2. Trends in Greenhouse Gas Emissions and Removals



2.1 Overview of U.S. Greenhouse Gas Emissions and Sinks Trends

In 2022, total gross U.S. greenhouse gas emissions were 6,343.2 million metric tons of carbon dioxide equivalent (MMT CO_2 Eq.).[1] Total gross U.S. emissions decreased by 3.0 percent from 1990 to 2022, down from a high of 15.2 percent above 1990 levels in 2007. Gross emissions increased from 2021 to 2022 by 0.2 percent (14.4 MMT CO_2 Eq.). Net emissions (i.e., including sinks) were 5,489.0 MMT CO_2 Eq. in 2022. Overall, net emissions increased by 1.3 percent from 2021 to 2022 and decreased by 16.7 percent from 2005 levels, as shown in Table 2-1. Between 2021 and 2022, the increase in total greenhouse gas emissions was driven largely by an increase in CO_2 emissions from fossil fuel combustion across most end-use sectors due in part to increased energy use from the continued rebound of economic activity after the height of the COVID-19 pandemic. The CO_2 emissions from fossil fuel combustion increased by 1.0 percent from 2021 to 2022, including a 5.0 percent increase in residential sector emissions, 8.9 percent increase in commercial sector emissions, 0.1 percent decrease in transportation sector emissions, 2.6 percent increase in industrial emissions, and 0.6 percent decrease in electric power sector emissions. Carbon sequestration in the Land Use, Land-Use Change, and Forestry (LULUCF) sector offset 14.5 percent of total emissions in 2022.

Figure 2-1 and Figure 2-2 illustrate the overall trend in total U.S. emissions and sinks since 1990, by gas and by annual percentage changes relative to the previous year.



[1] The gross emissions total presented in this report for the United States excludes emissions and sinks from removals from LULUCF. The net emissions total presented in this report for the United States includes emissions and sinks from removals from LULUCF.

Figure 2-1: U.S. Greenhouse Gas Emissions and Sinks by Gas

[a] The term "flux" is used to describe the exchange of CO_2 to and from the atmosphere, with net flux being either positive or negative depending on the overall balance. Removal and long-term storage of CO_2 from the atmosphere is also referred to as "carbon sequestration."

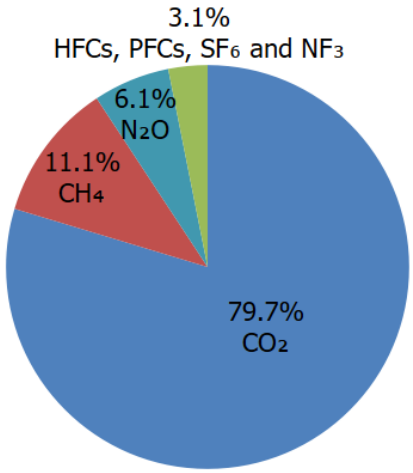


Figure 2-2: Annual Percentage Change in Gross U.S. Greenhouse Gas Emissions Relative to the Previous Year

Emissions and Sinks by Gas

Figure 2-3 illustrates the relative contribution of each gas to total gross U.S. greenhouse gas emissions in 2022, in CO_2 equivalents (i.e., weighted by global warming potential). The primary greenhouse gas emitted by human activities in the United States is CO_2, representing 79.7 percent of total greenhouse gas emissions. The largest source of CO_2—and of overall greenhouse gas emissions—is fossil fuel combustion, primarily from transportation and power generation. Methane (CH_4) emissions account for 11.1 percent of emissions. The major sources of methane include enteric fermentation associated with domestic livestock, natural gas systems, and decomposition of waste in landfills. Agricultural soil management, wastewater treatment, stationary sources of fuel combustion, and manure management are the major sources of N_2O emissions. Ozone depleting substance (ODS) substitute emissions were the primary contributor to aggregate hydrofluorocarbon (HFC) emissions. Perfluorocarbon (PFC) emissions were attributable primarily to fluorochemical production and electronics manufacturing. Electrical equipment accounted for most sulfur hexafluoride (SF_6) emissions. Nitrogen trifluoride (NF_3) emissions were approximately evenly split between electronics manufacturing and fluorochemical production.

Figure 2-3: 2022 Gross Total U.S. Greenhouse Gas Emissions by Gas (Percentages based on MMT CO_2 Eq.)

Note: Emissions and removals from LULUCF are excluded from the figure above.

From 1990 to 2022, total emissions of CO_2 decreased by 1.5 percent (78.6 MMT CO_2 Eq.), total emissions of methane (CH_4) decreased by 19.4 percent (169.3 MMT CO_2 Eq.), and total emissions of nitrous oxide (N_2O) decreased by 4.5 percent (18.4 MMT CO_2 Eq.). During the same period, emissions of fluorinated gases including HFCs, PFCs, SF_6, and NF_3 rose by 57.9 percent (72.7 MMT CO_2 Eq.). Rapidly growing emissions of HFCs drove this trend, overwhelming decreases in emissions of PFCs and SF_6. Despite being emitted in smaller quantities relative to the other principal greenhouse gases, emissions of HFCs, PFCs, SF_6, and NF_3 are significant because many of them have extremely high global warming potentials (GWPs), and, in the cases of PFCs, SF_6, and NF_3, very long atmospheric lifetimes. U.S. greenhouse gas emissions were partly offset by carbon sequestration in managed forests, trees in urban areas, agricultural soils, landfilled yard trimmings, and coastal wetlands. These were estimated to offset 14.5 percent (921.8 MMT CO_2 Eq.) of total gross emissions in 2022.

Table 2-1 provides information on trends in emissions and sinks from all U.S. anthropogenic sources and sinks in weighted units of MMT CO_2 Eq., while unweighted gas emissions and sinks in kilotons (kt) are provided in Table 2-2.

Table 2-1: Recent Trends in U.S. Greenhouse Gas Emissions and Sinks by Gas (MMT CO_2 Eq.)

+ Does not exceed 0.05 MMT CO_2 Eq.

NO (Not Occurring)

[a] Emissions from biomass and biofuel consumption are not included specifically in Energy sector totals. Net carbon fluxes from changes in biogenic carbon reservoirs are accounted for in the estimates for LULUCF.

[b] Emissions from international bunker fuels are not included in totals.

[c] LULUCF emissions of CH_4 and N_2O are reported separately from gross emissions totals. LULUCF emissions include the CH_4 and N_2O emissions reported for peatlands remaining peatlands, forest fires, drained organic soils, grassland fires, and coastal wetlands remaining coastal wetlands; CH_4 emissions from land converted to coastal wetlands, flooded land remaining flooded land, and land converted to flooded land; and N_2O emissions from forest soils and settlement soils. Refer to Table 2-8 for a breakout of emissions and removals for LULUCF by gas and source category.

[d] Small amounts of PFC emissions from this source are included under HFCs due to confidential business information.

[e] LULUCF carbon stock change is the net carbon stock change from the following categories: forest land remaining forest land, land converted to forest land, cropland remaining cropland, land converted to cropland, grassland remaining grassland, land converted to grassland, wetlands remaining wetlands, land converted to wetlands, settlements remaining settlements, and land converted to settlements. Refer to Table 2-8 for a breakout of emissions and removals for LULUCF by gas and source category.

[f] The LULUCF sector net total is the net sum of all LULUCF CH_4 and N_2O emissions to the atmosphere plus LULUCF net carbon stock changes.

Notes: Total (gross) emissions are presented without LULUCF. Net emissions are presented with LULUCF. Totals may not sum due to independent rounding. Parentheses indicate negative values or sequestration.

NO (Not Occurring)
[a] Emissions from biomass and biofuel consumption are not included specifically in Energy sector totals. Net carbon fluxes from changes in biogenic carbon reservoirs are accounted for in the estimates for LULUCF.
[b] Emissions from international bunker fuels are not included in totals.
[c] LULUCF emissions of LULUCF CH_4 and N_2O are reported separately from gross emissions totals. Refer to Table 2-8 for a breakout of emissions and removals for LULUCF by gas and source category.
[d] Small amounts of PFC emissions from this source are included under HFCs due to confidential business information.
Notes: Totals by gas may not sum due to independent rounding. Parentheses indicate negative values or sequestration.

Emissions and Sinks by UNFCCC/IPCC Sector

Emissions and removals of all gases can be summed from each source and sink category into a set of five sectors defined by the Paris Agreement and UNFCCC reporting guidelines and methodological framework provided by the Intergovernmental Panel on Climate Change (IPCC). Figure 2-4 and Table 2-3 illustrate that over the 33-year period of 1990 to 2022, total emissions from the Energy and Waste sectors decreased by 3.4 percent (181.2 MMT CO_2 Eq.) and 29.3 percent (69.1 MMT CO_2 Eq.), respectively. Emissions from Industrial Processes and Product Use and Agriculture grew by 3.9 percent (14.4 MMT CO_2 Eq.) and 7.7 percent (42.2 MMT CO_2 Eq.), respectively. Over the same period, total carbon sequestration in the LULUCF sector decreased by 12.5 percent (122.5 MMT CO_2), and emissions from the LULUCF sector increased by 16.5 percent (9.6 MMT CO_2 Eq.).

Figure 2-4: U.S. Greenhouse Gas Emissions and Sinks by IPCC Sector

+ Does not exceed 0.05 MMT CO_2 Eq.

[a] Includes CH_4 and N_2O emissions from fuel combustion.

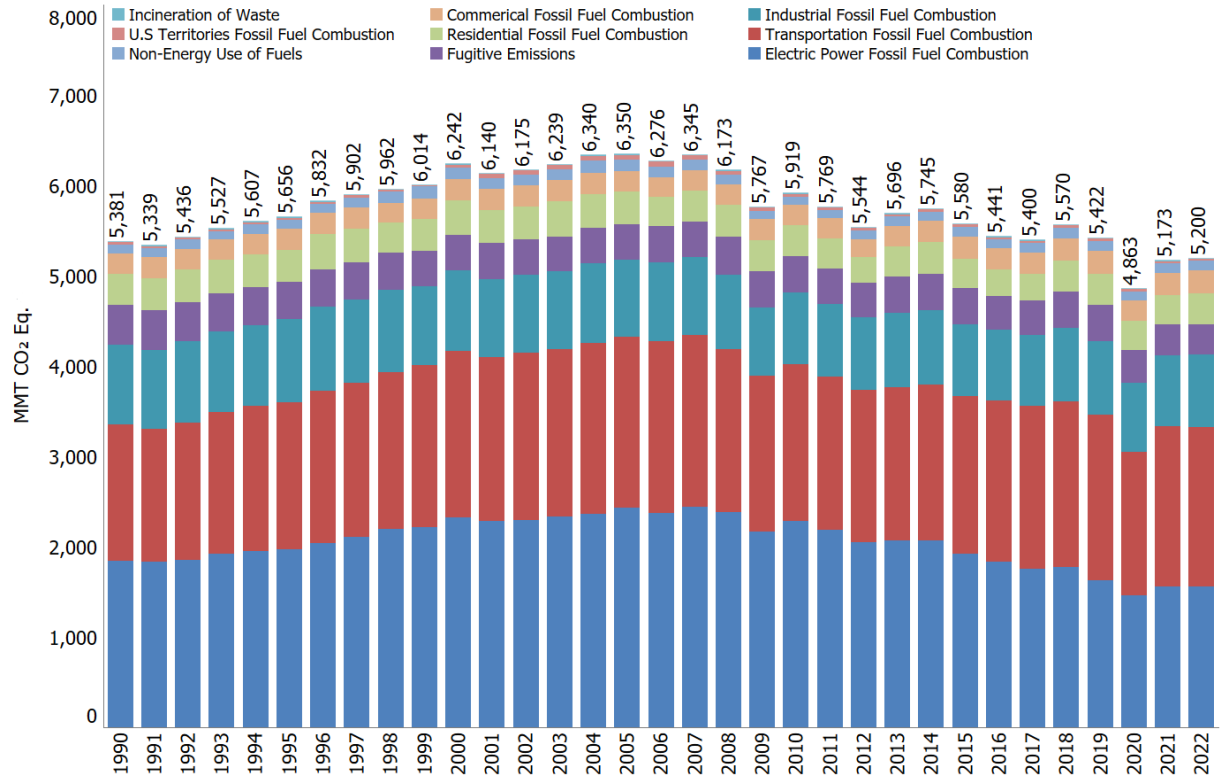
[b] Emissions from biomass and biofuel consumption are not included specifically in summing Energy sector totals. Net carbon fluxes from changes in biogenic carbon reservoirs are accounted for in the estimates for LULUCF.

[c] Emissions from international bunker fuels are not included in totals.

[d] Total emissions without LULUCF.

[e] LULUCF emissions of CH_4 and N_2O are reported separately from gross emissions totals. LULUCF emissions include the CH_4 and N_2O emissions reported for peatlands remaining peatlands, forest fires, drained organic soils, grassland fires, and coastal wetlands remaining coastal wetlands; CH_4 emissions from land converted to coastal wetlands, flooded land remaining flooded land, and land converted to flooded land; and N_2O emissions from forest soils and settlement soils. Refer to Table 2-8 for a breakout of emissions and removals for LULUCF by gas and source category.

[f] Net emissions with LULUCF.



Notes: Total (gross) emissions are presented without LULUCF. Net emissions are presented with LULUCF. Totals may not sum due to independent rounding. Parentheses indicate negative values or sequestration.

Energy

Emissions from energy-related activities come from two main categories: 1) direct emissions associated with fuel use (i.e., fossil fuel combustion, non-energy use of fossil fuels and waste combustion), and 2) fugitive emissions mainly from coal, natural gas, and oil production. Energy emissions also include some categories that are not added to Energy sector totals but are instead presented as memo items, including international bunker fuels and biomass emissions. Energy-related activities, primarily fossil fuel combustion, accounted for the vast majority of U.S. CO_2 emissions from 1990 through 2022. Fossil fuel combustion is the largest source of energy-related emissions, with CO_2 being the primary gas emitted (see Figure 2-5). Due to their relative importance, fossil fuel combustion-related CO_2 emissions are considered in detail in the Energy chapter (see Chapter 3).

In 2022, 83.0 percent of the energy used in the United States on a Btu basis was produced through the combustion of fossil fuels. The remaining 17.0 percent came from other energy sources such as hydropower, biomass, nuclear, wind, and solar energy. A discussion of specific trends related to CO_2 and other greenhouse gas emissions from energy use is presented here with more detail in the Energy chapter. Energy-related activities are also responsible for CH_4 and N_2O emissions (40.2 percent and 10.8 percent of gross total U.S. emissions of each gas, respectively).[2] Table 2-4 presents greenhouse gas emissions from the Energy chapter by source and gas.

Figure 2-5: Trends in Energy Sector Greenhouse Gas Sources

[2] The contribution of energy non-CO_2 emissions is based on gross totals so excludes LULUCF methane (CH_4) and nitrous oxide (N_2O) emissions. The contribution of energy-related CH_4 and N_2O including LULUCF non-CO_2 emissions, is 37.1 percent and 9.8 percent, respectively.

Table 2-4: Emissions from Energy by Gas (MMT CO_2 Eq.)[3]

+ Does not exceed 0.05 MMT CO_2 Eq.

[a] Emissions from biomass and biofuel consumption are not included specifically in Energy sector totals. Net carbon fluxes from changes in biogenic carbon reservoirs are accounted for in the estimates for LULUCF.

[b] Emissions from international bunker fuels are not included in totals. These values are presented for informational purposes only, in line with the *2006 IPCC Guidelines*, the Paris Agreement and the UNFCCC reporting obligations.

Note: Totals may not sum due to independent rounding.

[3] The full time series data is available in Common Reporting Tables (CRTs) included in the U.S. Paris Agreement and UNFCCC submission and in CSV format available at https://www.epa.gov/ghgemissions/inventory-us-greenhouse-gas-emissions-and-sinks.

Fossil Fuel Combustion CO_2 Emissions

As the largest contributor to U.S. greenhouse gas emissions, CO_2 from fossil fuel combustion has accounted for approximately 74.6 percent of CO_2-equivalent total gross emissions on average across the time series. Within the United States, fossil fuel combustion accounted for 93.0 percent of CO_2 emissions in 2022. Emissions from this source category include CO_2 associated with the combustion of fossil fuels (coal, natural gas, and petroleum) for energy use. Fossil fuel combustion CO_2 emissions decreased by 1.1 percent (52.8 MMT CO_2 Eq.) from 1990 to 2022 and were responsible for most of the decrease in national emissions during this period. Similarly, CO_2 emissions from fossil fuel combustion have decreased by 18.2 percent (1,044.7 MMT CO_2 Eq.) since 2005. From 2021 to 2022, these emissions increased by 1.0 percent (45.1 MMT CO_2 Eq.).

Historically, changes in emissions from fossil fuel combustion have been the main factor influencing U.S. emission trends. Changes in CO_2 emissions from fossil fuel combustion since 1990 are affected by many long-term and short-term factors, including population and economic growth, energy price fluctuations and market trends, technological changes, carbon intensity of energy fuel choices, and seasonal temperatures. On an annual basis, the overall consumption and mix of fossil fuels in the United States fluctuates in response to changes in general economic conditions, overall energy prices, the relative price of different fuels, weather, and the availability of non-fossil alternatives. For example, coal consumption for electric power is influenced by factors such as the relative price of coal and alternative sources, the ability to switch fuels, and longer-term trends in coal markets. Fossil fuel combustion CO_2 emissions also depend on the type of fuel consumed or energy used and its carbon intensity. Producing a unit of heat or electricity using natural gas instead of coal, for example, reduces CO_2 emissions because of the lower carbon content of natural gas (see Table 3-12 in Chapter 3 for more detail on electricity generation by source and see Table A-19 in Annex 2.1 for more detail on the carbon content coefficient of different fossil fuels).

Overall CO_2 emissions from electric power generation decreased by 36.2 percent from 2005 to 2022 (see Figure 2-7), reflecting the continued shift in the share of electric power generation from coal to natural gas and renewables since 2005. Carbon dioxide emissions from coal combustion for electric power generation gradually increased between 1990 and 2007, then began to decrease at a faster rate from 2008 to 2022. Carbon dioxide emissions from natural gas combustion for electric power generation remained relatively constant, with a slight increase between 1990 and 2009, then began to consistently increase between 2010 and 2022.

Petroleum use is another major driver of CO_2 emissions from fossil fuel combustion, particularly in the transportation sector, which has represented the largest source of CO_2 emissions from fossil fuel combustion since 2017. Emissions from petroleum consumption for transportation (including bunker fuels) decreased by 0.1 percent from 2021 to 2022. Fuel economy of light-duty vehicles is an important factor in transportation sector CO_2 emissions trends. The decline in new light-duty vehicle fuel economy between 1990 and 2004 reflected the increasing market share of light-duty trucks, which grew from about 29.6 percent of new vehicle sales in 1990 to 48.0 percent in 2004. Starting in 2005, average new vehicle fuel economy began to increase while light-duty VMT grew only modestly for much of the period and has slowed the rate of increase of CO_2 emissions.

Trends in CO_2 emissions from fossil fuel combustion by end-use sector are presented in Table 2-5 and Figure 2-6 based on the underlying U.S. energy consumer data collected by the U.S. Energy Information Administration (EIA). Figure 2-7 further describes trends in direct and indirect CO_2 emissions from fossil fuel combustion by end-use sector. Estimates of CO_2 emissions from fossil fuel combustion are calculated from these EIA "end-use sectors" based on total fuel consumption and appropriate fuel properties described below.[4]

- *Transportation.* EIA's fuel consumption data for the transportation sector consists of all vehicles whose primary purpose is transporting people and/or goods from one physical location to another.
- *Electric Power.* EIA's fuel consumption data for the electric power sector are composed of electricity-only and combined-heat-and-power (CHP) plants within the North American Industry Classification System (NAICS) 22 category whose primary business is to sell electricity, or electricity and heat, to the public.

[4] Additional analysis and refinement of the EIA data is further explained in the Energy chapter of this report.

(Non-utility power producers are included in this sector as long as they meet the electric power sector definition.)

- *Industry.* EIA statistics for the industrial sector include fossil fuel consumption that occurs in the fields of manufacturing, agriculture, mining, and construction. EIA's fuel consumption data for the industrial sector consist of all facilities and equipment used for producing, processing, or assembling goods. (EIA includes generators that produce electricity and/or useful thermal output primarily to support on-site industrial activities in this sector.)
- *Residential.* EIA's fuel consumption data for the residential sector consist of living quarters for private households.
- *Commercial.* EIA's fuel consumption data for the commercial sector consist of service-providing facilities and equipment from private and public organizations and businesses. (EIA includes generators that produce electricity and/or useful thermal output primarily to support the activities at commercial establishments in this sector.)

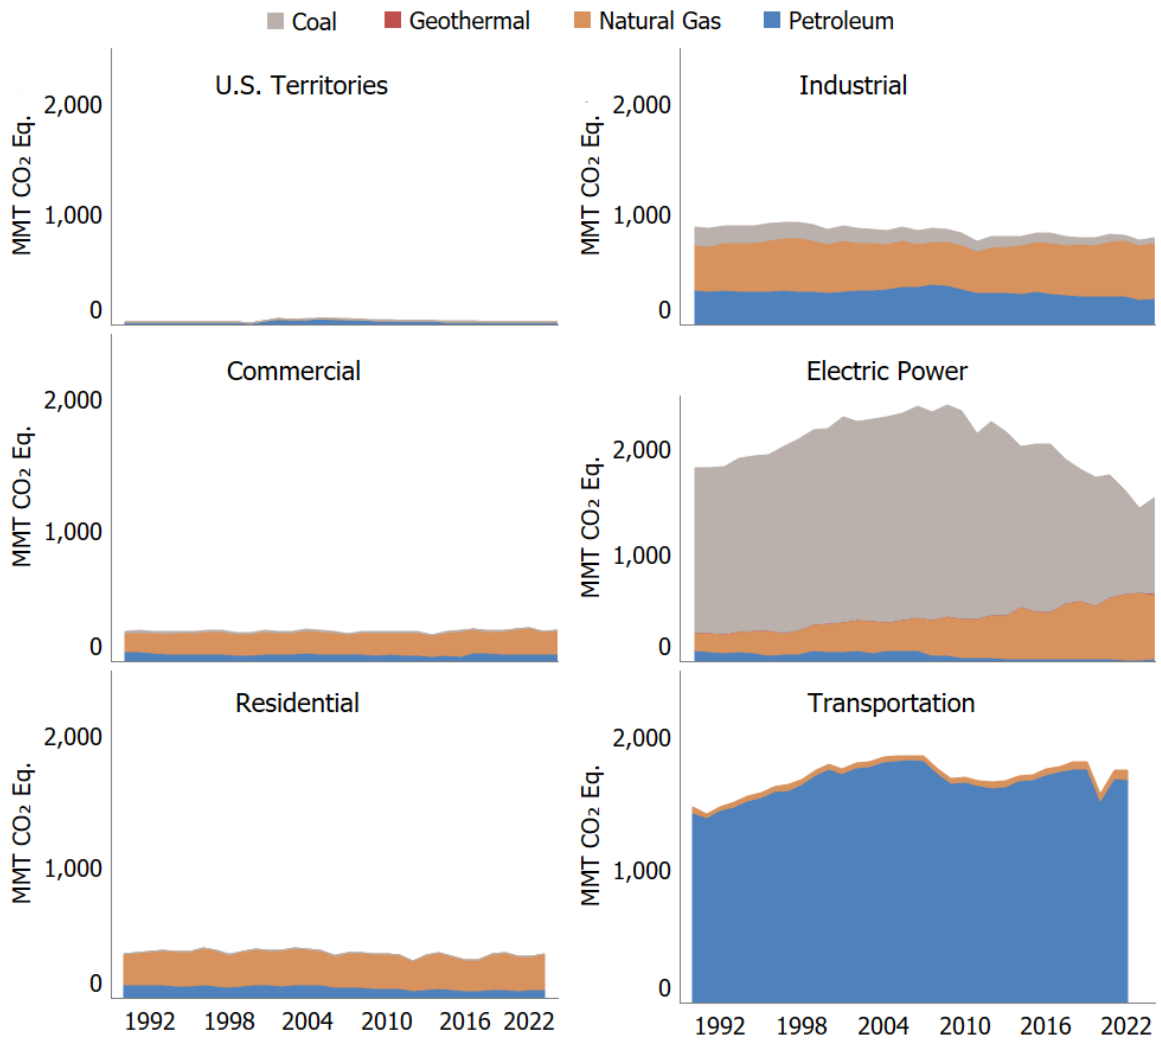

Table 2-5: CO_2 Emissions from Fossil Fuel Combustion by End-Use Sector (MMT CO_2 Eq.)

End-Use Sector	1990	2005	2018	2019	2020	2021	2022
Transportation	**1,472.0**	**1,863.3**	**1,817.9**	**1,821.4**	**1,576.9**	**1,758.6**	**1,757.4**

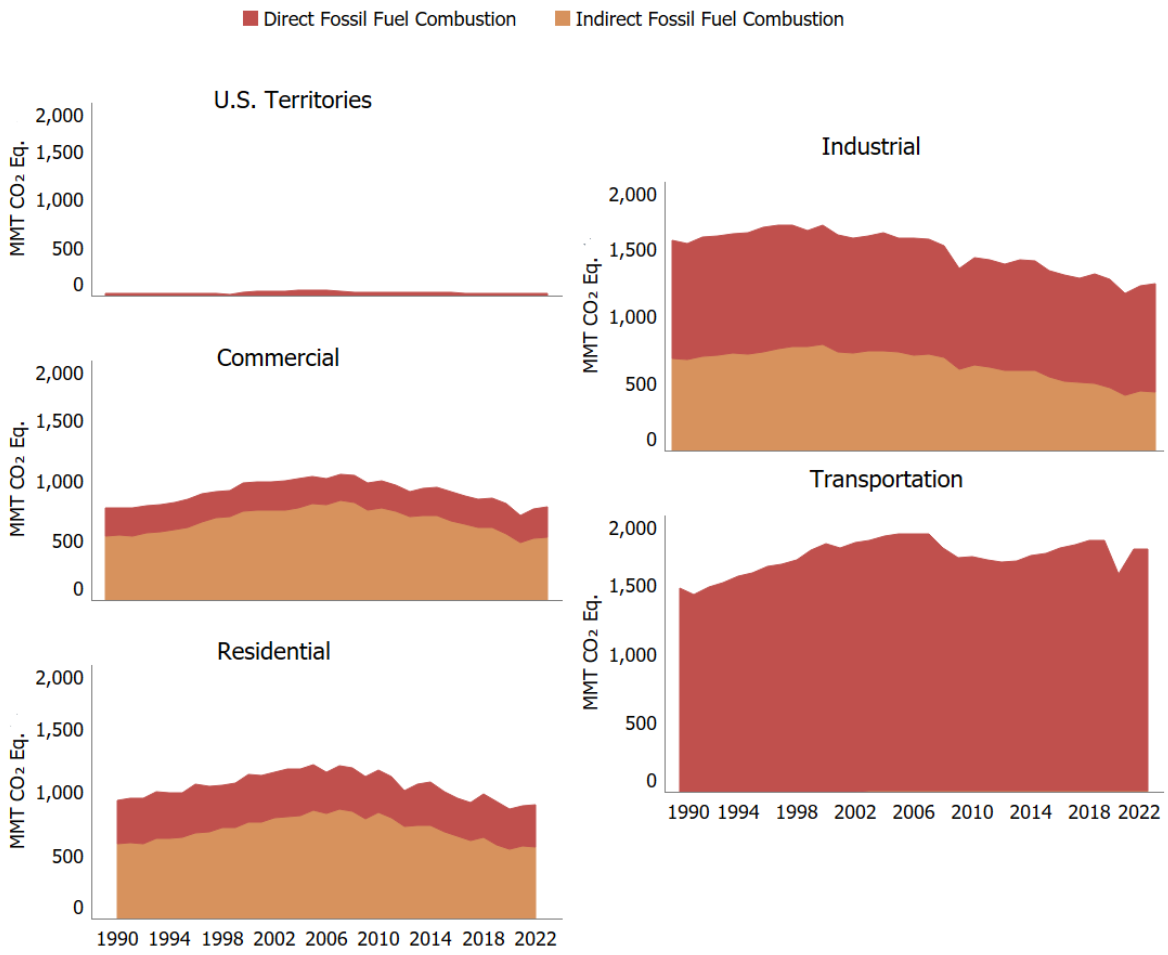
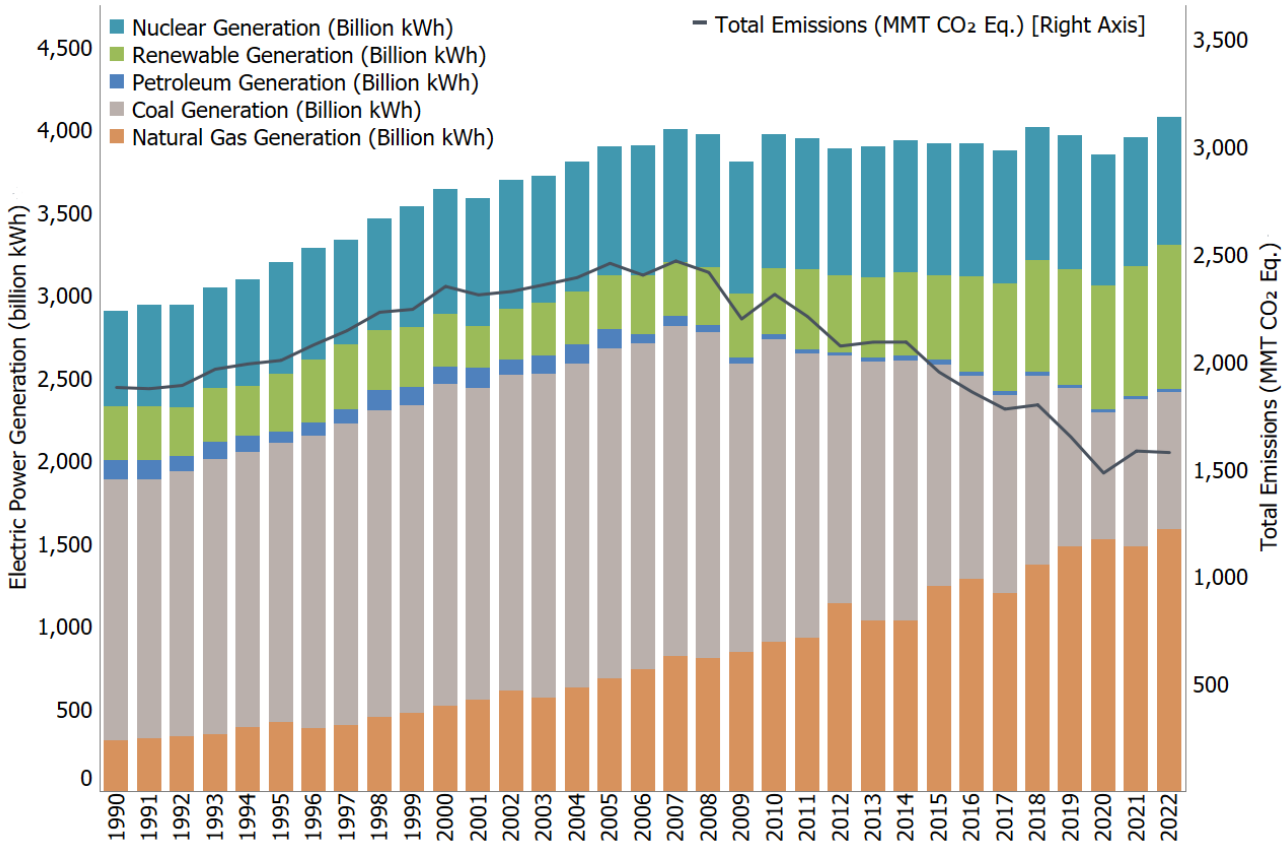
Commercial	**766.0**	**1,030.1**	**851.3**	**804.4**	**709.6**	**756.1**	**782.0**
Combustion	228.3	227.1	246.3	251.7	229.3	237.5	258.7
Electricity	537.7	803.0	605.0	552.7	480.3	518.5	523.3
U.S. Territories[a]	**20.0**	**51.9**	**25.9**	**24.8**	**23.3**	**23.8**	**22.6**
Total	**4,752.2**	**5,744.1**	**4,988.2**	**4,852.6**	**4,341.7**	**4,654.3**	**4,699.4**
Electric Power	**1,820.0**	**2,400.1**	**1,753.4**	**1,606.7**	**1,439.6**	**1,540.9**	**1,531.7**

[a] Fuel consumption by U.S. Territories (i.e., American Samoa, Guam, Puerto Rico, U.S. Virgin Islands, Wake Island, and other outlying U.S. Pacific Islands) is included in this report.



Notes: Combustion-related emissions from electric power are allocated based on aggregate national electricity use by each end-use sector. Totals may not sum due to independent rounding.

Figure 2-6: Trends in CO_2 Emissions from Fossil Fuel Combustion by End-Use Sector and Fuel Type



Note: Fossil fuel combustion for electric power also includes emissions of less than 0.5 MMT CO_2 Eq. from geothermal-based generation. Although not technically a fossil fuel, geothermal energy-related CO_2 emissions are included for reporting purposes. The source of CO_2 is non-condensable gases in subterranean heated water.

Figure 2-7: Trends in End-Use Sector Emissions of CO_2 from Fossil Fuel Combustion

Electric power was the second largest end-use emitter of CO_2 in 2022 (surpassed by transportation in 2017); electric power generators used 30.5 percent of U.S. energy from fossil fuels and emitted 32.6 percent of the CO_2 from fossil fuel combustion in 2022. CO_2 emissions from the fossil fuel combustion in the electric power sector decreased by 0.6 percent between 2021 and 2022 due to changes in the mix of electric generation resources. Between 2021 and 2022 overall electricity generation increased by 3 percent, coal electricity generation decreased by 10.2 percent, natural gas generation increased by 4.0 percent, and renewable energy generation increased by 7.6 percent. Changes in electricity demand and the carbon intensity of fuels used for electric power generation have a significant impact on CO_2 emissions. Carbon dioxide emissions from fossil fuel combustion from the electric power sector have decreased by 15.8 percent since 1990, and the carbon intensity of the electric power sector, in terms of CO_2 Eq. per QBtu input, has decreased by 27.6 percent during that same timeframe. This decoupling of electric power generation and the resulting CO_2 emissions is shown below in Figure 2-8.

Figure 2-8: Electric Power Generation (Billion kWh) and Emissions (MMT CO_2 Eq.)

Electric power CO_2 emissions can also be allocated to the end-use sectors that use electricity, as presented in Table 2-5. With electricity CO_2 emissions allocated to end-use sectors, the transportation end-use sector represents the largest source of fossil fuel combustion emissions accounting for 1,757.4 MMT CO_2 Eq. in 2022 or 37.4 percent of total CO_2 emissions from fossil fuel combustion, a 0.1 percent decrease since 2021. The industrial end-use sector accounted for 26.3 percent of CO_2 emissions from fossil fuel combustion when including allocated electricity emissions, an increase of 1.0 percent since 2021. From 2021 to 2022, total energy use in the industrial sector increased by 1.8 percent due to an increase in total industrial production and manufacturing output. The residential and commercial end-use sectors accounted for 19.1 and 16.6 percent, respectively, of CO_2 emissions from fossil fuel combustion when including allocated electricity emissions. Both of these end-use sectors were heavily reliant on electricity for meeting building-related energy needs, with electricity use for lighting, heating, air conditioning, and operating appliances contributing 62.9 and 66.9 percent of emissions from the residential and commercial end-use sectors, respectively. From 2021 to 2022, an increase in heating degree days (7.9 percent) increased energy demand for heating in the residential and commercial sectors; also, a 4.3 percent increase in cooling degree days compared to 2021 increased demand for air conditioning in the residential and commercial sectors. As a result, CO_2 emissions from the residential and commercial end-use sectors when including allocated electricity emissions increased by 1.0 and 3.4 percent since 2021, respectively.

Other Energy Sector Trends

Energy sector emissions increased by 0.5 percent since 2021 and decreased by 3.4 percent since 1990. Other notable trends in emissions from energy source categories (Figure 2-6 and Figure 2-7) over the 33-year period from 1990 through 2022 included the following:

- Emissions (CH_4, CO_2, and N_2O) from oil and gas systems decreased by 13.0 percent (38.8 MMT CO_2 Eq.) since 1990 and decreased by 4.2 percent (11.8 MMT CO_2 Eq.) from 2021 to 2022. Natural gas systems CH_4 emissions have decreased by 20.9 percent (45.7 MMT CO_2 Eq.) since 1990, due to a decrease in emissions from the distribution, transmission and storage, processing, and exploration segments. The decrease in distribution emissions is due mainly to reduced emissions from pipeline and distribution station leaks, and the decrease in transmission and storage emissions is due mainly to reduced compressor station emissions (including emissions from compressors and leaks). Over the same time period (i.e., since 1990), methane emissions from the natural gas production segment increased due to increased gathering and boosting emissions. Between 2021 and 2022, methane emissions from natural gas systems decreased 0.8 percent, due to a decrease in emissions from production segment pneumatic controllers. Petroleum systems CH_4 emissions decreased by 19.8 percent (9.8 MMT CO_2 Eq.) since 1990 and 18.5 percent between 2021 and 2022. This decrease is due primarily to decreases in emissions from offshore platforms, tanks, and pneumatic controllers. Carbon dioxide emissions from natural gas and petroleum systems increased by 39.1 percent (16.4 MMT CO_2) from 1990 to 2022 and decreased by 2.5 percent between 2021 and 2022. This increase since 1990 is due primarily to increases in the production segment, where emissions from associated gas flaring, tanks, and miscellaneous production flaring have increased over time. The decrease in emissions between 2021 and 2022 and is also due primarily to the production segment, where flaring emissions decreased for associated gas and tanks.
- Methane emissions from coal mining decreased by 59.6 percent (64.4 MMT CO_2 Eq.) from 1990 through 2022 and by 2.3 percent between 2021 and 2022 primarily due to a decrease in the number of active mines and annual coal production over the 1990 to 2022 time period. Between 2021 and 2022, the number of mines and coal production increased.
- Nitrous oxide emissions from mobile combustion decreased by 56.5 percent (21.7 MMT CO_2 Eq.) from 1990 through 2022 and by 0.7 percent (0.1 MMT CO_2 Eq.) between 2021 and 2022, primarily as a result of national vehicle criteria pollutant emissions standards and emission control technologies for on-road vehicles.
- Nitrous oxide emissions from stationary combustion were the third largest source of anthropogenic N_2O emissions in 2022, accounting for 6.3 percent of N_2O emissions and 0.4 percent of total gross U.S. greenhouse gas emissions in 2022. Stationary combustion emissions peaked in 2007 and have steadily decreased since then.
- Carbon dioxide emissions from non-energy uses of fossil fuels increased by 3.7 percent (3.7 MMT CO_2 Eq.) from 1990 through 2022 but decreased by 7.9 percent (8.8 MMT CO_2 Eq.) between 2021 and 2022. Emissions from non-energy uses of fossil fuels were 102.8 MMT CO_2 Eq. in 2022, which constituted 2.0 percent of total national CO_2 emissions, approximately the same proportion as in 1990.
- Carbon dioxide emissions from incineration of waste decreased slightly by 4.2 percent (0.5 MMT CO_2 Eq.) from 1990 through 2022, as the volume of scrap tires and other fossil carbon-containing materials in waste decreased. Emissions decreased 0.9 percent (0.1 MMT CO_2 Eq.) between 2021 and 2022, consistent with trends across the time series.

Industrial Processes and Product Use

Greenhouse gases can be generated and emitted by industry in two different ways. First, they are generated and emitted as the byproducts of many non-energy-related industrial activities. For example, industrial processes can chemically or physically transform raw materials, which often release waste gases such as CO_2, CH_4, N_2O, and fluorinated gases (e.g., HFC-23). In the case of byproduct emissions, the emissions are generated by an industrial process itself, and are not directly a result of energy consumed during the process.

Second, industrial manufacturing processes and use by end-consumers also release HFCs, PFCs, SF_6, and NF_3 and other man-made compounds. In addition to the use of HFCs and some PFCs as substitutes for ozone depleting substances (ODS), fluorinated compounds such as HFCs, PFCs, SF_6, NF_3, and others are also emitted through use by

a number of other industrial sources in the United States. These industries include the electronics industry, electrical equipment, and magnesium metal production and processing. In addition, N_2O is used in and emitted by the electronics industry and anesthetic and aerosol applications, PFCs and SF_6 are emitted from other product use, and CO_2 is consumed and emitted through various end-use applications.

Emission sources in the Industrial Processes and Product Use (IPPU) chapter accounted for 6.0 percent of U.S. greenhouse gas emissions in 2022. Emissions from the IPPU sector increased by 3.9 percent from 1990 to 2022. The use of HFCs as substitutes for ODS is the largest source of emissions in this sector, contributing 46.5 percent of IPPU emissions in 2022 and driving growth since 1990. From 2021 to 2022, total emissions from IPPU increased 0.4 percent between 2021 and 2022. Despite the sectoral increase in emissions, emissions from adipic acid production decreased by almost 70 percent, emissions from ferroalloy production decreased by over 10 percent, and emissions from aluminum production, petrochemical production and zinc production decreased by between 5 and 10 percent. Figure 2-9 presents greenhouse gas emissions from IPPU by source category.

Figure 2-9: Trends in Industrial Processes and Product Use Sector Greenhouse Gas Sources

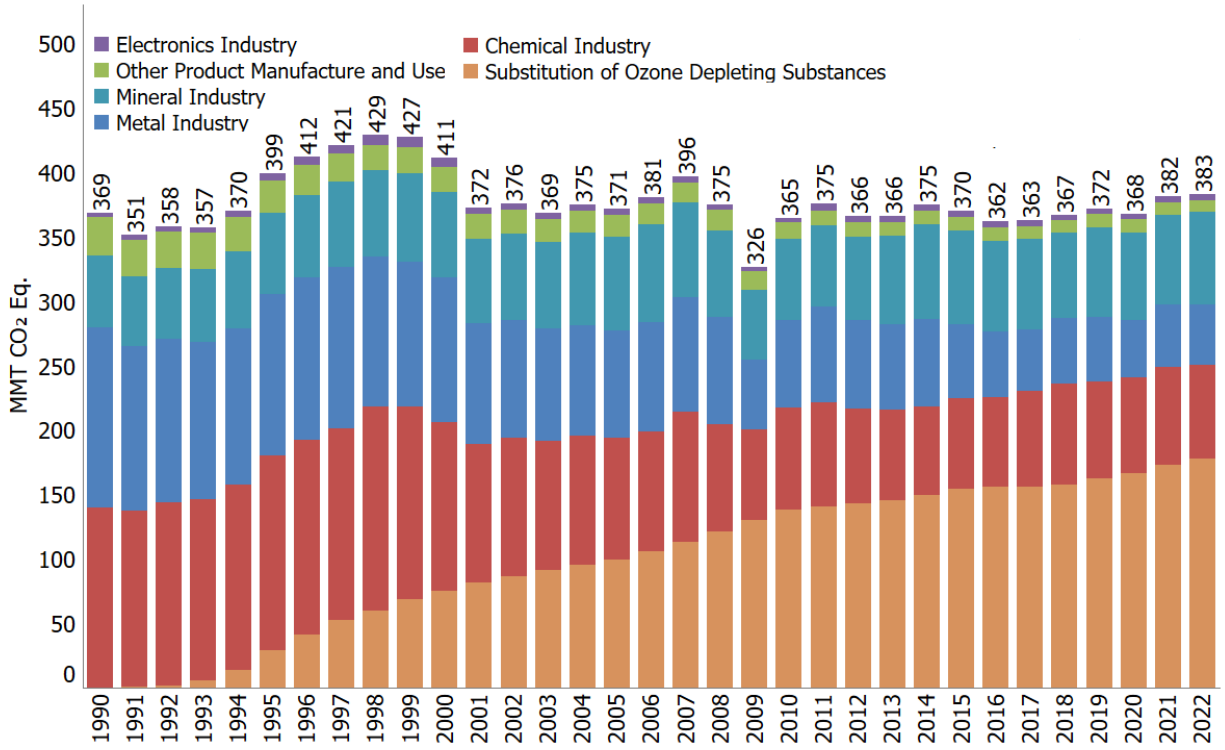


Table 2-6: Emissions from Industrial Processes and Product Use (MMT CO_2 Eq.)

	1990	2005	2018	2019	2020	2021	2022	Percent Change Since 1990

+ Does not exceed 0.05 MMT CO_2 Eq.

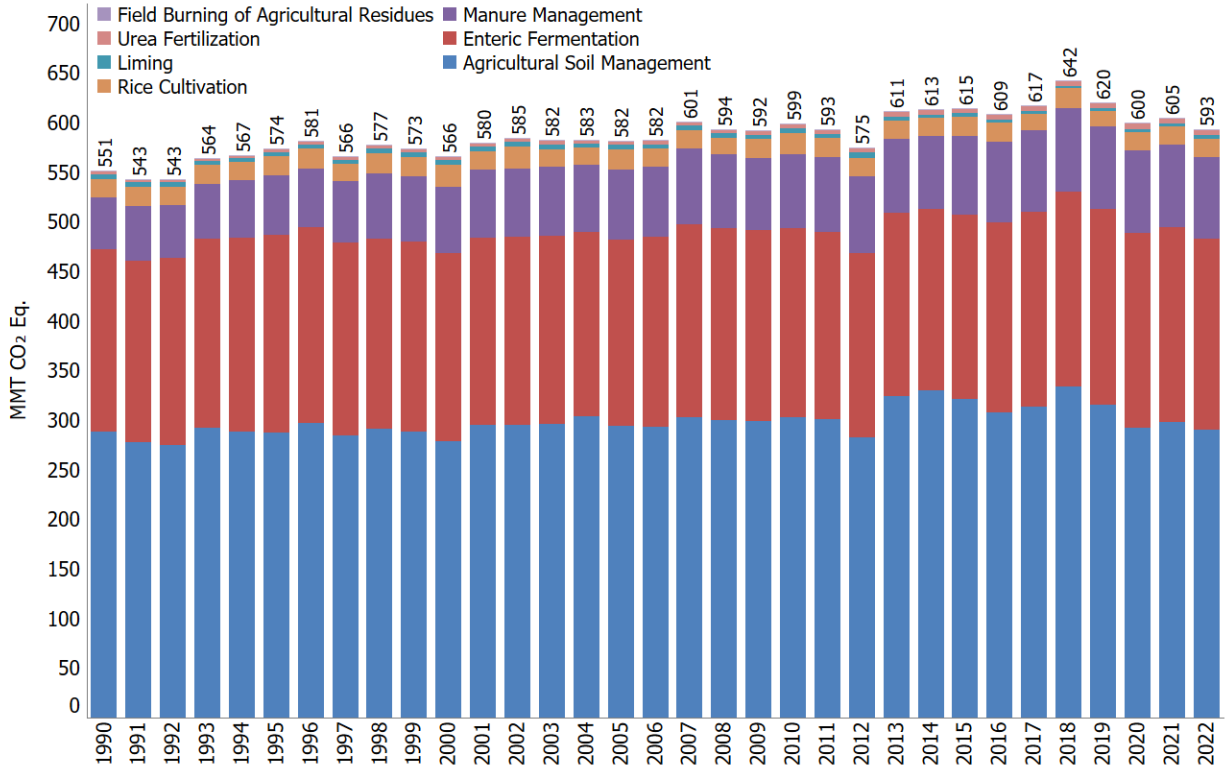
NO (Not Occurring)

[a] Small amounts of PFC emissions from this source are included under HFCs due to confidential business information.

Note: Totals may not sum due to independent rounding.

IPPU sector emissions increased 0.4 percent since 2021 and 3.9 percent since 1990. Some significant trends in U.S. emissions from IPPU source categories over the 33-year period from 1990 through 2022 included the following:

- HFC and PFC emissions resulting from the substitution of ODS (e.g., chlorofluorocarbons [CFCs]) increased from small amounts in 1990 to 178.1 MMT CO_2 Eq. in 2022 (an increase of 70,357 percent).
- Combined CO_2 and CH_4 emissions from iron and steel production and metallurgical coke production decreased by 2.9 percent from 2021 to 2022 to 40.7 MMT CO_2 Eq. and declined overall by 61.2 percent (64.1 MMT CO_2 Eq.) from 1990 through 2022, due to restructuring of the industry. The trend in the United States has been a shift toward fewer integrated steel mills and more electric arc furnaces (EAFs). EAFs use scrap steel as their main input and generally have lower on-site emissions.
- Carbon dioxide emissions from petrochemical production increased by 43.4 percent between 1990 and 2022, from 20.1 MMT CO_2 Eq. to 28.8 MMT CO_2 Eq. The increase in emissions is largely driven by the production of ethylene more than doubling over that period.
- Carbon dioxide emissions from ammonia production have decreased by 12.5 percent (1.8 MMT CO_2 Eq.) since 1990. Ammonia production relies on natural gas as both a feedstock and a fuel, and as such, market fluctuations and volatility in natural gas prices affect the production of ammonia from year to year. Emissions from ammonia production have increased since 2016, due to the addition of new ammonia production facilities and new production units at existing facilities. Agricultural demands continue to drive demand for nitrogen fertilizers and the need for new ammonia production capacity.
- Carbon dioxide emissions from cement production increased by 25.1 percent (8.4 MMT CO_2 Eq.) from 1990 through 2022. Emissions rose from 1990 through 2006 and then fell until 2009, due to a decrease in demand for construction materials during the economic recession. Since 2010, CO_2 emissions from cement production have risen by 33.2 percent.
- HFC, PFC, SF_6, and NF_3 emissions from fluorochemical production decreased by 89.0 percent (63.2 MMT CO_2 Eq.) from 1990 to 2022 due to a reduction in the HFC-23 emission rate from HCFC-22 production (kg HFC-23 emitted/kg HCFC-22 produced), the imposition of emissions controls at production facilities, and a decrease in SF_6 production due to the cessation of production at the major SF_6 production facility in 2010.
- PFC emissions from aluminum production decreased by 96.1 percent (18.5 MMT CO_2 Eq.) from 1990 to 2022, due to both industry emission reduction efforts and lower domestic aluminum production.
- SF_6 emissions from electrical equipment decreased by 79.4 percent (19.6 MMT CO_2 Eq.) from 1990 to 2022 due to a sharp increase in the price of SF_6 during the 1990s and industry emission reduction efforts.



Agriculture

Agricultural activities contribute directly to emissions of greenhouse gases through a variety of processes, including the following source categories: enteric fermentation in domestic livestock, livestock manure management, rice cultivation, agricultural soil management, liming, urea fertilization, and field burning of agricultural residues. Methane and N_2O are the primary greenhouse gases emitted by agricultural activities, with

small amounts of CO_2 also emitted.[5] Carbon stock changes from agricultural soils are included in the LULUCF sector.

In 2022, agricultural activities were responsible for emissions of 593.4 MMT CO_2 Eq., or 9.4 percent of total U.S. greenhouse gas emissions. Agricultural soil management activities, such as the application of synthetic and organic fertilizers, deposition of livestock manure, and growing N-fixing plants, were the largest contributors to agricultural-related emissions (49.0 percent) and were the largest source of U.S. N_2O emissions in 2022, accounting for 74.6 percent. Methane emissions from enteric fermentation and manure management represented 27.4 percent and 9.2 percent of total CH_4 emissions from anthropogenic activities, respectively, in 2022. Carbon dioxide emissions from the application of crushed limestone and dolomite (i.e., soil liming) and urea fertilization represented 0.2 percent of total CO_2 emissions from anthropogenic activities. Figure 2-10 and Table 2-7 illustrate agricultural greenhouse gas emissions by source and gas.

Figure 2-10: Trends in Agriculture Sector Greenhouse Gas Sources

[5] The contribution of agriculture non-CO_2 emissions is based on gross totals and excludes LULUCF methane (CH_4) and nitrous oxide (N_2O) emissions. The contribution of agriculture CH_4 and N_2O including LULUCF non-CO_2 emissions, is 40.5 percent and 48.3 percent, respectively.

Table 2-7: Emissions from Agriculture (MMT CO_2 Eq.)

Gas/Source	1990	2005	2018	2019	2020	2021	2022	Percent Change Since 1990
CO_2	**7.1**	**7.9**	**7.2**	**7.2**	**8.0**	**7.6**	**8.6**	**21.0%**
Urea Fertilization	2.4	3.5	4.9	5.0	5.1	5.2	5.3	120.4%

Field Burning of Agricultural Residues	0.2	0.2	0.2	0.2	0.2	0.2	0.2	15.5%
Total	**551.1**	**581.8**	**642.4**	**620.1**	**599.7**	**604.8**	**593.4**	**7.7%**

Note: Totals may not sum due to independent rounding.

Agriculture sector emissions decreased by 1.9 percent since 2021 and increased by 7.7 percent since 1990. Some significant trends in U.S. emissions from Agriculture source categories (Figure 2-10) over the 33-year time series from 1990 through 2022 included the following:

- Agricultural soils are the largest anthropogenic source of agriculture-related emissions and of N_2O emissions in the United States, accounting for 74.6 percent of N_2O emissions and 4.6 percent of total emissions in the United States in 2022. Annual N_2O emissions from agricultural soils fluctuated between 1990 and 2022, and overall emissions were 0.7 percent (2.0 MMT CO_2 Eq.) higher in 2022 than in 1990. Year-to-year fluctuations are largely a reflection of annual variation in weather patterns, synthetic fertilizer use, and crop production.
- Enteric fermentation is the largest anthropogenic source of CH_4 emissions in the United States. In 2022, enteric fermentation CH_4 emissions were 27.4 percent of total CH_4 emissions, which represents an increase of 5.2 percent (9.5 MMT CO_2 Eq.) since 1990. This increase in emissions from enteric fermentation from 1990 to 2022 generally follows the increasing trends in cattle populations. For example, from 1990 to 1995, emissions increased and then generally decreased from 1996 to 2004, mainly due to fluctuations in beef cattle populations and increased digestibility of feed for feedlot cattle. Emissions increased from 2005 to 2007, as both dairy and beef populations increased. Research indicates that the feed digestibility of dairy cow diets decreased during this period. Emissions decreased again from 2008 to 2014 as beef cattle populations again decreased. Emissions increased from 2014 to 2022, consistent with an increase in beef cattle population over those same years. CH_4 emissions from enteric fermentation decreased by 2.0 percent (3.9 MMT CO_2 Eq.) from 2021 to 2022, however, largely driven by a decrease in beef cattle populations.
- Manure management is the fourth largest anthropogenic source of CH_4 and N_2O emissions in the United States and accounted for 13.8 percent of Agriculture sector emissions in 2022. Emissions from manure management increased by 55.6 percent between 1990 and 2022. This includes an increase of 65.3 percent (25.6 MMT CO_2 Eq.) for CH_4 and an increase of 27.2 percent (3.6 MMT CO_2 Eq.) for N_2O. The majority of the increase observed in CH_4 emissions resulted from swine and dairy cattle manure, where emissions increased by 37.2 and 108.7 percent, respectively, from 1990 to 2022. From 2021 to 2022, CH_4 emissions from manure management decreased by 2.6 percent, mainly due to minor shifts in the animal populations and the resultant effects on manure management system allocations.

- Liming and urea fertilization are the only sources of CO_2 emissions reported in the Agriculture sector. All other CO_2 emissions and removals (e.g., carbon stock changes from the management of croplands) are included in the LULUCF sector. Liming emissions increased by 36.9 percent relative to 2021 and decreased by 30.3 percent (1.4 MMT CO_2 Eq.) relative to 1990, while urea fertilization emissions increased by 1.9 percent relative to 2021 and 120.4 percent (2.9 MMT CO_2 Eq.) relative to 1990.

Land Use, Land-Use Change, and Forestry

When humans alter the terrestrial biosphere through land use, changes in land use, and land management practices, they also influence the carbon stock fluxes on these lands and cause emissions of CH_4 and N_2O. Overall, managed land is a net sink for CO_2 (carbon sequestration) in the United States. The primary driver of fluxes on managed lands is from management of forest lands, but also includes trees in settlements (i.e., urban areas), afforestation, conversion of forest lands to settlements and croplands, the management of croplands and grasslands, flooded lands, and the landfilling of yard trimmings and food scraps. The main drivers for net forest sequestration include net forest growth, increasing forest area, and a net accumulation of carbon stocks in harvested wood pools. The net sequestration in settlements remaining settlements is driven primarily by carbon stock gains in urban forests (i.e., settlement trees) through net tree growth and increased urban area, as well as long-term accumulation of carbon in landfills from additions of yard trimmings and food scraps.

The LULUCF sector in 2022 resulted in a net increase in carbon stocks (i.e., net CO_2 removals) of 921.8 MMT CO_2 Eq. (Table 2-8).[6] This represents an offset of 14.5 percent of total (i.e., gross) greenhouse gas emissions in 2022. Emissions of CH_4 and N_2O from LULUCF activities in 2022 were 67.6 MMT CO_2 Eq. and represented 1.2 percent of net greenhouse gas emissions.[7] Between 1990 and 2022, total net carbon sequestration in the LULUCF sector decreased by 10.9 percent, primarily due to a decrease in the rate of net carbon accumulation in forests and cropland remaining cropland, as well as an increase in CO_2 emissions from land converted to settlements.

Flooded land remaining flooded land was the largest source of CH_4 emissions from LULUCF and the fifth largest source overall of net CH_4 emissions in 2022, totaling 44.2 MMT CO_2 Eq. (1,579 kt of CH_4). Forest fires were the second largest source of CH_4 emissions from LULUCF in 2022, totaling 9.1 MMT CO_2 Eq. (327 kt of CH_4). Forest fires were the largest source of N_2O emissions from LULUCF in 2022, totaling 5.7 MMT CO_2 Eq. (22 kt of N_2O). Figure 2-11 and Table 2-8 illustrate LULUCF emissions and removals by land-use category and gas.

[6] LULUCF carbon stock change is the net carbon stock change from the following categories: forest land remaining forest land, land converted to forest land, cropland remaining cropland, land converted to cropland, grassland remaining grassland, land converted to grassland, wetlands remaining wetlands, land converted to wetlands, settlements remaining settlements, and land converted to settlements.

[7] LULUCF emissions include the CH_4 and N_2O emissions reported for peatlands remaining peatlands, forest fires, drained organic soils, grassland fires, and coastal wetlands remaining coastal wetlands; CH_4 emissions from flooded land remaining flooded land, land converted to flooded land, and land converted to coastal wetlands; and N_2O emissions from forest soils and settlement soils.

Figure 2-11: Trends in Emissions and Removals (Net CO_2 Flux) from Land Use, Land-Use Change, and Forestry

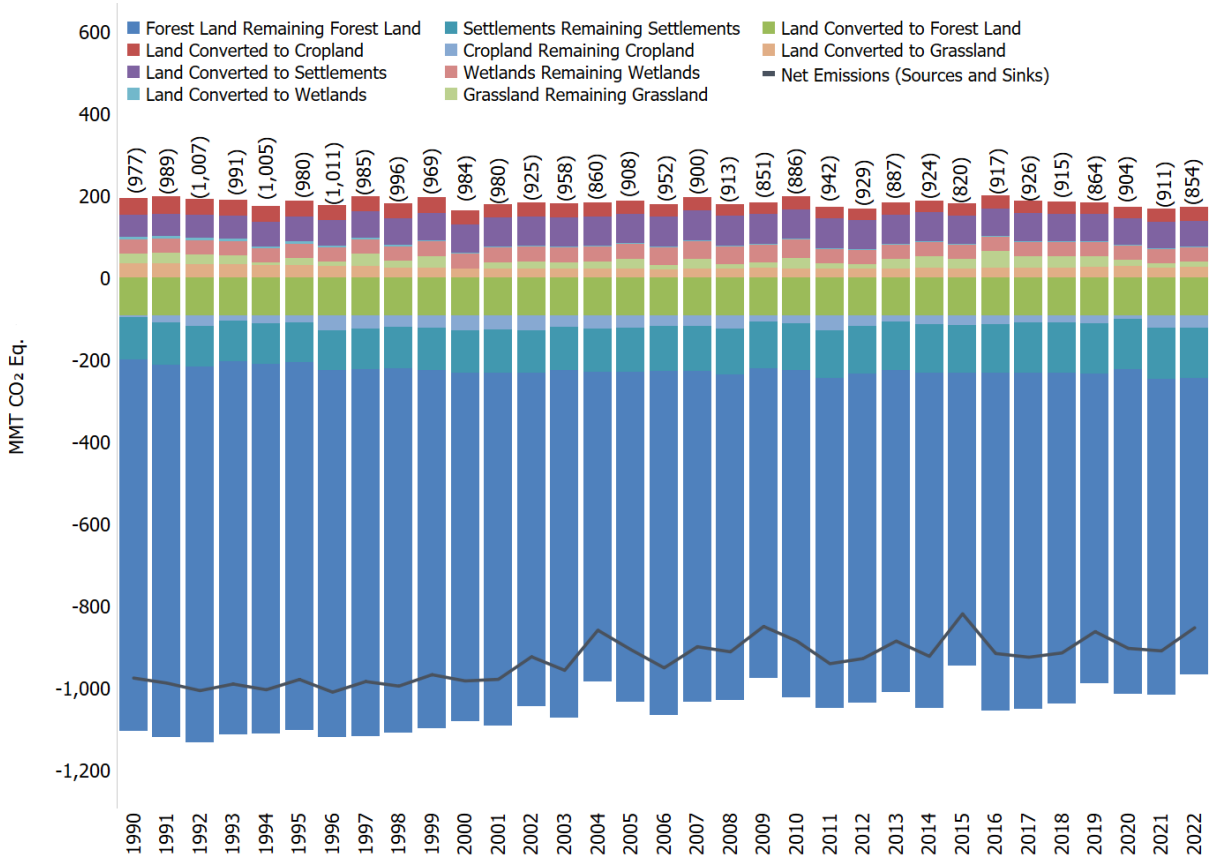

Table 2-8: U.S. Greenhouse Gas Emissions and Removals (Net Flux) from Land Use, Land-Use Change, and Forestry (MMT CO_2 Eq.)

+ Absolute value does not exceed 0.05 MMT CO_2 Eq.

[a] Includes the net changes to carbon stocks stored in all forest ecosystem pools (estimates include carbon stock changes from drained organic soils from both forest land remaining forest land and land converted to forest land) and harvested wood products.

[b] Estimates include emissions from fires on both forest land remaining forest land and land converted to forest land.

[c] Estimates include emissions from N fertilizer additions on both forest land remaining forest land and land converted to forest land.

[d] Estimates include CH_4 and N_2O emissions from drained organic soils on both forest land remaining forest land and land converted to forest land. Carbon stock changes from drained organic soils are included with the forest land remaining forest land forest ecosystem pools.
[e] Includes the net changes to carbon stocks stored in all forest ecosystem pools.
[f] Includes changes in mineral and organic soil carbon stocks for all land use conversions to cropland, grassland, and settlements. Also includes aboveground/belowground biomass, dead wood, and litter carbon stock changes for conversion of forest land to cropland, grassland, and settlements.
[g] Estimates include CH_4 and N_2O emissions from fires on both grassland remaining grassland and land converted to grassland.
[h] Estimates include N_2O emissions from N fertilizer additions on both settlements remaining settlements and land converted to settlements because it is not possible to separate the activity data at this time.
[i] LULUCF carbon stock change includes any carbon stock gains and losses from all land use and land-use conversion categories.
[j] LULUCF emissions subtotal includes the CH_4 and N_2O emissions reported for peatlands remaining peatlands, forest fires, drained organic soils, grassland fires, and coastal wetlands remaining coastal wetlands; CH_4 emissions from flooded land remaining flooded land, and land converted to flooded land, and land converted to coastal wetlands; and N_2O emissions from forest soils and settlement soils. Emissions values are included in land-use category rows.
[k] The LULUCF sector net total is the net sum of all LULUCF CH_4 and N_2O emissions to the atmosphere plus LULUCF net carbon stock changes in units of MMT CO_2 Eq.
Notes: Totals may not sum due to independent rounding. Parentheses indicate net sequestration.

Overall CH_4 and N_2O emissions from LULUCF decreased by 7.3 percent from 2021 and increased by 16.5 percent since 1990 while total net sequestration decreased by 10.9 percent since 1990 and 6.3 percent from 2021. Other trends from 1990 to 2022 in emissions from LULUCF categories (Figure 2-11) over the 33-year period included the following:

- Annual carbon sequestration by forest land (i.e., annual carbon stock accumulation in the five ecosystem carbon pools and harvested wood products for forest land remaining forest land and land converted to forest land) has decreased by 17.5 percent since 1990. This is primarily due to decreased carbon stock gains in land converted to forest land and the harvested wood products pools within forest land remaining forest land.
- Annual carbon sequestration from settlements remaining settlements (which includes organic soils, settlement trees, and landfilled yard trimmings and food scraps) has increased by 21.2 percent over the period from 1990 to 2022. This is primarily due to an increase in urbanized land area in the United States with trees growing on it.
- Annual emissions from land converted to settlements increased by 19.1 percent from 1990 to 2022 due primarily to carbon stock losses from forest land converted to settlements and mineral soils carbon stocks from grassland converted to settlements.

Waste

Waste management and treatment activities are sources of CH_4 and N_2O emissions (see Figure 2-12 and Table 2-9). Overall, emission sources accounted for in the Waste chapter generated 166.9 MMT CO_2 Eq., or 2.6 percent of total U.S. greenhouse gas emissions in 2022. In 2022, landfills were the largest source of waste emissions, accounting for 71.8 percent of waste-related emissions. Landfills are also the third-largest source of U.S. anthropogenic CH_4 emissions, generating 119.8 MMT CO_2 Eq. and accounting for 17.1 percent of total U.S. CH_4 emissions in 2022.[8] Additionally, wastewater treatment generated emissions of 42.7 MMT CO_2 Eq. and accounted for 25.6 percent of waste emissions, 3.0 percent of U.S. CH_4 emissions, and 5.6 percent of U.S. N_2O emissions in 2022. Emissions of CH_4 and N_2O from composting are also accounted for in this chapter, generating emissions of 2.6 MMT CO_2 Eq. and 1.8 MMT CO_2 Eq., accounting for 1.5 and 1.1 percent of Waste sector emissions, respectively. Anaerobic digestion

[8] Landfills also store carbon, due to incomplete degradation of organic materials such as wood products and yard trimmings, as described in the Land Use, Land-Use Change, and Forestry chapter.

at biogas facilities generated CH_4 emissions of less than 0.05 MMT CO_2 Eq., accounting for less than 0.05 percent of emissions from the Waste sector.

Figure 2-12: Trends in Waste Sector Greenhouse Gas Sources

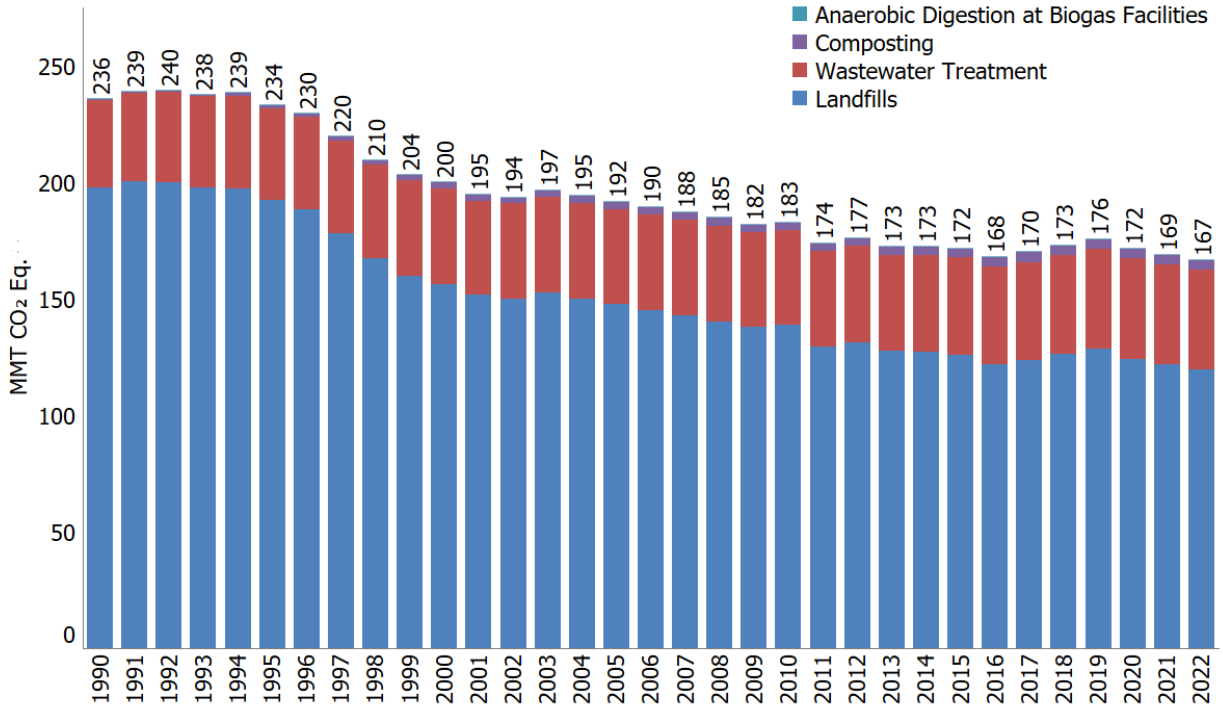

Table 2-9: Emissions from Waste (MMT CO_2 Eq.)

Gas/Source	1990	2005	2018	2019	2020	2021	2022	Percent Change Since 1990
CH_4	**220.9**	**172.4**	**150.2**	**152.4**	**147.6**	**145.3**	**143.2**	**(35.2%)**
Landfills	197.8	147.7	126.3	128.7	124.1	122.0	119.8	(39.4%)
Wastewater Treatment	22.7	22.7	21.4	21.1	21.0	20.7	20.8	(8.4%)
Composting	0.4	2.1	2.5	2.5	2.6	2.6	2.6	504.8%
Anaerobic Digestion at Biogas Facilities	+	+	+	+	+	+	+	1,109.3%
N_2O	**15.1**	**19.5**	**23.0**	**23.4**	**24.1**	**23.9**	**23.7**	**57.4%**
Wastewater Treatment	14.8	18.1	21.2	21.6	22.3	22.1	21.9	48.2%
Composting	0.3	1.5	1.8	1.8	1.8	1.8	1.8	504.8%
Total	**235.9**	**192.0**	**173.2**	**175.8**	**171.7**	**169.2**	**166.9**	**(29.3%)**

+ Does not exceed 0.05 MMT CO_2 Eq.

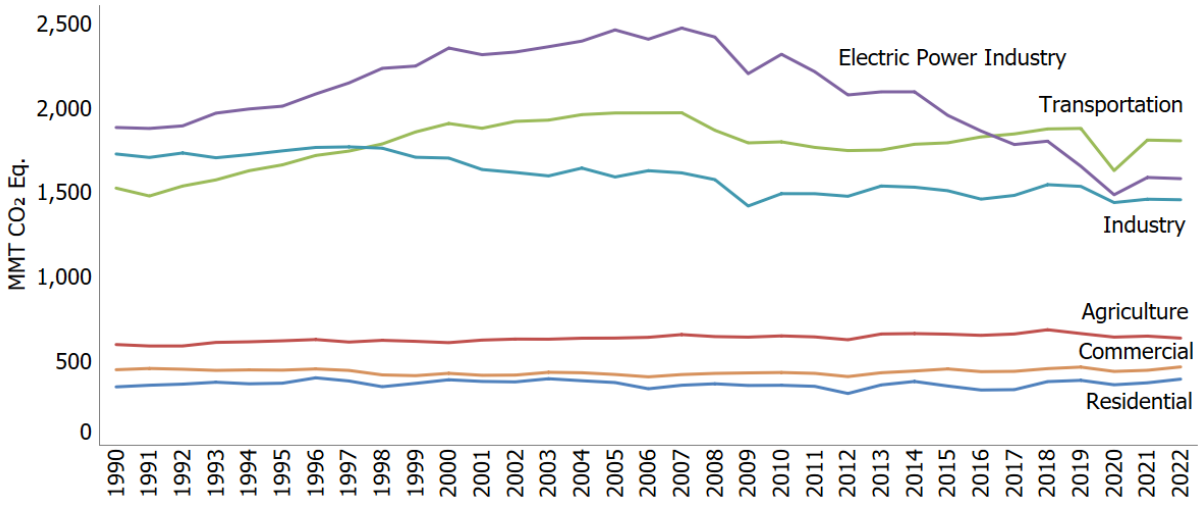
Note: Totals may not sum due to independent rounding.

Waste sector emissions decreased by 1.4 percent since 2021 and 29.3 percent since 1990. Some notable trends in U.S. emissions from Waste source categories (Figure 2-12) over the 33-year period from 1990 through 2022 included the following:

- Net CH_4 emissions from landfills decreased by 78.0 MMT CO_2 Eq. (39.4 percent), with small increases occurring in interim years. This downward trend in emissions coincided with increased landfill gas

collection and control systems, and a reduction of decomposable materials (i.e., paper and paperboard, food scraps, and yard trimmings) discarded in municipal solid waste (MSW) landfills over the time series.

- CH_4 and N_2O emissions from wastewater treatment decreased by 8.4 percent (1.9 MMT CO_2 Eq.) and increased by 48.2 percent (7.1 MMT CO_2 Eq.), respectively. Methane emissions from domestic wastewater treatment have decreased since 1999 due to decreasing percentages of wastewater being treated in anaerobic systems, including reduced use of on-site septic systems and central anaerobic treatment systems. N_2O emissions from wastewater treatment processes gradually increased across the time series as a result of increasing U.S. population and protein consumption.
- Combined CH_4 and N_2O emissions from composting have increased by 504.8 percent (3.7 MMT CO_2 Eq.) since 1990. The growth in composting since the 1990s is attributable to primarily four factors: (1) the enactment of legislation by state and local governments that discouraged the disposal of yard trimmings and food waste in landfills; (2) an increase in yard trimming collection and yard trimming drop-off sites provided by local solid waste management districts; (3) an increased awareness of the environmental benefits of composting; and (4) loans or grant programs to establish or expand composting infrastructure.



2.2 Emissions and Sinks by Economic Sector

In addition to the Paris Agreement and UNFCCC reporting sectors and methods defined by the IPCC, this report also characterizes gross emissions according to commonly used economic sector categories: residential, commercial, industry, transportation, electric power, and agriculture. Emissions from U.S. Territories are reported as their own end-use sector due to a lack of specific consumption data for the individual end-use sectors within U.S. Territories. See Box 2-1 for more information on how economic sectors are defined. For more information on trends in the LULUCF sector, see Section 2.1.

Using this categorization, transportation activities accounted for the largest portion (28.4 percent) of total U.S. greenhouse gas emissions in 2022. Emissions from electric power accounted for the second largest portion (24.9 percent), while emissions from industry accounted for the third-largest portion (22.9 percent) of total U.S. greenhouse gas emissions in 2022. Emissions from industry have in general declined over the past decade due to a number of factors, including structural changes in the U.S. economy (i.e., shifts from a manufacturing-based to a service-based economy), fuel switching, and efficiency improvements.

The remaining 23.8 percent of U.S. greenhouse gas emissions were contributed by, in order of magnitude, the agriculture, commercial, and residential sectors, plus emissions from U.S. Territories. Activities related to agriculture accounted for 10.0 percent of emissions; unlike other economic sectors, agricultural sector emissions were dominated by N_2O emissions from agricultural soil management and CH_4 emissions from enteric fermentation, rather than CO_2 from fossil fuel combustion. An increasing amount of carbon is stored in agricultural soils each year, but this carbon sequestration is assigned to the LULUCF sector rather than the agriculture economic sector. The commercial and residential sectors accounted for roughly 7.3 percent and 6.2 percent of greenhouse gas emissions, respectively, and U.S. Territories accounted for 0.4 percent of emissions; emissions from these sectors primarily consisted of CO_2 emissions from fossil fuel combustion. Carbon dioxide was also emitted and sequestered (in the form of carbon) by a variety of activities related to forest management practices, tree planting in urban areas, the management of agricultural soils, landfilling of yard trimmings, and changes in carbon stocks in coastal wetlands. Table 2-10 presents a detailed breakdown of emissions from each of these economic sectors by source category, as they are defined in this report. Figure 2-13 shows the trend in emissions by sector from 1990 to 2022.

Figure 2-13: U.S. Greenhouse Gas Emissions Allocated to Economic Sectors

Note: Emissions and removals from Land Use, Land-Use Change, and Forestry are excluded from figure above. Excludes U.S. Territories.

Table 2-10: U.S. Greenhouse Gas Emissions Allocated to Economic Sectors (MMT CO_2 Eq. and Percent of Total in 2022)

+ Does not exceed 0.05 MMT CO_2 Eq. or 0.05 percent.

[a] Percent of total (gross) emissions excluding emissions from LULUCF for 2022.

[b] Includes CH_4 and N_2O emissions from fuel combustion.

[c] The LULUCF sector net total is the net sum of all LULUCF CH_4 and N_2O emissions to the atmosphere plus LULUCF net carbon stock changes.

Notes: Total gross emissions presented are without LULUCF. Total net emissions are presented with LULUCF. Totals may not sum due to independent rounding. Parentheses indicate negative values or sequestration.

Box 2-1: Methodology for Aggregating Emissions by Economic Sector

In presenting the economic sectors in the annual *Inventory of U.S. Greenhouse Gas Emissions and Sinks*, the *Inventory* expands upon the standard sectors common for reporting under the Paris Agreement and the UNFCCC. Discussing greenhouse gas emissions relevant to U.S.-specific economic sectors improves communication of the report's findings.

The electric power economic sector includes CO_2, CH_4 and N_2O emissions from the combustion of fossil fuels that are included in the EIA electric power sector. Carbon dioxide, CH_4, and N_2O emissions from waste incineration are included in the electric power economic sector, as the majority of MSW is combusted in plants that produce electricity. The electric power economic sector also includes SF_6 from electrical equipment, and a portion of CO_2 from other process uses of carbonates (from pollution control equipment installed in electric power plants).

The transportation economic sector includes CO_2 emissions from the combustion of fossil fuels that are included in the EIA transportation fuel-consuming sector. (Additional analyses and refinement of the EIA data are further explained in the Energy chapter of this report.) Emissions of CH_4 and N_2O from mobile combustion are also

apportioned to the transportation economic sector based on the EIA transportation fuel-consuming sector. Emissions of ODS substitutes are apportioned to the transportation economic sector based on emissions from refrigerated transport and motor vehicle air-conditioning systems. Finally, CO_2 emissions from non-energy uses of fossil fuels identified as lubricants for transportation vehicles are included in the transportation economic sector.

The industry economic sector includes CO_2 emissions from the combustion of fossil fuels that are included in the EIA industrial fuel-consuming sector, minus the agricultural use of fuel explained below. The CH_4 and N_2O emissions from stationary and mobile combustion are also apportioned to the industry economic sector based on the EIA industrial fuel-consuming sector, minus emissions apportioned to the agriculture economic sector. Emissions of ODS substitutes are apportioned based on their specific end-uses within the source category, with most emissions falling within the industry economic sector. Finally, CH_4 emissions from industrial landfills and CH_4 and N_2O from industrial wastewater treatment are included in the industry economic sector.

Additionally, all process-related emissions from sources with methods considered within the IPCC IPPU sector are apportioned to the industry economic sector. This includes the process-related emissions (i.e., emissions from the actual process to make the material, not from fuels to power the plant) from activities such as cement production, iron and steel production and metallurgical coke production, and ammonia production. Additionally, fugitive emissions from energy production sources, such as natural gas systems, coal mining, and petroleum systems are included in the industry economic sector. A portion of CO_2 from other process uses of carbonates (from pollution control equipment installed in large industrial facilities) is also included in the industry economic sector. Finally, all remaining CO_2 emissions from non-energy uses of fossil fuels are assumed to be industrial in nature (besides the lubricants for transportation vehicles specified above) and are attributed to the industry economic sector.

The agriculture economic sector includes CO_2 emissions from the combustion of fossil fuels that are based on supplementary sources of agriculture fuel use data, because EIA includes agriculture equipment in the industrial fuel-consuming sector. Agriculture fuel use estimates are obtained from U.S. Department of Agriculture survey data, in combination with EIA Fuel Oil and Kerosene Sales (FOKS) data (EIA 1991 through 2022). Agricultural operations are based on annual energy expense data from the Agricultural Resource Management Survey (ARMS) conducted by the National Agricultural Statistics Service (NASS) of the USDA. NASS collects information on farm production expenditures including expenditures on diesel fuel, gasoline, LP gas, natural gas, and electricity use on the farm with the annual ARMS. A USDA publication (USDA/NASS 2023) shows national totals, as well as selected States and ARMS production regions. These supplementary data are subtracted from the industrial fuel use reported by EIA to obtain agriculture fuel use. Carbon dioxide emissions from fossil fuel combustion, and CH_4 and N_2O emissions from stationary and mobile combustion, are then apportioned to the agriculture economic sector based on agricultural fuel use.

The other IPCC Agriculture emission source categories apportioned to the agriculture economic sector include N_2O emissions from agricultural soils, CH_4 from enteric fermentation, CH_4 and N_2O from manure management, CH_4 from rice cultivation, CO_2 emissions from liming and urea application, and CH_4 and N_2O from field burning of agricultural residues.

The residential economic sector includes CO_2 emissions from the combustion of fossil fuels that are included in the EIA residential fuel-consuming sector. Stationary combustion emissions of CH_4 and N_2O are also based on the EIA residential fuel-consuming sector. Emissions of ODS substitutes are apportioned to the residential economic sector based on emissions from residential air-conditioning systems. N_2O emissions from the application of fertilizers to developed land (termed “settlements” by the IPCC) are also included in the residential economic sector.

The commercial economic sector includes CO_2 emissions from the combustion of fossil fuels that are included in the EIA commercial fuel-consuming sector. Emissions of CH_4 and N_2O from mobile combustion are also apportioned to the commercial economic sector based on the EIA commercial fuel-consuming sector. Emissions of ODS substitutes are apportioned to the commercial economic sector based on emissions from commercial refrigeration/air-conditioning systems. Public works sources, including direct CH_4 from municipal landfills, CH_4

from anaerobic digestion at biogas facilities, CH_4 and N_2O from domestic wastewater treatment, and composting, are also included in the commercial economic sector.

Emissions with Electricity Distributed to Economic Sectors

It is also useful to view greenhouse gas emissions from economic sectors with emissions related to electric power distributed into end-use categories (i.e., emissions from the electric power sector are allocated to the economic end-use sectors in which the electricity is used). For example, greenhouse gas emissions from some economic sectors, i.e., commercial and residential and industry, increase substantially when indirect emissions from electricity end-use are included, due to the relatively large share of electricity use by buildings (75 percent of the electricity generated in the United States for heating, ventilation, and air conditioning; lighting; and appliances, etc.)[9] and use of electricity for powering industrial machinery.

The generation, transmission, and distribution of electricity directly accounted for 24.9 percent of total U.S. greenhouse gas emissions in 2022. Electric power-related emissions decreased by 16.1 percent since 1990 mainly due to fuel switching in the electric power sector. From 2021 to 2022, electric power-related emissions decreased by 0.4 percent. Between 2021 and 2022, the consumption of natural gas and petroleum for electric power generation increased by 7.6 percent and 18.9 percent, respectively, while the consumption of coal decreased by 6.4 percent. Electric power-related emissions are still lower than pre-pandemic 2019 levels. Table 2-11 provides a detailed summary of emissions from electric power-related activities.

From 2021 to 2022, electricity sales to the residential end-use sector increased by 2.6 percent. Electricity sales to the commercial end-use and industrial sectors increased by 4.7 percent and 2.0 percent, respectively. Overall, from 2021 to 2022, the amount of electricity retail sales (in kWh) increased by 3.2 percent.

Table 2-11: Electric Power-Related Greenhouse Gas Emissions (MMT CO_2 Eq.)

[9] See https://www.nrel.gov/news/features/2023/nrel-researcher-reveal-how-buildings-across-the-united-states-do-and-could-use-energy.html#:~:text=Buildings%20are%20responsible%20for%2040,buildings%20stock%20is%20also%20essential.

[a] Includes only stationary combustion emissions related to the generation of electricity.
Note: Totals may not sum due to independent rounding.

To distribute electricity emissions among economic end-use sectors, emissions from the source categories assigned to the electric power sector were allocated to the residential, commercial, industry, transportation, and agriculture economic sectors according to each economic sector's share of retail sales of electricity (EIA 2020; USDA/NASS 2023). These source categories include CO_2 from fossil fuel combustion, CH_4 and N_2O from stationary combustion, incineration of waste, other process uses of carbonates, and SF_6 from electrical equipment. Note that only 50 percent of the emissions from other process uses of carbonates were associated with electric power and distributed as described; the remaining emissions from other process uses of carbonates were attributed to the industry economic end-use sector.[10]

When emissions from electricity use are distributed among these economic end-use sectors, 2022 emissions from industrial activities account for the largest share of total U.S. greenhouse gas emissions (29.5 percent), followed closely by emissions from transportation (28.5 percent). Emissions from the commercial and residential sectors also increase substantially when emissions from electricity are included (15.8 and 15.3 percent, respectively). In all economic end-use sectors except agriculture, CO_2 accounts for more than 78 percent of greenhouse gas emissions, primarily from the combustion of fossil fuels. Table 2-12 presents a detailed breakdown of emissions from each of these economic sectors, with emissions from electric power distributed to them. Figure 2-14 shows the trend in these emissions by sector from 1990 to 2022.

Figure 2-14: U.S. Greenhouse Gas Emissions with Electricity-Related Emissions Distributed to Economic Sectors

Note: Emissions and removals from Land Use, Land-Use Change, and Forestry are excluded from figure above. Excludes U.S. Territories.

Table 2-12: U.S. Greenhouse Gas Emissions by Economic Sector and Gas with Electricity-Related Emissions Distributed (MMT CO_2 Eq.) and Percent of Total in 2022

Emissions by Gas	1990	2005	2018	2019	2020	2021	2022	Percent[a]
Industry	**2,397.3**	**2,302.9**	**2,017.1**	**1,974.8**	**1,823.5**	**1,877.8**	**1,872.9**	**29.5%**

+ Does not exceed 0.05 MMT CO_2 Eq. or 0.05 percent.
[a] Percent of total (gross) emissions excluding emissions from LULUCF for the year 2022.
[b] Includes primarily HFC-134a.
[c] The LULUCF sector net total is the net sum of all LULUCF CH_4 and N_2O emissions to the atmosphere plus LULUCF net carbon stock changes.
Notes: Total gross emissions are presented without LULUCF. Net emissions are presented with LULUCF. Emissions from electric power are allocated based on aggregate electricity use in each end-use sector. Totals may not sum due to independent rounding.

Industry

The industry economic sector includes CO_2 emissions from fossil fuel combustion from all manufacturing facilities, in aggregate, and with the distribution of electricity-related emissions (e.g., powering industrial machinery), accounted for 29.5 percent of U.S. greenhouse gas emissions in 2022. This end-use sector also includes emissions that are produced as a byproduct of the non-energy-related industrial process activities. The variety of activities producing these non-energy-related emissions includes CH_4 emissions from petroleum and natural gas systems, fugitive CH_4 and CO_2 emissions from coal mining, byproduct CO_2 emissions from cement production, and HFC, PFC, SF_6, and NF_3 byproduct emissions from the electronics industry, to name a few.

Since 1990, industry sector emissions have declined by 21.9 percent. The decline has occurred both in direct emissions and indirect emissions associated with electricity use. Structural changes within the U.S. economy that led to shifts in industrial output away from energy-intensive manufacturing products to less energy-intensive products (e.g., shifts from producing steel to computer equipment) have had a significant effect on industrial emissions.

Transportation

When electricity-related emissions are distributed to economic end-use sectors, transportation activities accounted for 28.5 percent of U.S. greenhouse gas emissions in 2022. The largest sources of transportation greenhouse gas emissions in 2022 were light-duty trucks, which include sport utility vehicles, pickup trucks, and minivans (36.5 percent); medium- and heavy-duty trucks (22.9 percent); passenger cars (20.4 percent); commercial aircraft (7.2 percent); pipelines (3.8 percent); ships and boats (2.8 percent); other aircraft (2.0 percent), and rail (2.0 percent). These figures include direct CO_2, CH_4, and N_2O emissions from fossil fuel combustion used in transportation, indirect emissions from electricity use, and emissions from non-energy use (i.e., lubricants) used in transportation, as well as HFC emissions from mobile air conditioners and refrigerated transport allocated to these vehicle types.

From 1990 to 2022, total transportation emissions from fossil fuel combustion increased by 19.4 percent due, in large part, to increased demand for travel. From 2021 to 2022, emissions decreased by 0.1 percent. Vehicle miles traveled (VMT) by light-duty motor vehicles (passenger cars and light-duty trucks) increased by 46.7 percent from 1990 to 2022 as a result of a confluence of factors including population growth, economic growth, urban sprawl, and periods of low fuel prices. The primary driver of transportation-related emissions was CO_2 from fossil fuel combustion, which increased by 19.4 percent from 1990 to 2022 when including electricity. This rise in CO_2 emissions, combined with an increase in HFCs from close to zero emissions in 1990 to 29.6 MMT CO_2 Eq. in 2022, led to an increase in overall greenhouse gas emissions from transportation activities of 18.6 percent.

The decline in new light-duty vehicle fuel economy between 1990 and 2004 reflected the increasing market share of light-duty trucks, which grew from approximately 29.6 percent of new vehicle sales in 1990 to 48.0 percent in 2004. Starting in 2005, average new vehicle fuel economy began to increase while light-duty VMT grew only modestly between 2005 and 2013. Light-duty VMT grew by less than one percent or declined each year between 2005 and 2013, then grew at a faster rate until 2016 (2.6 percent from 2014 to 2015, and 2.5 percent from 2015 to 2016). Since 2016, the rate of light-duty VMT growth has slowed to one percent or less each year. Average new vehicle fuel economy has increased almost every year since 2005, while light-duty truck market share decreased to

33.0 percent in 2009 and has since varied from year to year between 35.6 and 63.1 percent. Light-duty truck market share was about 63.1 percent of new vehicles in model year 2022 (EPA 2023b).

Table 2-13 provides a detailed summary of greenhouse gas emissions from transportation-related activities with electricity-related emissions included in the totals. Historically, the majority of electricity use in the transportation sector was for rail transport. However, more recently there has been increased electricity use in on-road electric and plug-in hybrid vehicles. Despite this increase, almost all of the energy used for transportation was supplied by petroleum-based products, with more than half being related to gasoline consumption in automobiles and other highway vehicles. Other fuel uses, especially diesel fuel for freight trucks and jet fuel for aircraft, accounted for the remainder. Indirect emissions from electricity are less than 1 percent of direct emissions in the transportation sector. For a more detailed breakout of emissions by fuel type by vehicle see Table A-93 in Annex 3.

Figure 2-15: Trends in Transportation-Related Greenhouse Gas Emissions

+ Does not exceed 0.05 MMT CO_2 Eq.

[a] Consists of emissions from jet fuel consumed by domestic operations of commercial aircraft (no bunkers).

[b] Consists of emissions from jet fuel and aviation gasoline consumption by general aviation and military aircraft.

[c] Fluctuations in emission estimates are associated with fluctuations in reported fuel consumption and may reflect issues with data sources.

[d] Other emissions from electric power are a result of waste incineration (as the majority of MSW is combusted in "trash-to-steam" electric power plants), electrical equipment, and a portion of other process uses of carbonates (from pollution control equipment installed in electric power plants).

[e] CO_2 estimates reflect natural gas used to power pipelines, but not electricity. While the operation of pipelines produces CH_4 and N_2O, these emissions are not directly attributed to pipelines in the Inventory.

[f] Emissions from International Bunker Fuels include emissions from both civilian and military activities; these emissions are not included in the transportation totals.

[g] Ethanol and biodiesel CO_2 estimates are presented for informational purposes only. See Section 3.11 and the estimates in LULUCF (see Chapter 6), in line with IPCC methodological guidance and reporting obligations under the Paris Agreement and the UNFCCC, for more information on ethanol and biodiesel.

Notes: Passenger cars and light-duty trucks include vehicles typically used for personal travel and less than 8,500 lbs; medium- and heavy-duty trucks include vehicles larger than 8,500 lbs. HFC emissions primarily reflect HFC-134a. Totals may not sum due to independent rounding.

Residential

The residential end-use sector, including electricity-related emissions, accounted for 15.3 percent of U.S. greenhouse gas emissions in 2022. This sector is heavily reliant on electricity for meeting energy needs, with electricity use for building-related activities like lighting, heating, air conditioning, and operating appliances. The remaining emissions were largely due to the direct consumption of natural gas and petroleum products, primarily for heating and cooking needs. Emissions from the residential sector have generally been increasing since 1990, and annual variations are often correlated with short-term fluctuations in energy use caused by weather conditions, rather than prevailing economic conditions. In the long term, the residential sector is also affected by population growth, migration trends toward warmer areas, and changes in housing and building attributes (e.g., larger sizes and improved insulation). A shift toward energy-efficient products and more stringent energy efficiency standards for household equipment has also contributed to recent trends in energy demand in households.

Commercial

The commercial end-use sector, including electricity-related emissions, accounted for 15.8 percent of U.S. greenhouse gas emissions in 2022. Like the residential sector it is heavily reliant on electricity for meeting energy needs, with electricity use for building-related activities like lighting, heating, air conditioning, and operating appliances. The remaining emissions were largely due to the direct consumption of natural gas and petroleum products, primarily for heating and cooking needs. Energy-related emissions from the commercial sector have generally been increasing since 1990, and annual variations are often correlated with short-term fluctuations in energy use caused by weather conditions, rather than prevailing economic conditions. Decreases in energy-related emissions in the commercial sector in recent years can be largely attributed to an overall reduction in energy use driven by a reduction in heating degree days and increases in energy efficiency.

Municipal landfills and wastewater treatment are included in the commercial sector, with landfill emissions decreasing since 1990 and wastewater treatment emissions increasing slightly.

Agriculture

The agriculture end-use sector accounted for 10.5 percent of U.S. greenhouse gas emissions in 2022 when electricity-related emissions are distributed, and includes a variety of processes, including enteric fermentation in domestic livestock, livestock manure management, and agricultural soil management. In 2022, agricultural soil management was the largest source of N_2O emissions, and enteric fermentation was the largest source of CH_4 emissions in the United States. This sector also includes small amounts of CO_2 emissions from fossil fuel combustion by motorized farm equipment such as tractors. Indirect emissions from electricity use in agricultural activities (e.g., powering buildings and equipment) are about 5 percent of direct emissions.

Box 2-2: Trends in Various U.S. Greenhouse Gas Emissions-Related Data

Total (gross) greenhouse gas emissions can be compared to other economic and social indices to highlight changes over time. These comparisons include: (1) aggregate energy use, because energy-related activities are the largest sources of emissions; (2) energy use per capita as a measure of efficiency; (3) emissions per unit of total gross domestic product as a measure of national economic activity; and (4) emissions per capita.

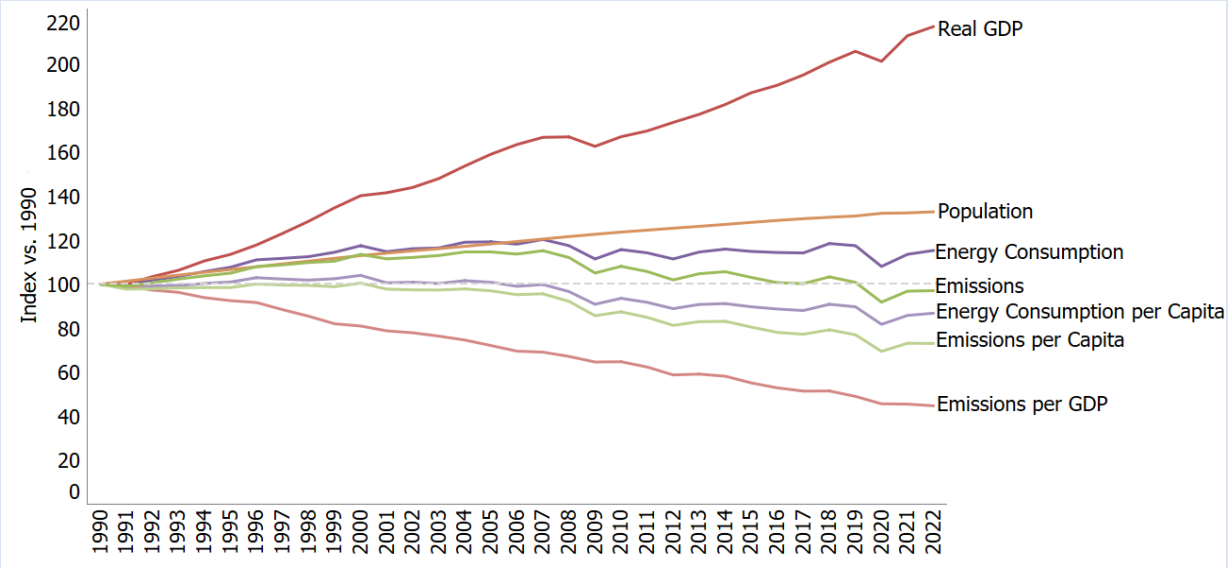

Table 2-14 provides data on various statistics related to U.S. greenhouse gas emissions normalized to 1990 as a baseline year. These values represent the relative change in each statistic since 1990. Greenhouse gas emissions in the United States have decreased at an average annual rate of 0.1 percent since 1990, although changes from year to year have been significantly larger. This growth rate is slightly slower than that for total energy use, overall gross domestic product (GDP) and national population (see Table 2-14 and Figure 2-16). The direction of these trends started to change after 2005, when greenhouse gas emissions, total energy use and associated fossil fuel consumption began to peak. Greenhouse gas emissions in the United States have decreased at an average annual rate of 0.9 percent since 2005. Since 2005, GDP, and national population, generally continued to increase, and energy use has decreased slightly, noting 2020 was impacted by the COVID-19 pandemic.

Table 2-14: Recent Trends in Various U.S. Data (Index 1990 = 100)

Variable	1990	2005	2018	2019	2020	2021	2022	Avg. Annual Change Since 1990[a]	Avg. Annual Change Since 2005[a]
Greenhouse Gas Emissions[b]	100	115	103	101	92	97	97	-0.1%	-0.9%

2.3 Precursor Greenhouse Gas Emissions (CO, NO_x, NMVOCs, and SO_2)

The reporting requirements of the Paris Agreement and the UNFCCC[11] request that information be provided on emissions of compounds that are precursors to greenhouse gases, which include carbon monoxide (CO), nitrogen oxides (NO_x), non-methane volatile organic compounds (NMVOCs), and sulfur dioxide (SO_2). These gases are not direct greenhouse gases, but can indirectly impact Earth's radiative balance, by altering the concentrations of other greenhouse gases (e.g., tropospheric ozone) and atmospheric aerosol (e.g., particulate sulfate). Carbon monoxide is produced when carbon-containing fuels are combusted incompletely in energy, transportation, and industrial processes, and is also emitted from practices such as agricultural burning and waste disposal and treatment. Anthropogenic sources of nitrogen oxides (i.e., NO and NO_2) are primarily fossil fuel combustion (for energy, transportation, industrial process) and agricultural burning. Anthropogenic sources of NMVOCs, which include hundreds of organic compounds that participate in atmospheric chemical reactions (propane, butane, xylene, toluene, ethane, and many others)—are emitted primarily from transportation, industrial processes, oil and natural gas production, waste practices, agricultural burning, and non-industrial consumption of organic solvents. In the United States, SO_2 is primarily emitted from coal combustion for electric power generation and the metals industry.

As noted above and summarized in Chapter 6 of IPCC (2021), these compounds can have important indirect effects on Earth's radiative balance. For example, reactions between NMVOCs and NO_x in the presence of sunlight lead to formation of tropospheric ozone, a greenhouse gas. Concentrations of NMVOCs, NO_x, and CO can also impact the abundance and lifetime of primary greenhouse gases. This largely occurs by altering the atmospheric concentrations of the hydroxyl radical (OH), which is the main sink for atmospheric CH_4. For example, NO_x emissions can lead to increases in O_3 concentrations and subsequent OH production, which will increase the amount of OH molecules that are available to destroy CH_4. In contrast, NMVOCs and CO can both react directly with OH, leading to lower OH concentrations, a longer atmospheric lifetime of CH_4, and a decrease in CO_2 production (i.e., CO+OH→ CO_2). Changes in atmospheric CH_4 can also feedback on background concentrations of tropospheric O_3. Other indirect impacts include the formation of sulfate and nitrate aerosol from emissions of NO_x and SO_2, both of which have a net negative impact on radiative forcing.

Since 1970, the United States has published triennial estimates of emissions of CO, NO_x, NMVOCs, and SO_2 (EPA 2023a), which are regulated under the Clean Air Act. Emissions of each of these precursor greenhouse gases has decreased significantly since 1990 as a result of implementation of Clean Air Act programs, as well as technological improvements.[12] Precursor emission estimates for this report for 1990 through 2022 were obtained from data published on EPA's National Emissions Inventory (NEI) Air Pollutants Emissions Trends Data website (EPA 2023a). For Table 2-15, NEI-reported emissions of CO, NO_x, SO_2, and NMVOCs are recategorized from NEI Emissions Inventory System (EIS) source categories to those more closely aligned with reporting sectors and categories under the Paris Agreement and the UNFCCC, based on the crosswalk detailed in Annex 6.3. Table 2-15 shows that fuel combustion accounts for the majority of emissions of these precursors. Industrial processes—such as the manufacture of chemical and allied products, metals processing, and industrial uses of solvents—are also significant sources of CO, NO_x, and NMVOCs. Precursor emissions from Agriculture and LULUCF categories are estimated separately and therefore are not taken from EPA (2023a).

NA (Not Available)

Note: Totals by gas may not sum due to independent rounding.

Source: (EPA 2023a) except for estimates from forest fires, grassland fires, and field burning of agricultural residues. Emission categories from EPA (2023a) are aggregated into sectors and categories reported under the Paris Agreement and the UNFCCC as shown in Table ES-3.

3. Energy

Energy-related activities were the primary sources of U.S. anthropogenic greenhouse gas emissions, accounting for 82.0 percent of total gross greenhouse gas emissions on a carbon dioxide (CO_2) equivalent basis in 2022.[1] This included 96.5, 40.2, and 10.8 percent of the nation's CO_2, methane (CH_4), and nitrous oxide (N_2O) emissions, respectively.[2] Energy-related CO_2 emissions alone constituted 76.9 percent of total gross U.S. greenhouse gas emissions from all sources on a CO_2-equivalent basis, while the non-CO_2 emissions from energy-related activities represented a much smaller portion of total gross national emissions (5.1 percent collectively).

Emissions from fossil fuel combustion contribute the vast majority of energy-related emissions, with CO_2 being the primary gas emitted (see Figure 3-1 and Figure 3-2). Globally, approximately 33,500 million metric tons (MMT) of CO_2 were added to the atmosphere through the combustion of fossil fuels in 2022, of which the United States accounted for approximately 14 percent.[3] Due to their relative importance over time (see Figure 3-2), fossil fuel combustion-related CO_2 emissions are considered in more detail than other energy-related emissions in this report (see Figure 3-3).

Fossil fuel combustion also emits CH_4 and N_2O. Stationary combustion of fossil fuels was the second largest source of N_2O emissions in the United States and mobile fossil fuel combustion was the fifth largest source. Energy-related activities other than fuel combustion, such as the production, transmission, storage, and distribution of fossil fuels, also emit greenhouse gases. These emissions consist primarily of fugitive CH_4 emissions from natural gas systems, coal mining, and petroleum systems.

[1] Estimates are presented in units of million metric tons of carbon dioxide equivalent (MMT CO_2 Eq.), which weight each gas by its global warming potential, or GWP, value. See section on global warming potentials in the Executive Summary.

[2] The contribution of energy non-CO_2 emissions is based on gross totals so excludes LULUCF methane (CH_4) and nitrous oxide (N_2O) emissions. The contribution of energy-related methane (CH_4) and (N_2O) including LULUCF non-CO_2 emissions, is 37.1 percent and 9.8 percent respectively.

[3] Global CO_2 emissions from fossil fuel combustion were taken from International Energy Agency *Global energy-related CO_2 emissions, 2022.* Available at: https://www.iea.org/reports/co2-emissions-in-2022 (IEA 2022).

Figure 3-1: 2022 Energy Sector Greenhouse Gas Sources

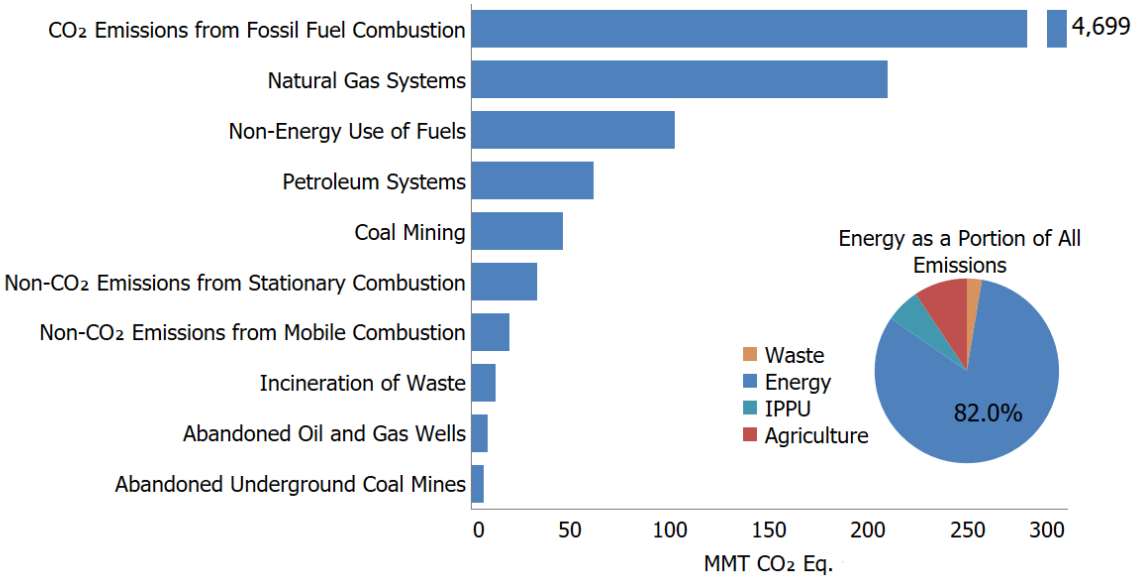

Figure 3-2: Trends in Energy Sector Greenhouse Gas Sources

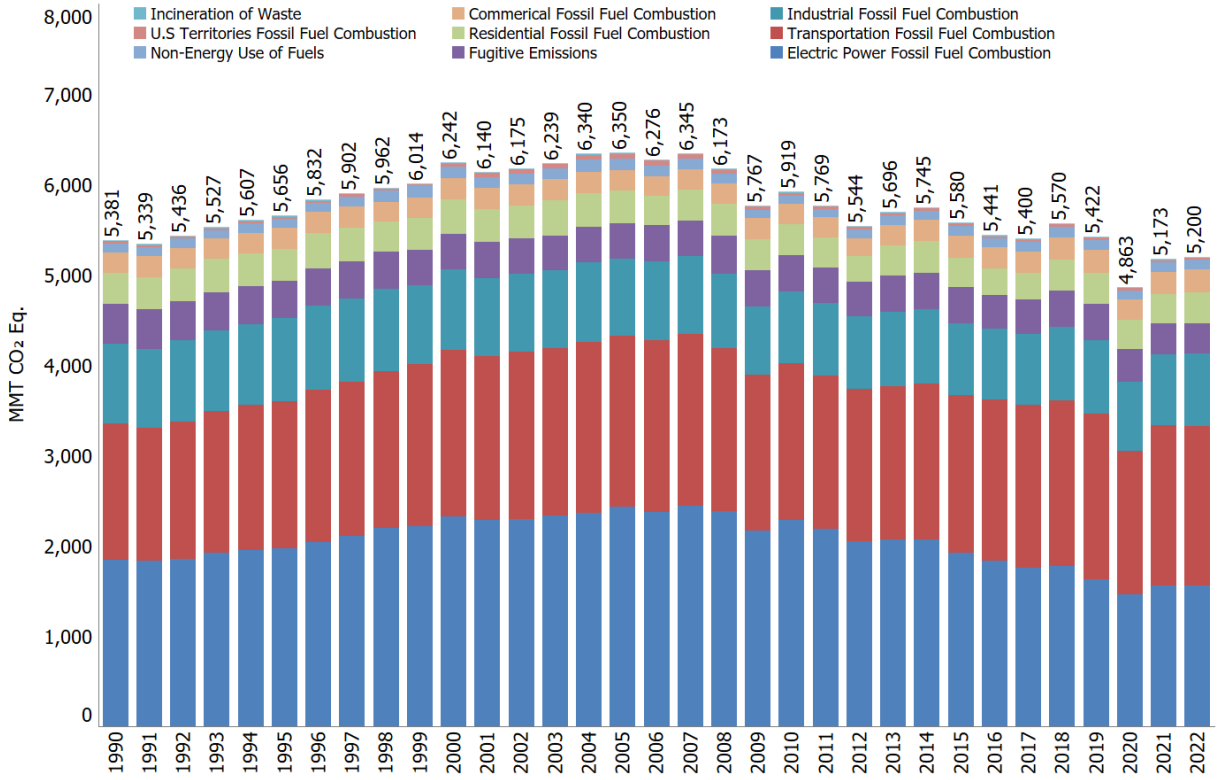

Figure 3-3: 2022 U.S. Fossil Carbon Flows (MMT CO_2 Eq.)

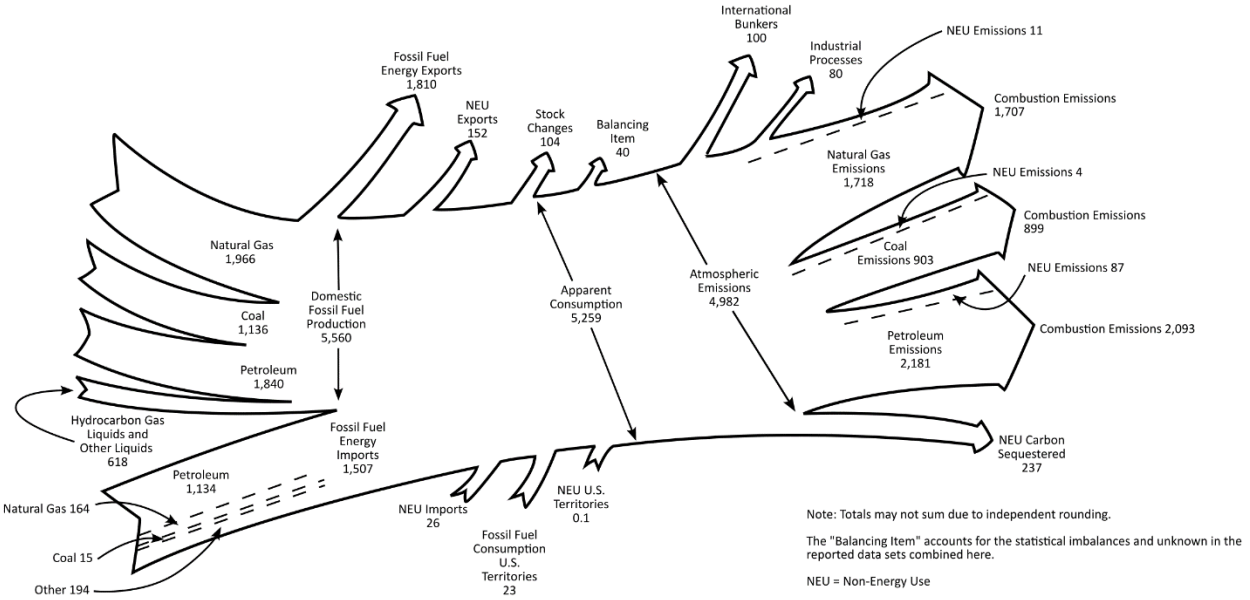

Table 3-1 summarizes emissions from the Energy sector in units of MMT CO_2 Eq., while unweighted gas emissions in kilotons (kt) are provided in Table 3-2. Overall, emissions due to energy-related activities were 5,199.8 MMT CO_2 Eq. in 2022,[4] a decrease of 3.4 percent since 1990 and an increase of 0.5 percent since 2021. The increase in emissions in 2021 and 2022 was due to continued rebounding activity levels after the coronavirus (COVID-19) pandemic reduced overall demand for fossil fuels across all sectors in 2020. Longer term trends are driven by a number of factors including a shift from coal to natural gas and renewables in the electric power sector.

+ Does not exceed 0.5 kt.

[a] Emissions from biomass and biofuel consumption are not included specifically in summing Energy sector totals. Net carbon fluxes from changes in biogenic carbon reservoirs are accounted for in the estimates for LULUCF.

[b] Emissions from international bunker fuels are not included in totals. These values are presented for informational purposes only, in line with the *2006 IPCC Guidelines* and UNFCCC reporting obligations.

Note: Totals by gas may not sum due to independent rounding.

Emissions estimates reported in the Energy chapter from fossil fuel combustion and fugitive sources include those from all 50 states, including Hawaii and Alaska, and the District of Columbia. Emissions are also included from U.S. Territories to the extent they are known to occur (e.g., coal mining does not occur in U.S. Territories). For some sources there is a lack of detailed information on U.S. Territories including some non-CO_2 emissions from biomass combustion. As part of continuous improvement efforts, EPA reviews this on an ongoing basis to ensure emission sources are included across all geographic areas including U.S. Territories if they are occurring. See Annex 5 for more information on EPA's assessment of the sources not included in this *Inventory*.

Each year, some emission and sink estimates in the *Inventory* are recalculated and revised with improved methods and/or data. In general, recalculations are made to the U.S. greenhouse gas emission estimates either to incorporate new methodologies or, most commonly, to update recent historical data. These improvements are implemented consistently across the previous *Inventory's* time series (i.e., 1990 to 2021) to ensure that the trend is accurate. Key updates in this year's *Inventory* include, updated methodologies for completion and workover emissions estimates and transmission compressor station activity from both natural gas systems and petroleum systems, a shift of all product supplied of natural gasoline and unfinished oils to crude oil transfers for the time series and changes to the non-energy use of fossil fuel methodology (e.g., updates to some of the data and updated methodology for the amount of NEU HGLs). The impact of these recalculations averaged a decrease of 0.2 MMT CO_2 Eq. (less than 0.1 percent) per year across the time series. For more information on specific methodological updates, please see the Recalculations Discussion section for each category in this chapter.

Box 3-1: Methodological Approach for Estimating and Reporting U.S. Emissions and Removals, including Relationship to EPA's Greenhouse Gas Reporting Program

Consistent with Article 13.7(a) of the Paris Agreement and Article 4.1(a) of the UNFCCC as well as relevant decisions under those agreements, the emissions and removals presented in this report and this chapter are organized by source and sink categories and calculated using internationally accepted methods in the *2006 IPCC Guidelines for National Greenhouse Gas Inventories (2006 IPCC Guidelines)*. Additionally, the calculated emissions and removals in a given year for the United States are presented in a common format in line with the reporting guidelines for the reporting of inventories under the Paris Agreement and the UNFCCC. The Parties' use of consistent methods to calculate emissions and removals for their inventories helps to ensure that these reports are comparable. The presentation of emissions and removals provided in the Energy chapter do not preclude alternative examinations (e.g., economic sectors). Rather, this chapter presents emissions and removals in a common format consistent with how Parties are to report their national inventories under the Paris Agreement and the UNFCCC. The report itself, and this chapter, follows this common format, and provides an explanation of the application of methods used to calculate emissions and removals from energy-related activities.

Energy Data from EPA's Greenhouse Gas Reporting Program

EPA's Greenhouse Gas Reporting Program (GHGRP)[5] dataset and the data presented in this Inventory are complementary. The *Inventory* was used to guide the development of the GHGRP, particularly in terms of scope and coverage of both sources and gases. The GHGRP dataset continues to be an important resource for the Inventory, providing not only annual emissions information, but also other annual information, such as activity data and emission factors that can improve and refine national emission estimates and trends over time. GHGRP data also allow EPA to disaggregate national inventory estimates in new ways that can highlight differences across regions and sub-categories of emissions, along with enhancing application of QA/QC procedures and assessment of uncertainties.

EPA uses annual GHGRP data in a number of Energy sector categories to improve the national estimates presented in this Inventory consistent with IPCC guidelines (see Box 3-3 of this chapter, and Sections 3.3 Incineration of Waste, 3.4 Coal Mining, 3.6 Petroleum Systems, and 3.7 Natural Gas Systems).[6] Methodologies used in EPA's GHGRP are consistent with IPCC guidelines, including higher tier methods. Under EPA's GHGRP, facilities collect detailed information specific to their operations according to detailed measurement standards. It should be noted that the definitions and provisions for reporting fuel types in EPA's GHGRP may differ from those used in the Inventory in meeting the Paris Agreement and UNFCCC reporting guidelines. In line with the Paris Agreement and UNFCCC reporting guidelines, the Inventory report is a comprehensive accounting of all emissions from fuel types identified in the IPCC guidelines and provides a separate reporting of emissions from biomass.

In addition to using GHGRP data to estimate emissions (Sections 3.3 Incineration of Waste, 3.4 Coal Mining, 3.6 Petroleum Systems, and 3.7 Natural Gas Systems), EPA also uses the GHGRP fuel consumption activity data in the Energy sector to disaggregate industrial end-use sector emissions in the category of CO_2 emissions from fossil fuel combustion, for use in reporting emissions in Common Reporting Tables (CRTs) (see Box 3-3). The industrial end-use sector activity data collected for the *Inventory* (EIA 2024) represent aggregated data for the industrial end-use sector. EPA's GHGRP collects industrial fuel consumption activity data by individual categories within the industrial end-use sector. Therefore, GHGRP data are used to provide a more detailed breakout of total emissions in the industrial end-use sector within that source category.

As indicated in the respective Planned Improvements sections for source categories in this chapter, EPA continues to examine the uses of facility-level GHGRP data to improve the national estimates presented in this *Inventory*. See Annex 9 for more information on use of EPA's GHGRP in the *Inventory*.

3.1 Fossil Fuel Combustion (CRT Source Category 1A)

Emissions from the combustion of fossil fuels for energy include the greenhouse gases CO_2, CH_4, and N_2O. Given that CO_2 is the primary gas emitted from fossil fuel combustion and represents the largest share of U.S. total emissions, CO_2 emissions from fossil fuel combustion are discussed at the beginning of this section. An overview of CH_4 and N_2O emissions from the combustion of fuels in stationary sources is then presented, followed by fossil fuel

[5] On October 30, 2009, the U.S. Environmental Protection Agency (EPA) published a rule requiring annual reporting of greenhouse gas data from large greenhouse gas emission sources in the United States. Implementation of the rule, codified at 40 CFR Part 98, is referred to as EPA's Greenhouse Gas Reporting Program (GHGRP).

[6] See http://www.ipcc-nggip.iges.or.jp/public/tb/TFI_Technical_Bulletin_1.pdf.

combustion emissions for all three gases by sector: electric power, industrial, residential, commercial, U.S. Territories, and transportation.

Methodologies for estimating CO_2 emissions from fossil fuel combustion differ from the estimation of CH_4 and N_2O emissions from stationary combustion and mobile combustion. Thus, three separate descriptions of methodologies, uncertainties, recalculations, and planned improvements are provided at the end of this section. Total CO_2, CH_4, and N_2O emissions from fossil fuel combustion are presented in Table 3-3 and Table 3-4.

Table 3-3: CO_2, CH_4, and N_2O Emissions from Fossil Fuel Combustion (MMT CO_2 Eq.)

Gas	1990	2005	2018	2019	2020	2021	2022
CO_2	4,752.2	5,744.1	4,988.2	4,852.6	4,341.7	4,654.3	4,699.4
CH_4	16.9	13.1	12.5	12.7	10.5	10.6	11.2

CO_2 from Fossil Fuel Combustion

Carbon dioxide is the primary gas emitted from fossil fuel combustion and represents the largest share of U.S. total greenhouse gas emissions. Carbon dioxide emissions from fossil fuel combustion are presented in Table 3-5. In 2022, CO_2 emissions from fossil fuel combustion increased by 1.0 percent relative to the previous year (as shown in Table 3-6). The increase in CO_2 emissions from fossil fuel combustion was a result of a 1.8 percent increase in fossil fuel energy use. This increase in fossil fuel energy use was due primarily to the continued rebound in economic activity after the COVID-19 pandemic. Carbon dioxide emissions from natural gas increased by 84.8 MMT CO_2 Eq., a 5.2 percent increase from 2021. In a shift from last year's trend, CO_2 emissions from coal consumption decreased by 58.6 MMT CO_2 Eq., a 6.1 percent decrease from 2021. Both the increase in natural gas and decrease in coal consumption and emissions in 2022 are observed across all sectors. Emissions from petroleum use also increased 19.0 MMT CO_2 Eq. (0.9 percent) from 2021 to 2022. In 2022, CO_2 emissions from fossil fuel combustion were 4,699,4 MMT CO_2 Eq., or 1.1 percent below emissions in 1990 (see Table 3-5).[7]

[7] An additional discussion of fossil fuel emission trends is presented in the Trends in U.S. Greenhouse Gas Emissions chapter.

Table 3-5: CO_2 Emissions from Fossil Fuel Combustion by Fuel Type and Sector (MMT CO_2 Eq.)

NO (Not Occurring)

[a] Although not technically a fossil fuel, geothermal energy-related CO_2 emissions are included for reporting purposes. The source of CO_2 is non-condensable gases in subterranean heated water.

Note: Totals may not sum due to independent rounding.

Trends in CO_2 emissions from fossil fuel combustion are influenced by many long-term and short-term factors. On a year-to-year basis, the overall demand for fossil fuels in the United States and other countries generally fluctuates in response to changes in general economic conditions, energy prices, weather, and the availability of non-fossil alternatives. For example, in a year with increased consumption of goods and services, low fuel prices, severe summer and winter weather conditions, nuclear plant closures, and lower precipitation feeding hydroelectric dams, there would likely be proportionally greater fossil fuel consumption than a year with poor economic performance, high fuel prices, mild temperatures, and increased output from nuclear and hydroelectric plants. The 2021 to 2022 trends reflect ongoing impacts of the COVID-19 pandemic which generally led to a reduction in demand for fossil fuels in 2020, but an increase in demand as activities continued to rebound in 2022.

Longer-term changes in energy usage patterns, however, tend to be more a function of aggregate societal trends that affect the scale of energy use (e.g., population, number of cars, size of houses, and number of houses), the efficiency with which energy is used in equipment (e.g., cars, HVAC systems, power plants, steel mills, and light bulbs), and social planning and consumer behavior (e.g., walking, bicycling, or telecommuting to work instead of driving).

Carbon dioxide emissions also depend on the source of energy and its carbon intensity. The amount of carbon in fuels varies significantly by fuel type. For example, coal contains the highest amount of carbon per unit of useful energy. Petroleum has roughly 75 percent of the carbon per unit of energy as coal, and natural gas has only about

55 percent.[8] Table 3-6 shows annual changes in emissions during the last five years for coal, petroleum, and natural gas in selected sectors.

Table 3-6: Annual Change in CO_2 Emissions and Total 2022 CO_2 Emissions from Fossil Fuel Combustion for Selected Fuels and Sectors (MMT CO_2 Eq. and Percent)

Sector	Fuel Type	2018 to 2019		2019 to 2020		2020 to 2021		2021 to 2022		Total 2022

[a] Includes sector and fuel combinations not shown in this table.

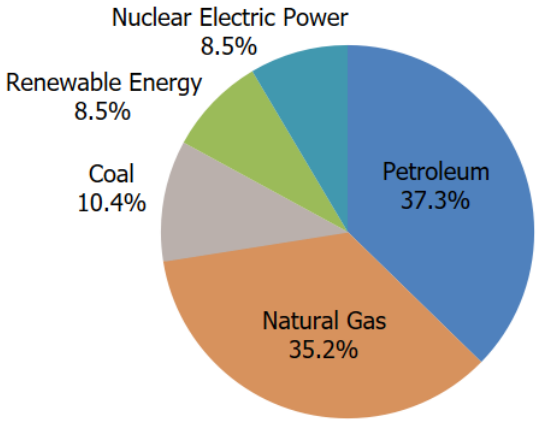
[b] Includes U.S. Territories.

Note: Totals may not sum due to independent rounding.

As shown in Table 3-6, recent trends in CO_2 emissions from fossil fuel combustion show a 2.7 percent decrease from 2018 to 2019, a 10.5 percent decrease from 2019 to 2020, a 7.2 percent increase from 2020 to 2021, and a 1.0 percent increase from 2021 to 2022. These changes contributed to an overall 5.8 percent decrease in CO_2 emissions from fossil fuel combustion from 2018 to 2022.

The overall 2021 to 2022 trends were largely driven by the gradual recovery from the COVID-19 pandemic, which saw reduced economic activity in 2020 and caused changes in energy demand and supply patterns across different sectors. The continued recovery from the COVID-19 pandemic has generally led to increased energy use and emissions across all economic sectors except electric power and transportation from 2021 to 2022. The decrease in emissions from 2021 to 2022 from electric power was due to the reduction in coal consumption for electricity generation, in a return to a pre-pandemic trend in declining coal-fired power generation.

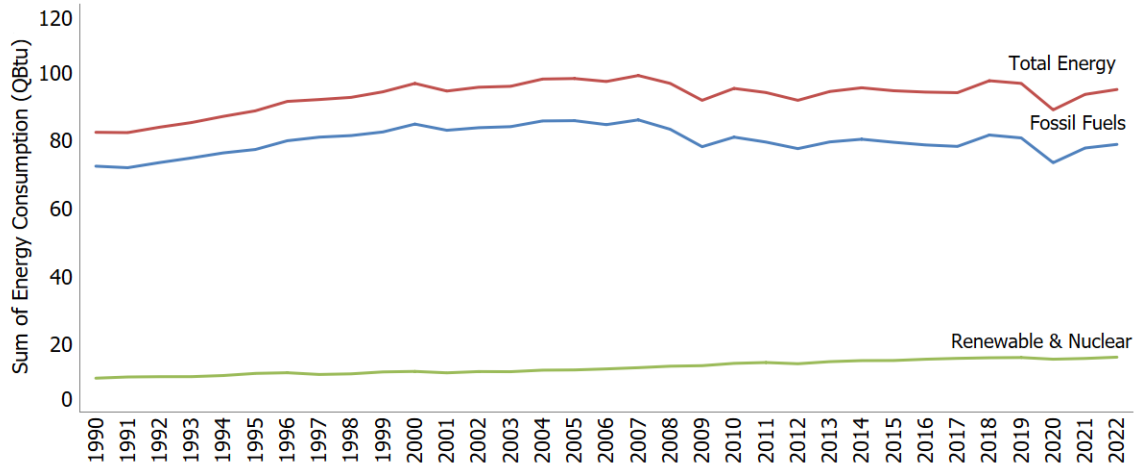
Recent trends in CO_2 emissions from fossil fuel combustion are largely driven by the electric power sector, which until 2017 has accounted for the largest portion of these emissions. The types of fuels consumed to produce electricity have changed in recent years. Electric power sector consumption of natural gas primarily increased due to increased production capacity as natural gas-fired plants replaced coal-fired plants and increased electricity demand related to heating and cooling needs (EIA 2018; EIA 2023a). Total net electric power generation from all fossil and non-fossil sources decreased by 1.3 percent from 2018 to 2019, decreased by 2.9 percent from 2019 to 2020, increased by 2.7 percent from 2020 to 2021, and increased by 3.0 percent from 2021 to 2022 (EIA 2024a). Carbon dioxide emissions from the electric power sector decreased from 2021 to 2022 by 0.6 percent due to increased production and use of natural gas and decreased production and use of coal for electric power generation. Carbon dioxide emissions from coal consumption for electric power generation decreased by 26.1 percent overall since 2018, including a 6.4 percent decrease from 2021 to 2022.



Petroleum use in the transportation sector is another major driver of emissions, representing the largest source of CO_2 emissions from fossil fuel combustion in 2022. Emissions from petroleum consumption for transportation have decreased by 4.6 percent since 2018 and are primarily attributed to a 1.4 percent decrease in VMT over the same

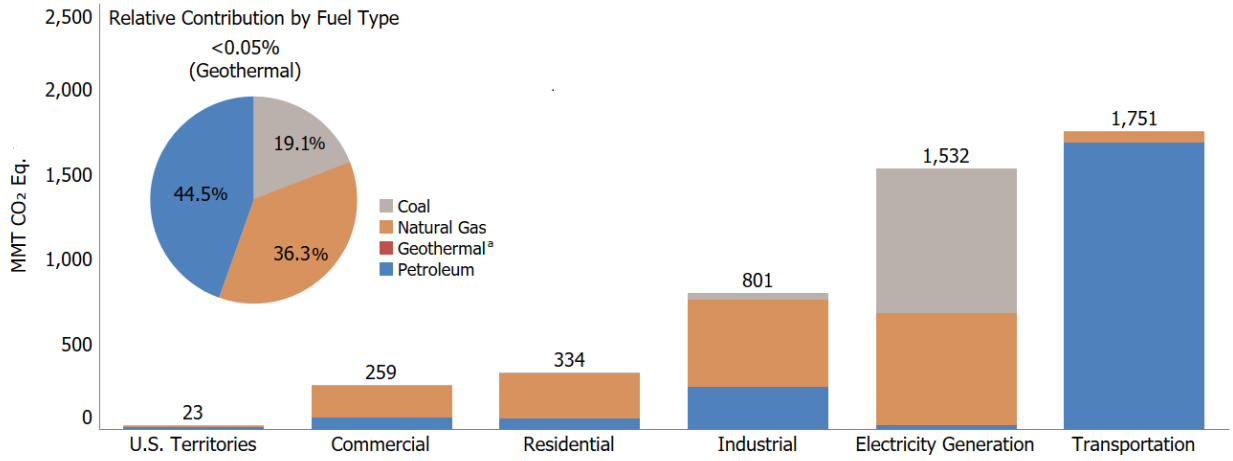
[8] Based on national aggregate carbon content of all coal, natural gas, and petroleum fuels combusted in the United States. See Annex 2.2 for more details on fuel carbon contents.

time period. As of 2017, the transportation sector is the largest source of national CO_2 emissions–whereas in prior years, electric power was the largest source sector.



In the United States, 83.0 percent of the energy used in 2022 was produced through the combustion of fossil fuels such as petroleum, natural gas, and coal (see Figure 3-4 and Figure 3-5). Specifically, petroleum supplied the largest share of domestic energy demands, accounting for 37 percent of total U.S. energy used in 2022. Natural gas and coal followed in order of fossil fuel energy demand significance, accounting for approximately 35 percent and 10 percent of total U.S. energy used, respectively. Petroleum was consumed primarily in the transportation end-use sector and the majority of coal was used in the electric power sector. Natural gas was broadly consumed in all end-use sectors except transportation (see Figure 3-6) (EIA 2024a). The remaining portion of energy used in 2022 was supplied by nuclear electric power (8 percent) and by a variety of renewable energy sources (9 percent), primarily wind energy, hydroelectric power, solar, geothermal and biomass (EIA 2024a).[9]

Figure 3-4: 2022 U.S. Energy Use by Energy Source



Note: Totals may not sum due to independent rounding.

Figure 3-5: Annual U.S. Energy Use

[9] Renewable energy, as defined in EIA's energy statistics, includes the following energy sources: hydroelectric power, geothermal energy, biomass, solar energy, and wind energy.

Figure 3-6: 2022 CO_2 Emissions from Fossil Fuel Combustion by Sector and Fuel Type

[a] Although not technically a fossil fuel, geothermal energy-related CO_2 emissions are included for reporting purposes. The source of CO_2 is non-condensable gases in subterranean heated water.

Fossil fuels are generally combusted for the purpose of producing energy for useful heat and work. During the combustion process, the carbon stored in the fuels is oxidized and emitted as CO_2 and smaller amounts of other gases, including CH_4, carbon monoxide (CO), and non-methane volatile organic compounds (NMVOCs).[10] These other C-containing non-CO_2 gases are emitted as a byproduct of incomplete fuel combustion, but are, for the most part, eventually oxidized to CO_2 in the atmosphere. Therefore, as per IPCC guidelines, it is assumed that all of the carbon in fossil fuels used to produce energy is eventually converted to atmospheric CO_2.

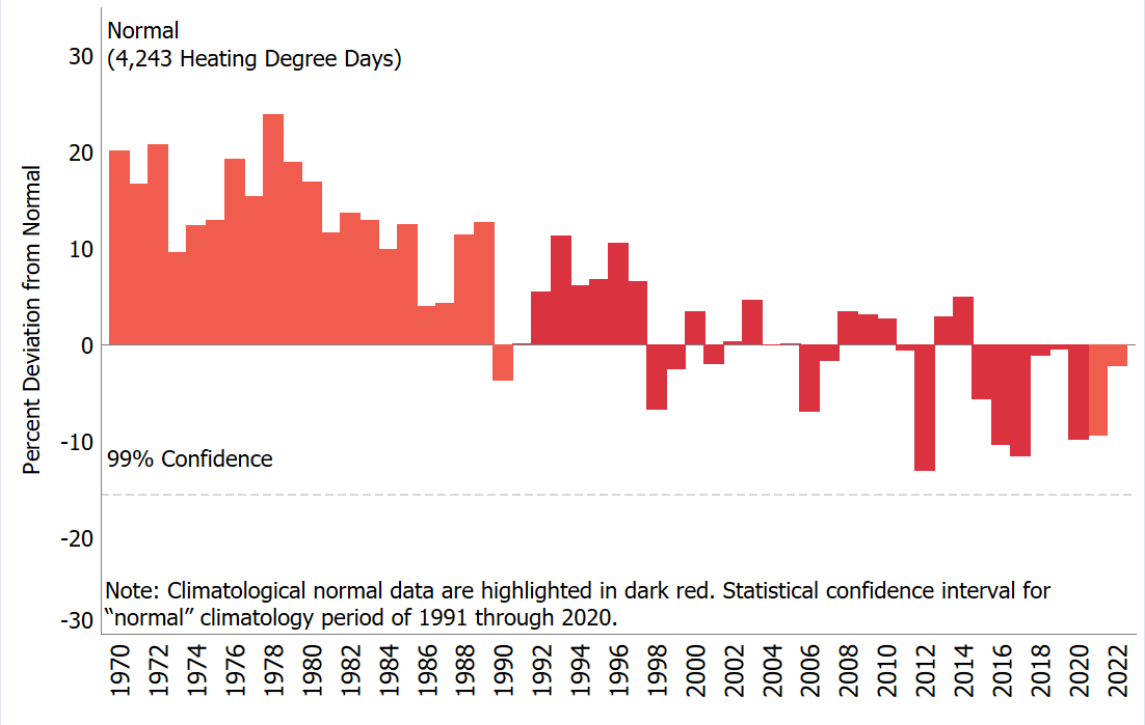
Box 3-2: Weather and Non-Fossil Energy Effects on CO_2 Emissions from Fossil Fuel Combustion Trends

The United States in 2022 experienced a colder winter overall compared to 2021, with a 7.9 percent increase in heating degree days, although 2022 heating degree days were 2.3 percent below normal (see Figure 3-7). Along with a colder winter, 2022 experienced a warmer summer, with cooling degree days 16.9 percent above normal and 4.3 percent higher compared to 2021 (see Figure 3-8) (EIA 2024a).[11] Warmer summers and colder winters can lead to increased energy use to heat and cool building spaces in the residential and commercial sectors. The combination of colder winter and warmer summer conditions in 2022 as compared to 2021 led to an overall increase in direct emissions from fossil fuel combustion in the residential and commercial sectors of 5.0 and 8.9 percent, respectively.

[10] See the sections entitled Stationary Combustion and Mobile Combustion in this chapter for information on non-CO_2 gas emissions from fossil fuel combustion.

[11] Degree days are relative measurements of outdoor air temperature. Heating degree days are deviations of the mean daily temperature below 65 degrees Fahrenheit, while cooling degree days are deviations of the mean daily temperature above 65 degrees Fahrenheit. Heating degree days have a considerably greater effect on energy demand and related emissions than do cooling degree days. Excludes Alaska and Hawaii. Normals are based on data from 1991 through 2020. The variation in these normals during this time period was ±16 percent and ±27 percent for heating and cooling degree days, respectively (99 percent confidence interval).

Figure 3-7: Annual Deviations from Normal Heating Degree Days for the United States (1970–2022, Index Normal = 100)



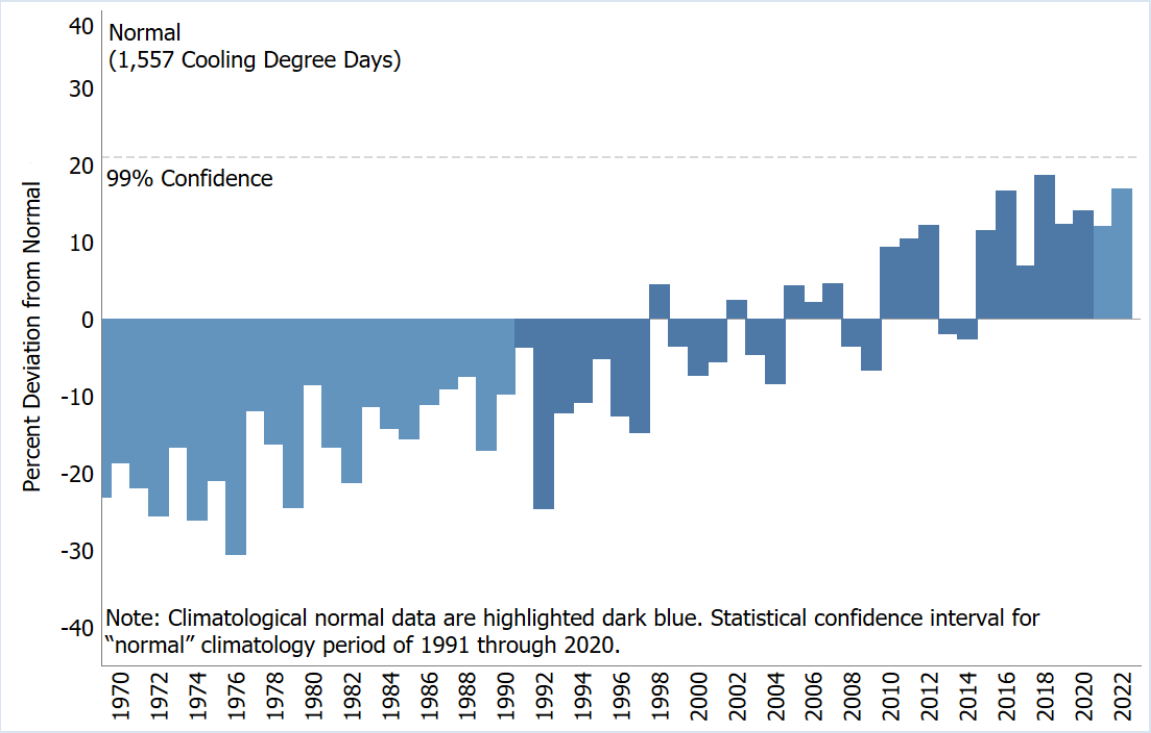


Figure 3-8: Annual Deviations from Normal Cooling Degree Days for the United States (1970–2022, Index Normal = 100)

The carbon intensity of the electric power sector is impacted by the amount of non-fossil energy sources of electricity. The utilization (i.e., capacity factors)[12] of nuclear power plants in 2022 remained high at 93 percent. In 2022, nuclear power represented 19 percent of total electricity generation. Since 1990, the wind and solar power sectors have shown strong growth and have become relatively important sources of electricity. Between 1990 and 2022, renewable energy generation (in kWh) from solar and wind energy have increased from 0.1 percent in 1990 to 14 percent of total electricity generation in 2022, which helped drive the decrease in the carbon intensity of the electricity supply in the United States.

Stationary Combustion

The direct combustion of fuels by stationary sources in the electric power, industrial, commercial, and residential sectors represent the greatest share of U.S. greenhouse gas emissions. Table 3-7 presents CO_2 emissions from fossil fuel combustion by stationary sources. The CO_2 emitted is closely linked to the type of fuel being combusted in each sector (see the Methodology section of CO_2 from Fossil Fuel Combustion). In addition to CO_2 emissions, CH_4 and N_2O are emitted from fossil fuel combustion as well. Table 3-8 and Table 3-9 present CH_4 and N_2O emissions from the combustion of fuels in stationary sources. The CH_4 and N_2O emissions are linked to the type of fuel being combusted as well as the combustion technology (see the Methodology section for CH_4 and N_2O from Stationary Combustion).

Table 3-7: CO_2 Emissions from Stationary Fossil Fuel Combustion (MMT CO_2 Eq.)

Note: Totals may not sum due to independent rounding.

[12] The capacity factor equals generation divided by net summer capacity. Summer capacity is defined as "The maximum output that generating equipment can supply to system load, as demonstrated by a multi-hour test, at the time of summer peak demand (period of June 1 through September 30)" (EIA 2020a). Data for both the generation and net summer capacity are from EIA (2024a).

[a] U.S. Territories are not apportioned by sector, and emissions shown in the table are total greenhouse gas emissions from all fuel combustion sources.
Note: Totals may not sum due to independent rounding.

Other than the greenhouse gases CO_2, CH_4, and N_2O, gases emitted from stationary combustion include the greenhouse gas precursors nitrogen oxides (NO_x), CO, NMVOCs, and sulfur dioxide (SO_2). Methane and N_2O emissions from stationary combustion sources depend upon fuel characteristics and the size and vintage of combustion device, along with combustion technology, pollution control equipment, ambient environmental conditions, and operation and maintenance practices. Nitrous oxide emissions from stationary combustion are closely related to air-fuel mixes and combustion temperatures, as well as the characteristics of any pollution control equipment that is employed. Methane emissions from stationary combustion are primarily a function of the CH_4 content of the fuel and combustion efficiency.

Mobile combustion also produces emissions of CH_4, N_2O, and greenhouse gas precursors including NO_x, CO, and NMVOCs. As with stationary combustion, N_2O and NO_x emissions from mobile combustion are closely related to fuel characteristics, air-fuel mixes, combustion temperatures, and the use of pollution control equipment. Nitrous oxide from mobile sources, in particular, can be formed by the catalytic processes used to control NO_x, CO, and hydrocarbon emissions. Carbon monoxide emissions from mobile combustion are significantly affected by combustion efficiency and the presence of post-combustion emission controls. Carbon monoxide emissions are highest when air-fuel mixtures have less oxygen than required for complete combustion. These emissions occur especially in vehicle idle, low speed, and cold start conditions. Methane and NMVOC emissions from motor vehicles are a function of the CH_4 content of the motor fuel, the amount of hydrocarbons passing uncombusted through the engine, and any post-combustion control of hydrocarbon emissions (such as catalytic converters).

An alternative method of presenting combustion emissions is to allocate emissions associated with electric power to the sectors in which it is used. Four end-use sectors are defined: transportation, industrial, residential, and commercial. In Table 3-11 below, electric power emissions have been distributed to each end-use sector based upon the sector's share of national electricity use, with the exception of CH_4 and N_2O from transportation electricity use.[13] Emissions from U.S. Territories are also calculated separately due to a lack of end-use-specific consumption data.[14] This method assumes that emissions from combustion sources are distributed across the four end-use sectors based on the ratio of electricity use in that sector. The results of this alternative method are presented in Table 3-11.

Table 3-11: CO_2, CH_4, and N_2O Emissions from Fossil Fuel Combustion by End-Use Sector with Electricity Emissions Distributed (MMT CO_2 Eq.)

End-Use Sector	1990	2005	2018	2019	2020	2021	2022

U.S. Territories[a]	**20.1**	**52.1**	**26.0**	**24.9**	**23.4**	**23.9**	**22.7**
Total	**4,829.9**	**5,824.8**	**5,043.4**	**4,906.6**	**4,388.9**	**4,703.7**	**4,752.0**

[a] U.S. Territories are not apportioned by sector, and emissions are total greenhouse gas emissions from all fuel combustion sources.

Notes: Totals may not sum due to independent rounding. Emissions from fossil fuel combustion by electric power are allocated based on aggregate national electricity use by each end-use sector.

[13] Separate calculations are performed for transportation-related CH_4 and N_2O. The methodology used to calculate these emissions is discussed in the Mobile Combustion section.

[14] U.S. Territories (including American Samoa, Guam, Puerto Rico, U.S. Virgin Islands, Wake Island, and other outlying U.S. Pacific Islands) consumption data obtained from EIA are only available at the aggregate level and cannot be broken out by end-use sector. The distribution of emissions to each end-use sector for the 50 states does not apply to territories data.

Electric Power Sector

The process of generating electricity is the largest stationary source of CO_2 emissions in the United States, representing 30.3 percent of total CO_2 emissions from all CO_2 emissions sources across the United States. Methane and N_2O accounted for a small portion of total greenhouse gas emissions from electric power, representing 0.1 percent and 1.4 percent, respectively. Electric power also accounted for 32.6 percent of CO_2 emissions from fossil fuel combustion in 2022. Methane and N_2O from electric power represented 11.4 and 52.2 percent of total CH_4 and N_2O emissions from fossil fuel combustion in 2022, respectively.

For the underlying energy data used in this chapter, the Energy Information Administration (EIA) places electric power generation into three functional categories: the electric power sector, the commercial sector, and the industrial sector. The energy use and emissions associated with the electric power sector are included here. The electric power sector consists of electric utilities and independent power producers whose primary business is the production of electricity. This includes both regulated utilities and non-utilities (e.g., independent power producers, qualifying co-generators, and other small power producers). Energy use and emissions associated with electric generation in the commercial and industrial sectors is reported in those other sectors where the producer of the power indicates that its primary business is something other than the production of electricity.[15]

Total greenhouse gas emissions from the electric power sector have decreased by 15.5 percent since 1990. From 1990 to 2007, electric power sector emissions increased by 33 percent, driven by a significant increase in electricity demand (39 percent) while the carbon intensity of electricity generated showed a modest decline (2.1 percent). From 2008 to 2022, as electricity demand increased by 5.2 percent, electric power sector emissions decreased by 35 percent, driven by a significant drop (25 percent) in the carbon intensity of electricity generated. Overall, the carbon intensity of the electric power sector, in terms of CO_2 Eq. per QBtu, decreased by 28 percent from 1990 to 2022 with additional trends detailed in Box 3-4. This decoupling of electric power generation and the resulting CO_2 emissions is shown in Figure 3-9. This recent decarbonization of the electric power sector is a result of several key drivers.

Coal-fired electric generation (in kilowatt-hours [kWh]) decreased from 54 percent of generation in 1990 to 20 percent in 2022.[16] This corresponded with an increase in natural gas generation and renewable energy generation, largely from wind and solar energy. Natural gas generation (in kWh) represented 11 percent of electric power generation in 1990 and increased over the 33-year period to represent 39 percent of electric power sector generation in 2022 (see Table 3-12). Natural gas has a much lower carbon content than coal and is generated in power plants that are generally more efficient in terms of kWh produced per Btu of fuel combusted, which has led to lower emissions as natural gas replaces coal-powered electricity generation. Natural gas and coal used in the United States in 2022 had an average carbon content of 14.43 MMT C/Qbtu and 26.13 MMT C/Qbtu respectively.

[15] Utilities primarily generate power for the U.S. electric grid for sale to retail customers. Non-utilities typically generate electricity for sale on the wholesale electricity market (e.g., to utilities for distribution and resale to retail customers). Where electricity generation occurs outside the EIA-defined electric power sector, it is typically for the entity's own use.

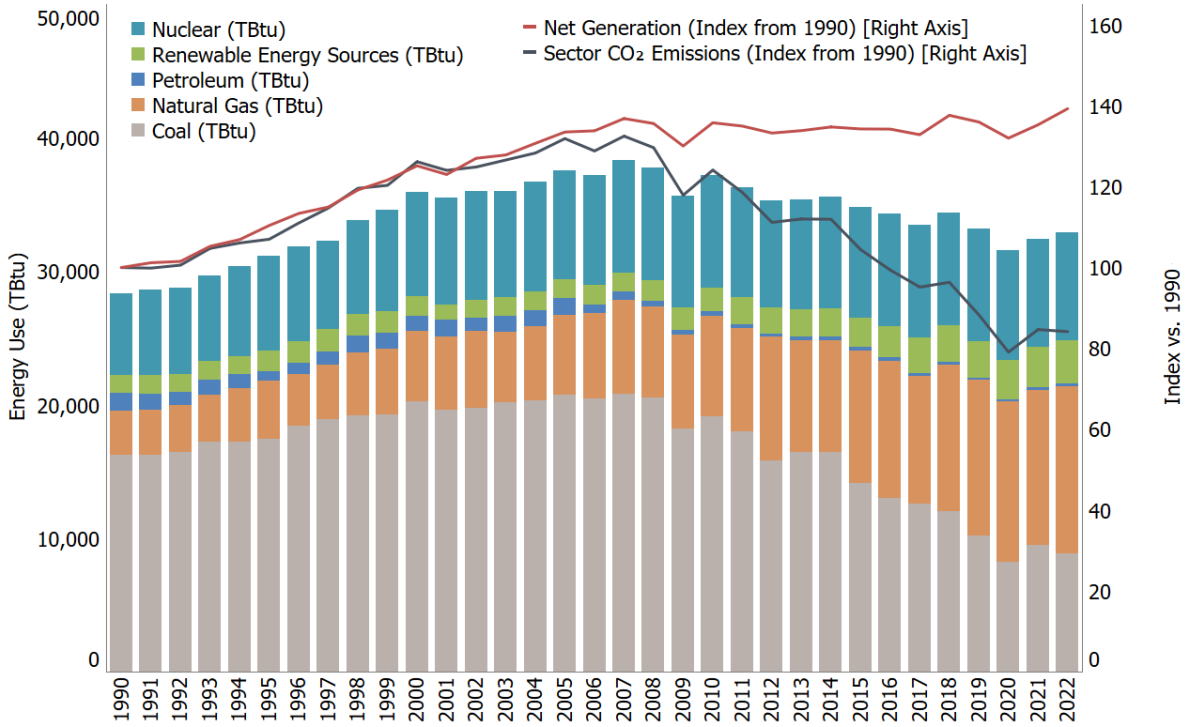
[16] Values represent electricity *net* generation from the electric power sector (EIA 2024a).

Table 3-12: Electric Power Generation by Fuel Type (Percent)

Fuel Type	1990	2005	2018	2019	2020	2021	2022
Coal	54.1%	51.1%	28.4%	24.2%	19.9%	22.6%	20.3%
Natural Gas	10.7%	17.5%	34.0%	37.3%	39.5%	37.3%	38.8%
Nuclear	19.9%	20.0%	20.1%	20.4%	20.5%	19.7%	18.9%
Renewables	11.3%	8.3%	16.8%	17.6%	19.5%	19.8%	21.4%
Petroleum	4.1%	3.0%	0.6%	0.4%	0.4%	0.5%	0.5%
Other Gases[a]	+	0.1%	0.1%	0.1%	0.1%	0.1%	0.1%
Net Electricity Generation (Billion kWh)[b]	2,905	3,902	4,020	3,966	3,851	3,955	4,076

+ Does not exceed 0.05 percent.

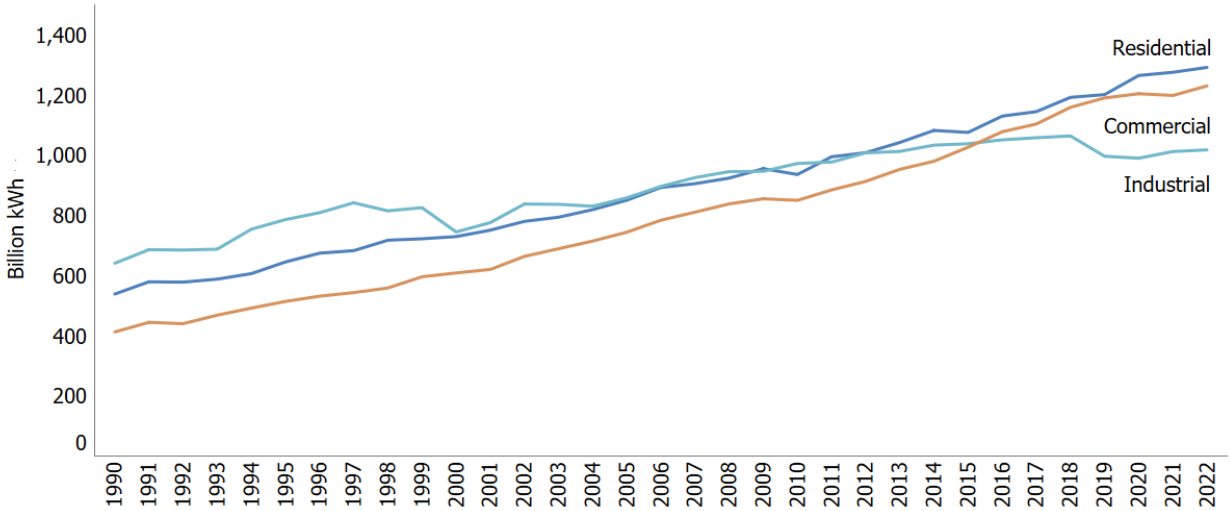
[a] Other gases include blast furnace gas, propane gas, and other manufactured and waste gases derived from fossil fuels.



[b] Represents net electricity generation from the electric power sector. Excludes net electricity generation from commercial and industrial combined-heat-and-power and electricity-only plants. Does not include electricity generation from purchased steam as the fuel used to generate the steam cannot be determined.

In 2022, CO_2 emissions from the electric power sector decreased by 0.6 percent relative to 2021. This decrease in CO_2 emissions was primarily driven by a decrease in coal consumed to produce electricity in the electric power sector. Consumption of coal for electric power decreased by 6.4 percent while consumption of natural gas increased 7.6 percent from 2021 to 2022, leading to an overall decrease in emissions. There has also been a rapid increase in renewable energy electricity generation in the electric power sector in recent years. Electricity generation from renewable sources increased by 11 percent from 2021 to 2022 (see Table 3-12). A decrease in coal-fired electricity generation and increases in natural gas and renewable energy sources for electricity generation contributed to a decoupling of emissions trends from electric power generation trends over the recent time series (see Figure 3-9).

Decreases in natural gas prices and the associated increase in natural gas generation, particularly between 2005 and 2019, was a primary driver of the fuel switching from using coal to using natural gas for electricity generation, which led to a significant decrease in CO_2 emissions from electricity generation. During this time period, the cost of natural gas (in $/MMBtu) decreased by 56 percent while the cost of coal (in $/MMBtu) increased by 74 percent (EIA 2024a). However, from 2020 to 2022, natural gas prices increased 200 percent and are now 9 percent higher than 2005 levels due to the COVID-19 pandemic and other factors disrupting the domestic and global natural gas markets. While the increase in natural gas prices led to a temporary trend reversal, with coal consumption increasing and natural gas consumption decreasing from 2020 to 2021, the broader trend of declining coal consumption for electricity generation continues. From 2021 to 2022, coal consumption decreased 6 percent while natural gas consumption increased 8 percent.



Moving forward, the shift away from coal—and increasingly towards renewable energy sources in addition to natural gas—for electricity generation will further contribute to reductions in power sector emissions. Renewable energy generation (in kWh) from wind and solar energy increased from 0.1 percent of total generation in 1990 to 5 percent in 2015 and increased at a faster pace to 14 percent of total generation in 2022. The decrease in carbon intensity occurred even as total electricity retail sales increased 45 percent, from 2,713 billion kWh in 1990 to 3,927 billion kWh in 2022.

Figure 3-9: Fuels Used in Electric Power Generation and Total Electric Power Sector CO_2 Emissions

Electricity was used primarily in the residential, commercial, and industrial end-use sectors for lighting, heating, electric motors, appliances, electronics, and air conditioning (see Figure 3-10). Note that transportation is an end-use sector as well but is not shown in Figure 3-10 due to the sector's relatively low percentage of electricity use. The Transportation Sector and Mobile Combustion section provides a break-out of CO_2 emissions from electricity use in the transportation end-use sector.

Figure 3-10: Electric Power Retail Sales by End-Use Sector

In 2022, electricity sales to the residential and commercial end-use sectors, as presented in Figure 3-10, increased by 2.6 percent and 4.7 percent relative to 2021, respectively. Electricity sales to the industrial sector in 2022

increased by approximately 2.0 percent relative to 2021. The sections below describe end-use sector energy use in more detail. Overall, in 2022, the amount of electricity retail sales (in kWh) increased by 3.2 percent relative to 2021.

Industrial Sector

Industrial sector CO_2, CH_4, and N_2O emissions accounted for 17, 14, and 5 percent of CO_2, CH_4, and N_2O emissions from fossil fuel combustion, respectively, in 2022. Carbon dioxide, CH_4, and N_2O emissions resulted from the direct consumption of fossil fuels for steam and process heat production.

The industrial end-use sector, per the underlying energy use data from EIA, includes activities such as manufacturing, construction, mining, and agriculture. The largest of these activities in terms of energy use is manufacturing, of which six industries—petroleum refineries, chemicals, paper, primary metals, food, and nonmetallic mineral products—represent the majority of the energy use (EIA 2024a; EIA 2009b).

There are many dynamics that impact emissions from the industrial sector including economic activity, changes in the make-up of the industrial sector, changes in the emissions intensity of industrial processes, and weather-related impacts on heating and cooling of industrial buildings.[17] Structural changes within the U.S. economy that lead to shifts in industrial output away from energy-intensive manufacturing products to less energy-intensive products (e.g., from steel to computer equipment) have had a significant effect on industrial emissions.

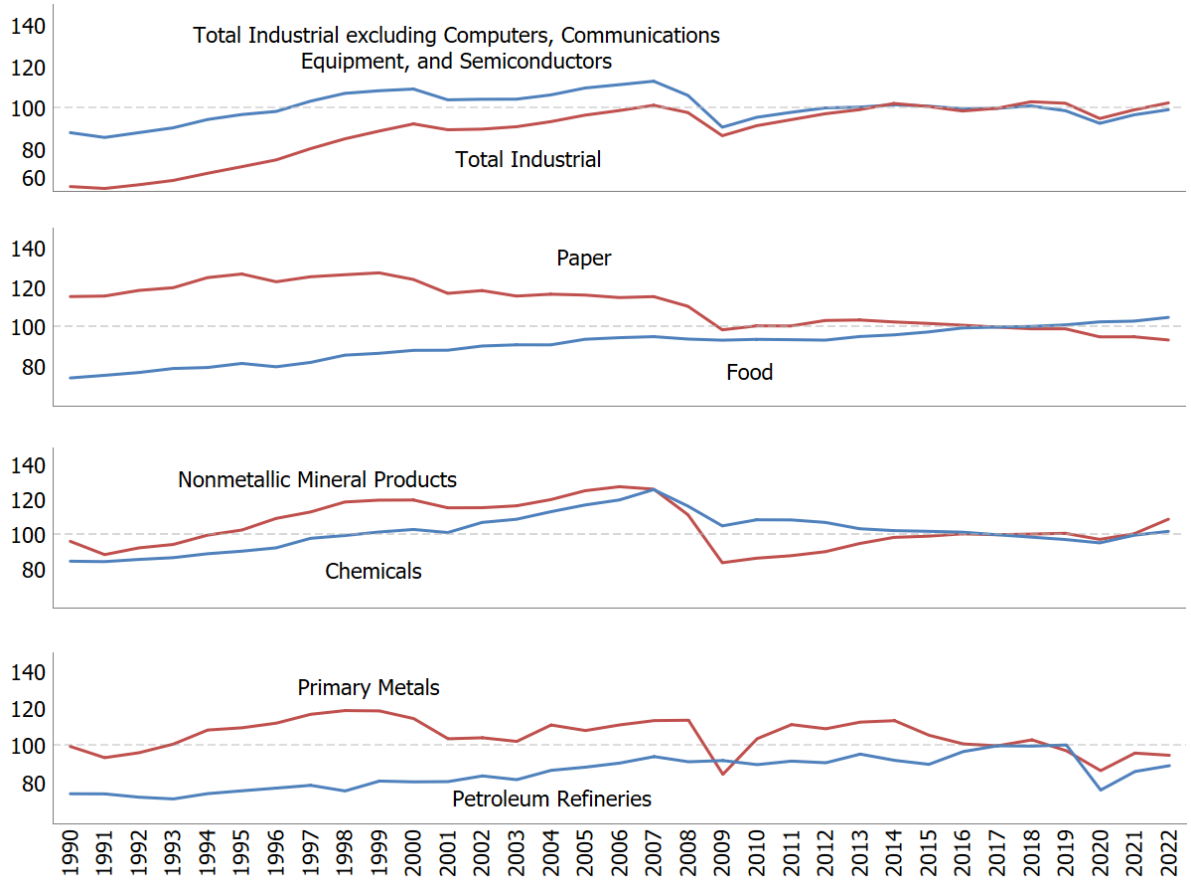
From 2021 to 2022, total industrial production and manufacturing output increased by 3.4 percent (FRB 2022). Over this period, output increased slightly across production indices for Food, Nonmetallic Mineral Products, Paper, Petroleum Refineries, and Primary Metals. Production of chemicals declined slightly between 2021 and 2022 (see Figure 3-11). From 2021 to 2022, total energy use in the industrial sector increased by 2.0 percent, driven mainly by a 2.6 percent increase in fossil fuel consumption in the industrial sector. Consumption of renewables decreased 1.6 percent from 2021 to 2022. Due to the relative increases and decreases of individual indices there was an increase in natural gas and an increase in electricity used by this sector (see Figure 3-12). In 2022, CO_2, CH_4, and N_2O emissions from fossil fuel combustion and electricity use within the industrial end-use sector totaled 1,248.2 MMT CO_2 Eq., a 1.1 percent increase from 2021 emissions.

Through EPA's Greenhouse Gas Reporting Program (GHGRP), specific industrial sector trends can be discerned from the overall total EIA industrial fuel consumption data used for these calculations. For example, from 2021 to 2022, the underlying EIA data showed increased consumption of natural gas and petroleum and decreased consumption of coal in the industrial sector. The GHGRP data highlights that several industries contributed to these trends, including chemical manufacturing; pulp, paper and print; food processing, beverages and tobacco; minerals manufacturing; and agriculture-forest-fisheries.[18]

[17] Some commercial customers are large enough to obtain an industrial price for natural gas and/or electricity and are consequently grouped with the industrial end-use sector in U.S. energy statistics. These misclassifications of large commercial customers likely cause the industrial end-use sector to appear to be more sensitive to weather conditions.

[18] Further details on industrial sector combustion emissions are provided by EPA's GHGRP. See http://ghgdata.epa.gov/ghgp/main.do.

Figure 3-11: Industrial Production Indices (Index 2017=100)



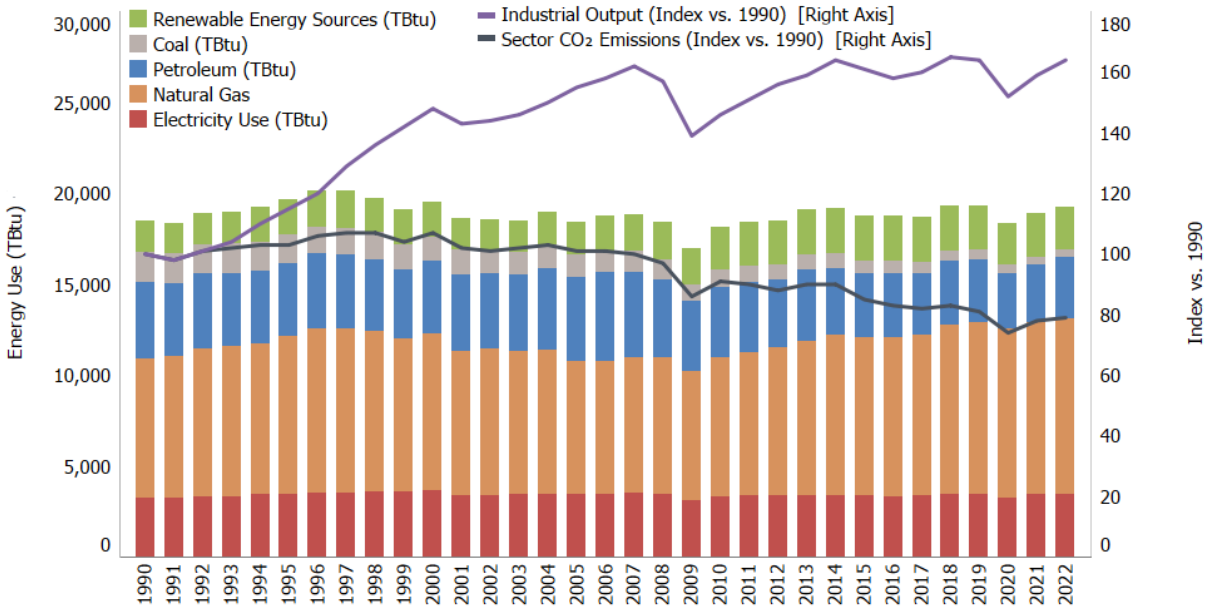


Figure 3-12: Fuels and Electricity Used in Industrial Sector, Industrial Output, and Total Sector CO_2 Emissions (Including Electricity)

Despite the growth in industrial output (65 percent) and the overall U.S. economy (114 percent) from 1990 to 2022, direct CO_2 emissions from fossil fuel combustion in the industrial sector decreased by 8.6 percent over the same time series. A number of factors are assumed to result in decoupling of growth in industrial output from industrial greenhouse gas emissions, for example: (1) more rapid growth in output from less energy-intensive industries relative to traditional manufacturing industries, and (2) energy-intensive industries such as steel are employing new methods, such as electric arc furnaces, that are less carbon-intensive than the older methods.

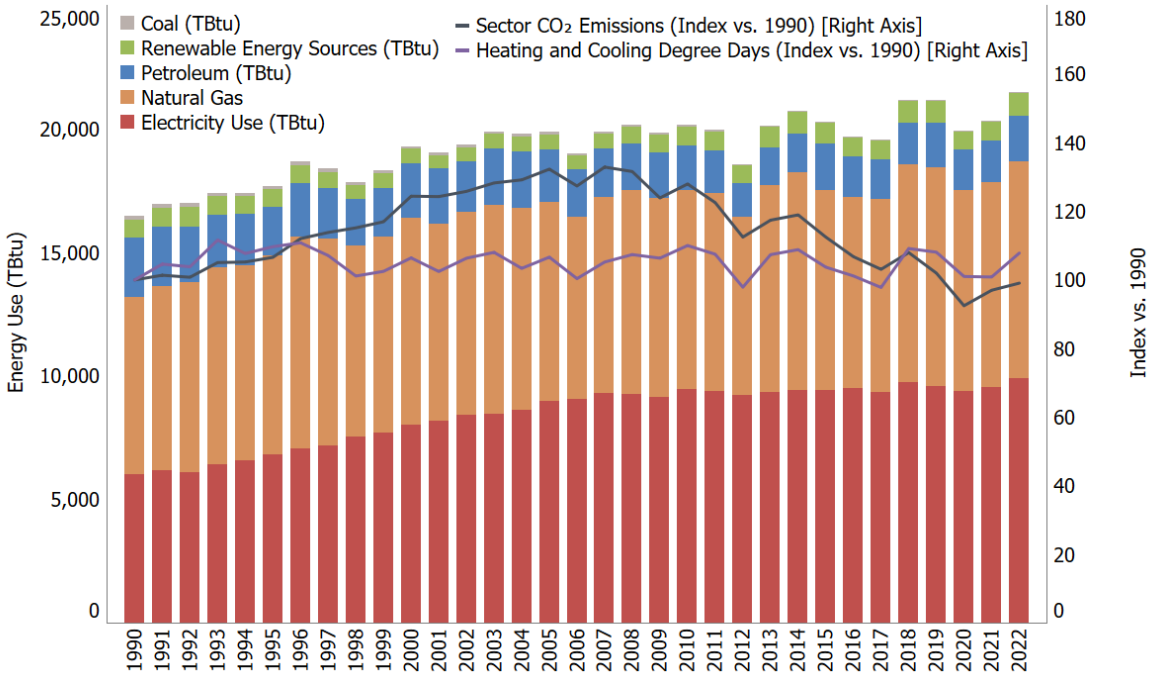
Box 3-3: Uses of Greenhouse Gas Reporting Program Data and Improvements in Reporting Emissions from Industrial Sector Fossil Fuel Combustion

As described in the calculation methodology, total fossil fuel consumption for each year is based on aggregated end-use sector consumption published by the EIA. The availability of facility-level combustion emissions through EPA's GHGRP has provided an opportunity to better characterize the industrial sector's energy consumption and emissions in the United States, through a disaggregation of EIA's industrial sector fuel consumption data from select industries.

For GHGRP 2010 through 2022 reporting years, facility-level fossil fuel combustion emissions reported through EPA's GHGRP were categorized and distributed to specific industry types by utilizing facility-reported NAICS codes (as published by the U.S. Census Bureau). As noted previously in this report, the definitions and provisions for reporting fuel types in EPA's GHGRP include some differences from the *Inventory's* use of EIA national fuel statistics to meet Paris Agreement and UNFCCC reporting guidelines. The IPCC has provided guidance on aligning facility-level reported fuels and fuel types published in national energy statistics, which guided this exercise.[19]

As with previous *Inventory* reports, the current effort represents an attempt to align, reconcile, and coordinate the facility-level reporting of fossil fuel combustion emissions under EPA's GHGRP with the national-level approach presented in this report. Consistent with recommendations for reporting the *Inventory* to the UNFCCC, progress was made on certain fuel types for specific industries and has been included in the Common Reporting Tables (CRTs) that are submitted to the UNFCCC along with this report.[20] The efforts in reconciling fuels focus on standard, common fuel types (e.g., natural gas, distillate fuel oil) where the fuels in EIA's national statistics aligned well with facility-level GHGRP data. For these reasons, the current information presented in the CRTs should be viewed as an initial attempt at this exercise. Additional efforts will be made for future *Inventory* reports to improve the mapping of fuel types and examine ways to reconcile and coordinate any differences between facility-level data and national statistics. The current analysis includes the full time series presented in the CRTs. Analyses were conducted linking GHGRP facility-level reporting with the information published by EIA in its MECS data in order to disaggregate the full 1990 through 2022 time period in the CRTs. It is believed that the current analysis has led to improvements in the presentation of data in the *Inventory*, but further work will be conducted, and future improvements will be realized in subsequent *Inventory* reports. This includes incorporating the latest MECS data as it becomes available.

Residential and Commercial Sectors



Emissions from the residential and commercial sectors have generally decreased since 2005. Short-term trends are often correlated with seasonal fluctuations in energy use caused by weather conditions, rather than prevailing economic conditions. Population growth and a trend towards larger houses has led to increasing energy use over

[19] See Section 4 "Use of Facility-Level Data in Good Practice National Greenhouse Gas Inventories" of the IPCC meeting report, and specifically the section on using facility-level data in conjunction with energy data, at http://www.ipcc-nggip.iges.or.jp/public/tb/TFI_Technical_Bulletin_1.pdf.

[20] See https://www.epa.gov/ghgemissions/inventory-us-greenhouse-gas-emissions-and-sinks.

the time series, while population migration to warmer areas and improved energy efficiency and building insulation have slowed the increase in energy use in recent years. Starting in around 2014, energy use and emissions begin to decouple due to decarbonization of the electric power sector (see Figure 3-13).

Figure 3-13: Fuels and Electricity Used in Residential and Commercial Sectors, Heating and Cooling Degree Days, and Total Sector CO_2 Emissions (Including Electricity)

In 2022, excluding indirect emissions from electricity use, the residential and commercial sectors accounted for 7 and 6 percent of CO_2 emissions from fossil fuel combustion, respectively; 39 and 13 percent of CH_4 emissions from fossil fuel combustion, respectively; and 2 and 1 percent of N_2O emissions from fossil fuel combustion, respectively. Emissions from these sectors are primarily attributable to building -related activities such as the direct consumption of natural gas and petroleum products, primarily for heating and cooking needs. Coal consumption was a minor component of energy use in the commercial sector and did not contribute to any energy use in the residential sector. Greenhouse gas emissions from commercial and residential buildings also increase substantially when emissions from electricity end-use are included, because the building sector uses 75 percent of the electricity generated in the United States (e.g., for heating, ventilation, and air conditioning; lighting; and appliances) (NREL 2023). In 2022, total emissions (CO_2, CH_4, and N_2O) from fossil fuel combustion and electricity use within the residential and commercial end-use sectors were 912.9 MMT CO_2 Eq. and 791.6 MMT CO_2 Eq., respectively. Total CO_2, CH_4, and N_2O emissions from combined fossil fuel combustion and electricity use within the residential and commercial end-use sectors increased by 1.2 and 3.5 percent from 2021 to 2022, respectively. An increase in heating degree days (7.9 percent) and cooling degree days (4.3 percent) increased energy demand for heating and cooling in the residential and commercial sectors. This resulted in a 2.6 percent increase in residential sector electricity use. From 2021 to 2022 there was a 8.4 percent higher direct energy use in the commercial sector. In addition, a shift toward energy efficient products and more stringent energy efficiency standards for household equipment has contributed to a decrease in energy demand in households (EIA 2022), resulting in a decrease in energy-related emissions in the residential sector since 1990. In the long term, the residential sector is also affected by population growth, migration trends toward warmer areas, and changes in total housing units and building attributes (e.g., larger sizes and improved insulation).

In 2022, combustion emissions from natural gas consumption represented 81 and 74 percent of the direct fossil fuel CO_2 emissions from the residential and commercial sectors, respectively. Carbon dioxide emissions from natural gas combustion in the residential and commercial sectors in 2022 increased by 5.2 percent and 6.6 percent from 2021, respectively.

U.S. Territories

Emissions from U.S. Territories are based on the fuel consumption in American Samoa, Guam, Puerto Rico, U.S. Virgin Islands, Wake Island, and other outlying U.S. Pacific Islands. As described in the Methodology section of CO_2 from Fossil Fuel Combustion, this data is collected separately from the sectoral-level data available for the general calculations. As sectoral information is not available for U.S. Territories, CO_2, CH_4, and N_2O emissions are not presented for U.S. Territories in the tables above by sector, though the emissions will occur across all sectors and sources including stationary, transportation and mobile combustion sources.

Transportation Sector and Mobile Combustion

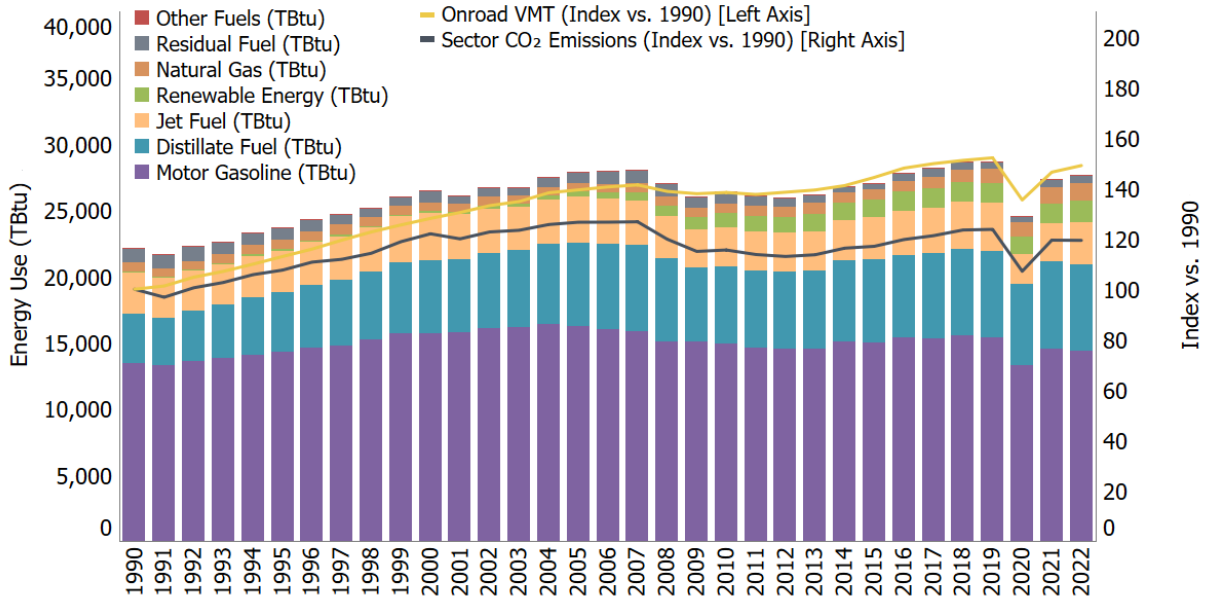
This discussion of transportation emissions follows the alternative method of presenting combustion emissions by allocating emissions associated with electricity generation to the transportation end-use sector, as presented in Table 1-9. Table 1-8 presents direct CO_2, CH_4, and N_2O emissions from all transportation sources (i.e., excluding emissions allocated to electricity consumption in the transportation end-use sector).

The transportation end-use sector and other mobile combustion accounted for 1,776.7 MMT CO_2 Eq. in 2022, which represented 37 percent of CO_2 emissions, 23 percent of CH_4 emissions, and 41 percent of N_2O emissions from fossil fuel combustion, respectively.[21] Fuel purchased in the U.S. for international aircraft and marine travel accounted for an additional 98.9 MMT CO_2 Eq. in 2022; these emissions are recorded as international bunkers and are not included in U.S. totals according to Paris Agreement and UNFCCC reporting protocols.

Transportation End-Use Sector

From 1990 to 2019, transportation emissions from fossil fuel combustion rose by 21 percent, followed by a reduction of 13 percent from 2019 to 2020, followed by an increase of 12 percent from 2020 to 2022. Overall, from 1990 to 2022, transportation emissions from fossil fuel combustion increased by 17 percent. The increase in transportation emissions from fossil fuel combustion from 1990 to 2022 was due, in large part, to increased demand for travel (see Figure 3-14). The number of vehicle miles traveled by light-duty motor vehicles (passenger cars and light-duty trucks) increased 47 percent from 1990 to 2022, as a result of a confluence of factors including population growth, economic growth, urban sprawl, and low fuel prices over much of this period. Between 2019 and 2020, emissions from light-duty vehicles fell by 11 percent, primarily the result of the COVID-19 pandemic and associated restrictions, such as people working from home and traveling less. Light-duty vehicle VMT rebounded in 2022 but is still estimated to be 2 percent below 2019 levels.

Commercial aircraft emissions decreased by 5 percent between 2019 and 2022 but have decreased 7 percent since 2007 (FAA 2024 and DOT 1991 through 2023).[22] Decreases in jet fuel emissions (excluding bunkers) started in 2007 due in part to improved operational efficiency that results in more direct flight routing, improvements in aircraft and engine technologies to reduce fuel burn and emissions, and the accelerated retirement of older, less fuel-efficient aircraft; however, the sharp decline in commercial aircraft emissions from 2019 to 2020 and their gradual recovery since is primarily due to COVID-19 impacts on scheduled passenger air travel.



Almost all of the energy consumed for transportation was supplied by petroleum-based products, with more than half being related to gasoline consumption in automobiles and other highway vehicles. Other fuel uses, especially

[21] Note that these totals include CO_2, CH_4 and N_2O emissions from some sources in the U.S. Territories (ships and boats, recreational boats, non-transportation mobile sources) and CH_4 and N_2O emissions from transportation rail electricity.

[22] Commercial aircraft consists of passenger aircraft, cargo, and other chartered flights.

diesel fuel for freight trucks and jet fuel for aircraft, accounted for the remainder. The primary driver of transportation-related emissions was CO_2 from fossil fuel combustion, which increased by 19 percent from 1990 to 2022. Annex 3.2 presents the total emissions from all transportation and mobile sources, including CO_2, N_2O, CH_4, and HFCs.

Figure 3-14: Fuels Used in Transportation Sector, On-road VMT, and Total Sector CO_2 Emissions

Notes: Distillate fuel, residual fuel, and jet fuel include adjustments for international bunker fuels. Distillate fuel and motor gasoline include adjustments for the sectoral allocation of these fuels. Other Fuels includes aviation gasoline and propane.

Source: Information on fuel consumption was obtained from EIA (2022).

Transportation Fossil Fuel Combustion CO_2 Emissions

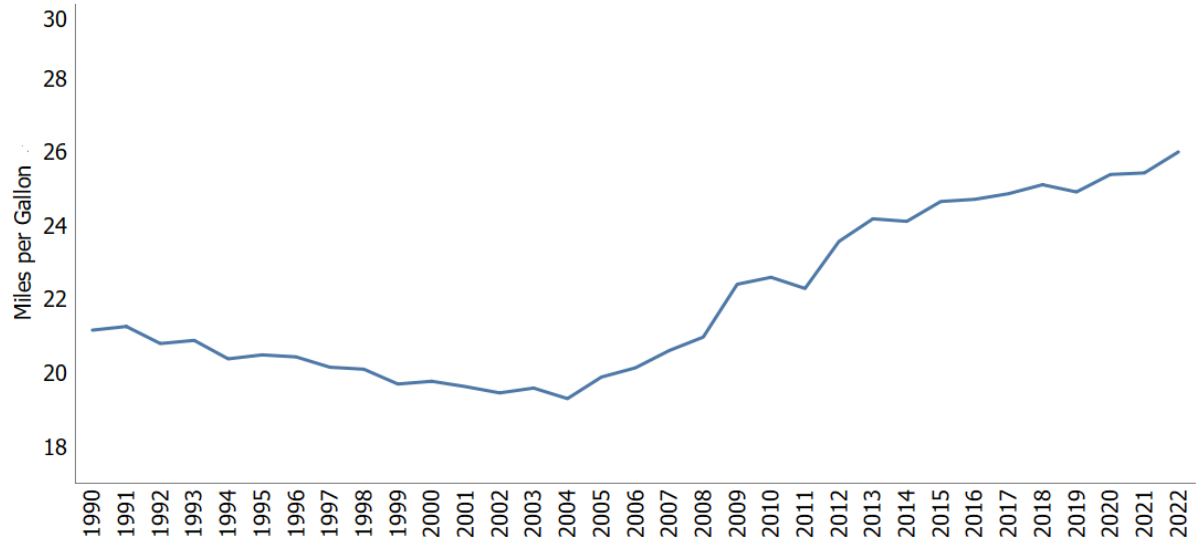
Domestic transportation CO_2 emissions increased by 19 percent (285.4 MMT CO_2 Eq.) between 1990 and 2022, an annualized increase of 0.6 percent. This includes a 24 percent increase in CO_2 emissions between 1990 and 2019, followed by a 13 percent decrease in 2020. Carbon dioxide emissions then increased by 11 percent between 2020 and 2022. Among domestic transportation sources, light-duty vehicles (including passenger cars and light-duty trucks) represented 57 percent of CO_2 emissions, medium- and heavy-duty trucks and buses 24 percent, commercial aircraft 7 percent, and other sources 11 percent. See Table 3-13 for a detailed breakdown of transportation CO_2 emissions by mode and fuel type.

Almost all of the energy consumed by the transportation sector is petroleum-based, including motor gasoline, diesel fuel, jet fuel, and residual oil. Carbon dioxide emissions from the combustion of ethanol and biodiesel for transportation purposes, along with the emissions associated with the agricultural and industrial processes involved in the production of biofuel, are captured in other *Inventory* sectors.[23] Ethanol consumption from the transportation sector has increased from 0.7 billion gallons in 1990 to 12.9 billion gallons in 2022, while biodiesel

[23] Biofuel estimates are presented in the Energy chapter for informational purposes only, in line with IPCC methodological guidance and UNFCCC reporting obligations. Net carbon fluxes from changes in biogenic carbon reservoirs in croplands are accounted for in the estimates for Land Use, Land-Use Change, and Forestry (see Chapter 6). More information and additional analyses on biofuels are available at EPA's Renewable Fuels Standards website. See https://www.epa.gov/renewable-fuel-standard-program.

consumption has increased from 0.01 billion gallons in 2001 to 1.6 billion gallons in 2022." For additional information, see Section 3.10 on biofuel consumption at the end of this chapter and Table A-74 in Annex 3.2.

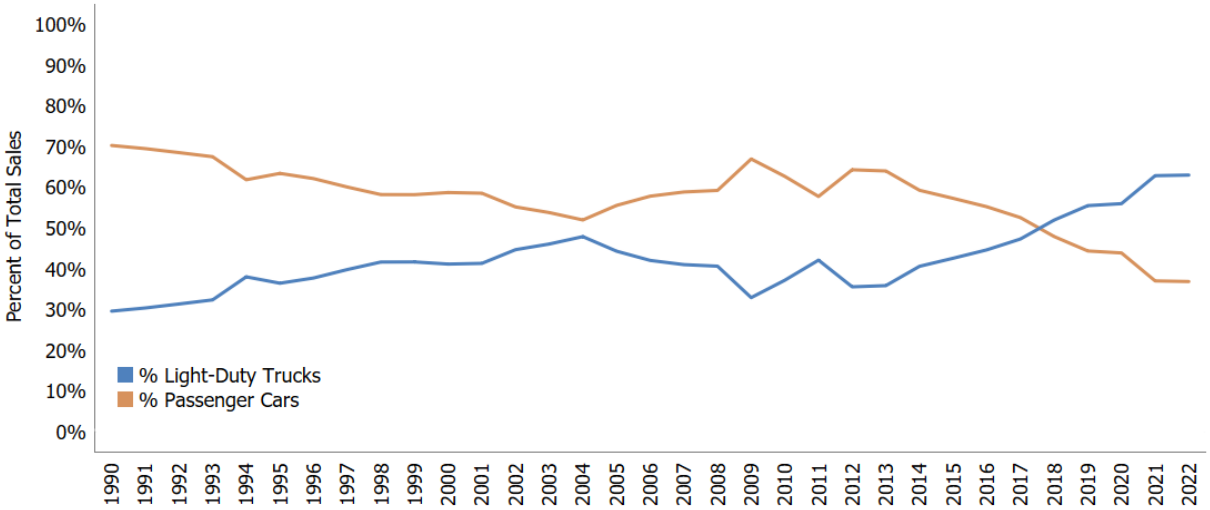
Carbon dioxide emissions from passenger cars and light-duty trucks totaled 1,005.5 MMT CO_2 in 2022, an increase of 10 percent (91.2 MMT CO_2) from 1990. The increase in CO_2 emissions from passenger cars and light-duty trucks from 1990 to 2022 was due, in large part, to increased demand for travel as fleet-wide light-duty vehicle fuel economy was relatively stable (average new vehicle fuel economy declined slowly from 1990 through 2004 and then increased more rapidly from 2005 through 2022). Carbon dioxide emissions from passenger cars and light-duty trucks peaked at 1,145.5 MMT in 2004, and since then have declined about 12 percent. The decline in new light-duty vehicle fuel economy between 1990 and 2004 (see Figure 3-15) reflects the increasing market share of light-duty trucks, which grew from about 30 percent of new vehicle sales in 1990 to 48 percent in 2004. Starting in 2005, average new vehicle fuel economy began to increase while light-duty vehicle VMT grew only modestly for much of the period. Light-duty vehicle VMT grew by less than one percent or declined each year between 2005 and 2013, and again between 2017 and 2019. VMT grew at faster rates of 1.6 percent from 2014 to 2015, and 1.6 percent from 2015-2016. From 2019 to 2020, light-duty vehicle VMT declined by 11.0 percent due to COVID-19 pandemic; from 2020 to 2022 light-duty vehicle VMT rebounded as a part of the ongoing recovery from the pandemic, increasing by 9.8 percent.



Average new vehicle fuel economy has improved almost every year since 2005 while the light-duty truck share of new vehicle sales decreased to about 33 percent of new vehicles in 2009 and has since varied from year to year between 36 and 63 percent. Since 2014, the light-duty truck share has steadily increased, reaching 62 percent of new vehicle sales in model year 2022. See Annex 3.2 for data by vehicle mode and information on VMT and the share of new vehicles (in VMT).

Medium- and heavy-duty truck CO_2 emissions increased by 73 percent from 1990 to 2022. This increase was largely due to a substantial growth in medium- and heavy-duty truck VMT, which increased by 72 percent between 1990 and 2022.

Carbon dioxide from the domestic operation of commercial aircraft increased by 18 percent (19.8 MMT CO_2) from 1990 to 2022. Across all categories of aviation, excluding international bunkers, CO_2 emissions decreased by 11 percent (20.8 MMT CO_2) between 1990 and 2022.[24] Carbon dioxide emissions from military aircraft decreased 65 percent between 1990 and 2022. Commercial aircraft CO_2 emissions increased 27 percent between 1990 and 2007, dropped 2 percent from 2007 to 2019, dropped another 33 percent from 2019 to 2020, then increased by 30 percent from 2020 to 2022. Overall, this represents a change of approximately 18 percent between 1990 and 2022. Transportation sources also produce CH_4 and N_2O; these emissions are included in Figure 3-14 and Table 3-15 and in the CH_4 and N_2O from Mobile Combustion section. Annex 3.2 presents total emissions from all transportation and mobile sources, including CO_2, CH_4, N_2O, and HFCs.



[24] Includes consumption of jet fuel and aviation gasoline. Does not include aircraft bunkers, which are not included in national emission totals, in line with IPCC methodological guidance and UNFCCC reporting obligations.

+ Does not exceed 0.05 MMT CO_2 Eq.

[a] On-road fuel consumption data from FHWA Table MF-21 and MF-27 were used to determine total on-road use of motor gasoline and diesel fuel (FHWA 1996 through 2023). Ratios developed from MOVES3 output are used to apportion FHWA fuel consumption data to vehicle type and fuel type (see Annex 3.2 for information about the MOVES model).

[b] Includes medium- and heavy-duty trucks over 8,500 lbs.

[c] In 2014, EPA incorporated the NONROAD2008 model into the MOVES model framework. The current *Inventory* uses the Nonroad component of MOVES3 for years 1999 through 2022. See Annex 3.2 for information about the MOVES model.

[d] Note that large year over year fluctuations in emission estimates partially reflect nature of data collection for these sources.

[e] Official estimates exclude emissions from the combustion of both aviation and marine international bunker fuels; however, estimates of international bunker fuel-related emissions are presented for informational purposes.

[f] Commercial aircraft, as modeled in FAA's Aviation Environmental Design Tool (AEDT), consists of passenger aircraft, cargo, and other chartered flights.

[g] Pipelines reflect CO_2 emissions from natural gas-powered pipelines transporting natural gas.

[h] Ethanol and biodiesel estimates are presented for informational purposes only. See Section 3.10 of this chapter and the estimates in Land Use, Land-Use Change, and Forestry (see Chapter 6), in line with IPCC methodological guidance and Paris Agreement and UNFCCC reporting obligations, for more information on ethanol and biodiesel.

[i] Transportation sector natural gas and LPG consumption are based on data from EIA (2023b). Prior to the 1990 to 2015 *Inventory*, data from DOE TEDB were used to estimate each vehicle class's share of the total natural gas and LPG consumption. Since TEDB does not include estimates for natural gas use by medium and heavy-duty trucks or LPG use by passenger cars, EIA Alternative Fuel Vehicle Data (Browning 2017) is now used to determine each vehicle class's share of the total natural gas and LPG consumption. These changes were first incorporated in the 1990 to 2016 *Inventory* and apply to the 1990 to 2022 time period.

[j] Includes emissions from rail electricity.

[k] Electricity consumption by passenger cars, light-duty trucks (SUVs), and buses is based on plug-in electric vehicle sales and engine efficiency data, as outlined in Browning (2018). In prior *Inventory* years, CO_2 emissions from electric vehicle charging were allocated to the residential and commercial sectors. They are now allocated to the transportation sector. These changes apply to the 2010 through 2022 time period.

Notes: This table does not include emissions from non-transportation mobile sources, such as agricultural equipment and construction/mining equipment; it also does not include emissions associated with electricity consumption by pipelines or lubricants used in transportation. In addition, this table does not include CO_2 emissions from U.S. Territories, since these are covered in a separate chapter of the *Inventory*. Totals may not sum due to independent rounding.

Mobile Fossil Fuel Combustion CH_4 and N_2O Emissions

Mobile combustion includes emissions of CH_4 and N_2O from all transportation sources identified in the U.S. *Inventory* with the exception of pipelines and electric locomotives;[25] mobile sources also include non-transportation sources such as construction/mining equipment, agricultural equipment, vehicles used off-road, and other sources (e.g., snowmobiles, lawnmowers, etc.).[26] Annex 3.2 includes a summary of all emissions from both transportation and mobile sources. Table 3-14 and Table 3-15 provide mobile fossil fuel CH_4 and N_2O emission estimates in MMT CO_2 Eq.[27]

Mobile combustion was responsible for a small portion of national CH_4 emissions (0.4 percent) and was the fifth largest source of national N_2O emissions (4.3 percent) in 2022. From 1990 to 2022, mobile source CH_4 emissions declined by 64 percent, to 2.6 MMT CO_2 Eq. (93 kt), due largely to emissions control technologies employed in on-road vehicles since the mid-1990s to reduce CO, NO_x, NMVOC, and CH_4 emissions. Mobile source emissions of N_2O decreased by 57 percent, to 16.7 MMT CO_2 Eq. (63 kt) in 2022. Earlier generation control technologies initially resulted in elevated N_2O emissions, causing a 31 percent increase in N_2O emissions from mobile sources between 1990 and 1997. Improvements in later-generation emission control technologies have reduced N_2O output, resulting in a 67 percent decrease in mobile source N_2O emissions from 1997 to 2022 (see Figure 3-17). Overall, CH_4 and N_2O emissions were predominantly from gasoline-fueled passenger cars, light-duty trucks, and non-highway sources. See Annex 3.2 for data by vehicle mode and information on VMT and the share of new vehicles.

[25] Emissions of CH_4 from natural gas systems are reported separately. More information on the methodology used to calculate these emissions are included in this chapter and Annex 3.4.

[26] See the methodology sub-sections of the CO_2 from Fossil Fuel Combustion and CH_4 and N_2O from Mobile Combustion sections of this chapter. Note that N_2O and CH_4 emissions are reported using different categories than CO_2. CO_2 emissions are reported by end-use sector (transportation, industrial, commercial, residential, U.S. Territories), and generally adhere to a top-down approach to estimating emissions. CO_2 emissions from non-transportation mobile sources (e.g., lawn and garden equipment, farm equipment, construction equipment) are allocated to their respective end-use sector (i.e., construction equipment CO_2 emissions are included in the Industrial end-use sector instead of the transportation end-use sector). CH_4 and N_2O emissions are reported using the "mobile combustion" category, which includes non-transportation mobile sources. CH_4 and N_2O emission estimates are bottom-up estimates, based on total activity (fuel use, VMT) and emissions factors by source and technology type. These reporting schemes are in accordance with IPCC guidance. For informational purposes only, CO_2 emissions from non-transportation mobile sources are presented separately from their overall end-use sector in Annex 3.2.

[27] See Annex 3.2 for a complete time series of emission estimates for 1990 through 2022.

Figure 3-17: Mobile Source CH_4 and N_2O Emissions

Note: Totals may not sum due to independent rounding.

CO_2 from Fossil Fuel Combustion

Methodology and Time-Series Consistency

CO_2 emissions from fossil fuel combustion are estimated in line with a Tier 2 method described by the IPCC in the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (IPCC 2006) Chapter 2, Figure 2.1 decision tree and

available data on energy use and country specific fuel carbon contents with some exceptions as discussed below.[28] A detailed description of the U.S. methodology is presented in Annex 2.1, and is characterized by the following steps:

1. *Determine total fuel consumption by fuel type and sector*. Total fossil fuel consumption for each year is estimated by aggregating consumption data by end-use sector (e.g., commercial, industrial), primary fuel type (e.g., coal, petroleum, gas), and secondary fuel category (e.g., motor gasoline, distillate fuel oil). Fuel consumption data for the United States were obtained directly from the EIA of the U.S. Department of Energy (DOE), primarily from the *Monthly Energy Review* (EIA 2024a). EIA data include fuel consumption statistics from the 50 U.S. states and the District of Columbia, including tribal lands. The EIA does not include territories in its national energy statistics, so fuel consumption data for territories were collected separately from EIA's International Energy Statistics (EIA 2024b).[29]

   For consistency of reporting, the IPCC has recommended that countries report energy data using the International Energy Agency (IEA) reporting convention and/or IEA data. Data in the IEA format are presented "top down"—that is, energy consumption for fuel types and categories are estimated from energy production data (accounting for imports, exports, stock changes, and losses). The resulting quantities are referred to as "apparent consumption." The data collected in the United States by EIA on an annual basis and used in this *Inventory* are predominantly from mid-stream or conversion energy consumers such as refiners and electric power generators. These annual surveys are supplemented with end-use energy consumption surveys, such as the Manufacturing Energy Consumption Survey, that are conducted on a periodic basis (every four years). These consumption datasets help inform the annual surveys to arrive at the national total and sectoral breakdowns for that total.[30]

   Also, note that U.S. fossil fuel energy statistics are generally presented using gross calorific values (GCV) (i.e., higher heating values). Fuel consumption activity data presented here have not been adjusted to correspond to international standards, which are to report energy statistics in terms of net calorific values (NCV) (i.e., lower heating values).[31]

2. *Subtract uses accounted for in the Industrial Processes and Product Use chapter*. Portions of the fuel consumption data for seven fuel categories—coking coal, distillate fuel, industrial other coal, petroleum coke, natural gas, residual fuel oil, and other oil—were reallocated to the Industrial Processes and Product Use chapter, as they were consumed during non-energy-related industrial activity. To make these adjustments, additional data were collected from AISI (2004 through 2021), Coffeyville (2012), U.S. Census Bureau (2001 through 2011), EIA (2024a, 2023c, 2023d), USAA (2008 through 2021), USGS (1991 through 2020), (USGS 2019), USGS (2014 through 2021a), USGS (2014 through 2021b), USGS (1995 through 2013), USGS (1995, 1998, 2000, 2001, 2002, 2007), USGS (2021a), USGS (1991 through 2015a), USGS (1991 through 2020), USGS (2014 through 2021a), USGS (1991 through 2015b), USGS (2021b), USGS (1991 through 2020).[32]

3. *Adjust for biofuels and petroleum denaturant*. Fossil fuel consumption estimates are adjusted downward to exclude fuels with biogenic origins and avoid double counting in petroleum data statistics. Carbon

[28] The IPCC Tier 3B methodology is used for estimating emissions from commercial aircraft.

[29] Fuel consumption by U.S. Territories (i.e., American Samoa, Guam, Puerto Rico, U.S. Virgin Islands, Wake Island, and other U.S. Pacific Islands) is included in this report and contributed total emissions of 22.6 MMT CO_2 Eq. in 2022.

[30] See IPCC Reference Approach for Estimating CO_2 Emissions from Fossil Fuel Combustion in Annex 4 for a comparison of U.S. estimates using top-down and bottom-up approaches.

[31] A crude convention to convert between gross and net calorific values is to multiply the heat content of solid and liquid fossil fuels by 0.95 and gaseous fuels by 0.9 to account for the water content of the fuels. Biomass-based fuels in U.S. energy statistics, however, are generally presented using net calorific values.

[32] See sections on Iron and Steel Production and Metallurgical Coke Production, Ammonia Production and Urea Consumption, Petrochemical Production, Titanium Dioxide Production, Ferroalloy Production, Aluminum Production, and Silicon Carbide Production and Consumption in the Industrial Processes and Product Use chapter.

dioxide emissions from ethanol added to motor gasoline and biodiesel added to diesel fuel are not included specifically in summing energy sector totals. Net carbon fluxes from changes in biogenic carbon reservoirs are accounted for in the estimates for LULUCF, therefore, fuel consumption estimates are adjusted to remove ethanol and biodiesel.[33] For the years 1993 through 2008, petroleum denaturant is currently included in EIA statistics for both natural gasoline and finished motor gasoline. To avoid double counting, petroleum denaturant is subtracted from finished motor gasoline for these years.[34]

4. *Adjust for exports of CO_2.* Since October 2000, the Dakota Gasification Plant has been exporting CO_2 produced in the coal gasification process to Canada by pipeline. Because this CO_2 is not emitted to the atmosphere in the United States, the associated fossil fuel (lignite coal) that is gasified to create the exported CO_2 is subtracted from EIA (2023d) coal consumption statistics that are used to calculate greenhouse gas emissions from the Energy Sector. The associated fossil fuel is the total fossil fuel burned at the plant with the CO_2 capture system multiplied by the fraction of the plant's total site-generated CO_2 that is recovered by the capture system. To make these adjustments, data for CO_2 exports were collected from Environment and Climate Change Canada (2022). A discussion of the methodology used to estimate the amount of CO_2 captured and exported by pipeline is presented in Annex 2.1.

5. *Adjust sectoral allocation of distillate fuel oil and motor gasoline.* EPA conducted a separate bottom-up analysis of transportation fuel consumption based on data from the Federal Highway Administration that indicated that the amount of distillate and motor gasoline consumption allocated to the transportation sector in the EIA statistics should be adjusted. Therefore, for these estimates, the transportation sector's distillate fuel and motor gasoline consumption were adjusted to match the value obtained from the bottom-up analysis. As the total distillate and motor gasoline consumption estimate from EIA are considered to be accurate at the national level, the distillate and motor gasoline consumption totals for the residential, commercial, and industrial sectors were adjusted proportionately. The data sources used in the bottom-up analysis of transportation fuel consumption include AAR (2008 through 2022), Benson (2002 through 2004), DOE (1993 through 2020), EIA (2007), EIA (2024a), EPA (2022), and FHWA (1996 through 2023).[35]

6. *Adjust for fuels consumed for non-energy uses*. U.S. aggregate energy statistics include consumption of fossil fuels for non-energy purposes. These are fossil fuels that are manufactured into plastics, asphalt, lubricants, or other products. Depending on the end-use, this can result in storage of some or all of the carbon contained in the fuel for a period of time. As the emission pathways of carbon used for non-energy purposes are vastly different than fuel combustion (since the carbon in these fuels ends up in products instead of being combusted), these emissions are estimated separately in Section3.2. Therefore, the amount of fuels used for non-energy purposes was subtracted from total fuel consumption. Data on non-fuel consumption were provided by EIA (2023c).

7. *Subtract consumption of international bunker fuels.* According to the Paris Agreement and UNFCCC reporting guidelines emissions from international transport activities, or bunker fuels, should not be included in national totals. U.S. energy consumption statistics include these bunker fuels (e.g., distillate fuel oil, residual fuel oil, and jet fuel) as part of consumption by the transportation end-use sector, however, so emissions from international transport activities were calculated separately following the same procedures used to calculate emissions from consumption of all fossil fuels (i.e., estimation of consumption, and determination of carbon content).[36] The Office of the Under Secretary of Defense (Installations and Environment) and the Defense Logistics Agency Energy (DLA Energy) of the U.S. Department of Defense (DoD) (DLA Energy 2022) supplied data on military jet fuel and marine fuel use.

---

[33] Natural gas energy statistics from EIA (2023a) are already adjusted downward to account for biogas in natural gas.

[34] These adjustments are explained in greater detail in Annex 2.1.

[35] Bottom-up gasoline and diesel highway vehicle fuel consumption estimates are based on data from FHWA Highway Statistics Table MF-21, MF-27, and VM-1 (FHWA 1996 through 2021).

[36] See International Bunker Fuels section in this chapter for a more detailed discussion.

Commercial jet fuel use was estimated based on data from FAA (2024) and DOT (1991 through 2022); residual and distillate fuel use for civilian marine bunkers was obtained from DOC (1991 through 2022) for 1990 through 2001 and 2007 through 2020, and DHS (2008) for 2003 through 2006.[37] Consumption of these fuels was subtracted from the corresponding fuels totals in the transportation end-use sector. Estimates of international bunker fuel emissions for the United States are discussed in detail in Section 3.9.

8. *Determine the total carbon content of fuels consumed.* Total carbon was estimated by multiplying the amount of fuel consumed by the amount of carbon in each fuel. This total carbon estimate defines the maximum amount of carbon that could potentially be released to the atmosphere if all of the carbon in each fuel was converted to CO_2. A discussion of the methodology and sources used to develop the carbon content coefficients are presented in Annexes 2.1 and 2.2.

9. *Estimate CO_2 Emissions.* Total CO_2 emissions are the product of the adjusted energy consumption (from the previous methodology steps 1 through 7), the carbon content of the fuels consumed, and the fraction of carbon that is oxidized. The fraction oxidized was assumed to be 100 percent for petroleum, coal, and natural gas based on guidance in IPCC (2006) (see Annex 2.1). Carbon emissions were multiplied by the molecular-to-atomic weight ratio of CO_2 to carbon (44/12) to obtain total CO_2 emitted from fossil fuel combustion in million metric tons (MMT).

10. *Allocate transportation emissions by vehicle type.* This report provides a more detailed accounting of emissions from transportation because it is such a large consumer of fossil fuels in the United States. For fuel types other than jet fuel, fuel consumption data by vehicle type and transportation mode were used to allocate emissions by fuel type calculated for the transportation end-use sector. Heat contents and densities were obtained from EIA (2023c) and USAF (1998).[38]

    - For on-road vehicles, annual estimates of combined motor gasoline and diesel fuel consumption by vehicle category were obtained from FHWA (1996 through 2023); for each vehicle category, the percent gasoline, diesel, and other (e.g., CNG, LPG) fuel consumption are estimated using data from EPA's MOVES model and DOE (1993 through 2022).[39,40]

    - For non-road vehicles, activity data were obtained from AAR (2008 through 2022), APTA (2007 through 2022), APTA (2006), BEA (1991 through 2015), Benson (2002 through 2004), BTS (2019 through 2022), DLA Energy (2022), DOC (1991 through 2022), DOE (1993 through 2022), DOT (1991 through 2022), EIA (2009a), EIA (2023a), EIA (2002), EIA (1991 through 2022), EPA (2022),[41] and Gaffney (2007).

[37] Data for 2002 were interpolated due to inconsistencies in reported fuel consumption data.

[38] For a more detailed description of the data sources used for the analysis of the transportation end use sector see the Mobile Combustion (excluding CO_2) and International Bunker Fuels sections of the Energy chapter, Annex 3.2, and Annex 3.8, respectively.

[39] On-road fuel consumption data from FHWA Table MF-21 and MF-27 were used to determine total on-road use of motor gasoline and diesel fuel (FHWA 1996 through 2020). Data for 2021 is proxied using FHWA Traffic Volume Travel Trends. Ratios developed from MOVES3 output are used to apportion FHWA fuel consumption data to vehicle type and fuel type (see Annex 3.2 for information about the MOVES model).

[40] Transportation sector natural gas and LPG consumption are based on data from EIA (2024a). In previous Inventory years, data from DOE (1993 through 2022) TEDB was used to estimate each vehicle class's share of the total natural gas and LPG consumption. Since TEDB does not include estimates for natural gas use by medium- and heavy-duty trucks or LPG use by passenger cars, EIA Alternative Fuel Vehicle Data (Browning 2017) is now used to determine each vehicle class's share of the total natural gas and LPG consumption. These changes were first incorporated in the 1990 through 2015 Inventory and apply to the time period from 1990 to 2015.

[41] In 2014, EPA incorporated the NONROAD2008 model into the MOVES model framework (EPA 2022b). The current *Inventory* uses the Nonroad component of MOVES3 for years 1999 through 2022.

- For jet fuel used by aircraft, CO_2 emissions from commercial aircraft were developed by the U.S. Federal Aviation Administration (FAA) using a Tier 3B methodology, consistent IPCC (2006) (see Annex 3.3). Carbon dioxide emissions from other aircraft were calculated directly based on reported consumption of fuel as reported by EIA. Allocation to domestic military uses was made using DoD data (see Annex 3.8). General aviation jet fuel consumption is calculated as the remainder of total jet fuel use (as determined by EIA) nets all other jet fuel use as determined by FAA and DoD. For more information, see Annex 3.2.

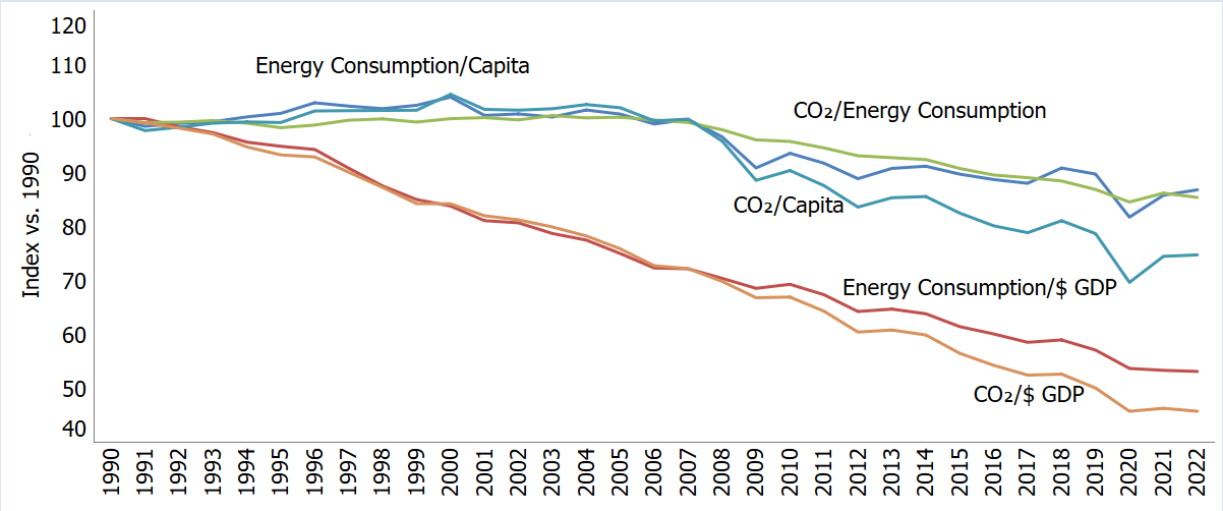
Methodological recalculations were applied to the entire time series to ensure time-series consistency from 1990 through 2022. Due to data availability and sources, some adjustments outlined in the methodology above are not applied consistently across the full 1990 to 2022 time series. As described in greater detail in Annex 2.1, to align with EIA's methodology for calculating motor gasoline consumption, petroleum denaturant adjustments are applied to motor gasoline consumption only for the period 1993 through 2008. In addition to ensuring time-series consistency, to ensure consistency in reporting between the *Inventory* and the Canadian National Greenhouse Gas Inventory, the amount of associated fossil fuel (lignite coal) that is gasified to create the exported CO_2 from the Dakota Gasification Plant is adjusted to align with the Canadian National Greenhouse Gas Inventory (Environment and Climate Change Canada 2022). This adjustment is explained in greater detail in Annex 2.1. As discussed in Annex 5, data are unavailable to include estimates of CO_2 emissions from any liquid fuel used in pipeline transport or non-hazardous industrial waste incineration, but those emissions are assumed to be insignificant.

Box 3-4: Carbon Intensity of U.S. Energy Consumption

The amount of carbon emitted from the combustion of fossil fuels is dependent upon the carbon content of the fuel and the fraction of that carbon that is oxidized. Fossil fuels vary in their average carbon content, ranging from about 53 MMT CO_2 Eq./QBtu for natural gas to upwards of 95 MMT CO_2 Eq./QBtu for coal and petroleum coke (see Tables A-42 and A-43 in Annex 2.1 for carbon contents of all fuels). In general, the carbon content per unit of energy of fossil fuels is the highest for coal products, followed by petroleum, and then natural gas. The overall carbon intensity of the U.S. economy is thus dependent upon the quantity and combination of fuels and other energy sources employed to meet demand.

Table 3-16 provides a time series of the carbon intensity of direct emissions for each sector of the U.S. economy. The time series incorporates only the energy from the direct combustion of fossil fuels in each sector. For example, the carbon intensity for the residential sector does not include the energy from or emissions related to the use of electricity for lighting, as it is instead allocated to the electric power sector. For the purposes of maintaining the focus of this section, renewable energy and nuclear energy are not included in the energy totals used in Table 3-16 in order to focus attention on fossil fuel combustion as detailed in this chapter. Looking only at this direct consumption of fossil fuels, the residential sector exhibited the lowest carbon intensity, which is related to the large percentage of its energy derived from natural gas for heating. The carbon intensity of the commercial sector has predominantly declined since 1990 as commercial businesses shift away from petroleum to natural gas. The industrial sector was more dependent on petroleum and coal than either the residential or commercial sectors, and thus had higher carbon intensities over this period. The carbon intensity of the transportation sector was closely related to the carbon content of petroleum products (e.g., motor gasoline and jet fuel, both around 70 MMT CO_2 Eq./QBtu), which were the primary sources of energy. Lastly, the electric power sector had the highest carbon intensity due to its heavy reliance on coal for generating electricity.

Table 3-16: Carbon Intensity from Direct Fossil Fuel Combustion by Sector (MMT CO_2 Eq./QBtu)



Sector	1990	2005	2018	2019	2020	2021	2022
Residential[a]	57.4	56.8	55.3	55.3	55.1	55.2	55.2
Commercial[a]	59.7	57.8	56.0	56.2	56.3	56.2	56.5
Industrial[a]	64.8	64.6	60.5	60.2	59.6	59.6	59.6
Transportation[a]	71.1	71.5	71.0	70.9	70.8	70.9	70.8
Electric Power[b]	87.3	85.8	75.5	72.9	70.5	72.4	70.9

U.S. Territories[c]	73.1	73.4	70.4	70.8	71.7	70.1	71.3
All Sectors[c]	**73.1**	**73.6**	**68.3**	**67.3**	**66.3**	**67.0**	**66.5**

[a] Does not include electricity or renewable energy consumption.
[b] Does not include electricity produced using nuclear or renewable energy.
[c] Does not include nuclear or renewable energy consumption.
Note: Excludes non-energy fuel use emissions and consumption. Totals may not sum due to independent rounding.

For the time period of 1990 through about 2008, the carbon intensity of U.S. energy consumption was fairly constant, as the proportion of fossil fuels used by the individual sectors did not change significantly over that time. Starting in 2008 the carbon intensity of U.S. energy consumption has decreased, reflecting the shift from coal to natural gas in the electric power sector during that time period. Per capita energy consumption fluctuated little from 1990 to 2007, but then started decreasing after 2007 and, in 2022, was approximately 13.2 percent below levels in 1990 (see Figure 3-18). To differentiate these estimates from those of Table 3-16, the carbon intensity trend shown in Figure 3-18 and described below includes nuclear and renewable energy EIA data to provide a comprehensive economy-wide picture of energy consumption. Due to a general shift from a manufacturing-based economy to a service-based economy, as well as overall increases in efficiency, energy consumption and energy-related CO_2 emissions per dollar of gross domestic product (GDP) have both declined since 1990 (BEA 2024).

Figure 3-18: U.S. Energy Consumption and Energy-Related CO_2 Emissions Per Capita and Per Dollar GDP

Carbon intensity estimates were developed using nuclear and renewable energy data from EIA (2023c), EPA (2010), and fossil fuel consumption data as discussed above and presented in Annex 2.1.

Uncertainty

For estimates of CO_2 from fossil fuel combustion, the amount of CO_2 emitted is directly related to the amount of fuel consumed, the fraction of the fuel that is oxidized, and the carbon content of the fuel. Therefore, a careful accounting of fossil fuel consumption by fuel type, average carbon contents of fossil fuels consumed, and production of fossil fuel-based products with long-term carbon storage should yield an accurate estimate of CO_2 emissions.

Nevertheless, there are uncertainties in the consumption data, carbon content of fuels and products, and carbon oxidation efficiencies. For example, given the same primary fuel type (e.g., coal, petroleum, or natural gas), the

amount of carbon contained in the fuel per unit of useful energy can vary. For the United States, however, the impact of these uncertainties on overall CO_2 emission estimates is believed to be relatively small. See, for example, Marland and Pippin (1990). See also Annex 2.2 for a discussion of uncertainties associated with fuel carbon contents. Recent updates to carbon factors for natural gas and coal utilized the same approach as previous Inventories with updated recent data, therefore, the uncertainty estimates around carbon contents of the different fuels as outlined in Annex 2.2 were not impacted and the historic uncertainty ranges still apply.

Although national statistics of total fossil fuel and other energy consumption are relatively accurate, the allocation of this consumption to individual end-use sectors (i.e., residential, commercial, industrial, and transportation) is less certain. For example, for some fuels the sectoral allocations are based on price rates (i.e., tariffs), but a commercial establishment may be able to negotiate an industrial rate or a small industrial establishment may end up paying an industrial rate, leading to a misallocation of emissions. Also, the deregulation of the natural gas industry and the more recent deregulation of the electric power industry have likely led to some minor challenges in collecting accurate energy statistics as firms in these industries have undergone significant restructuring.

To calculate the total CO_2 emission estimate from energy-related fossil fuel combustion, the amount of fuel used in non-energy production processes were subtracted from the total fossil fuel consumption. The amount of CO_2 emissions resulting from non-energy related fossil fuel use has been calculated separately and reported in the Carbon Emitted from Non-Energy Uses of Fossil Fuels section of this report (Section 3.2). These factors all contribute to the uncertainty in the CO_2 estimates. Detailed discussions on the uncertainties associated with carbon emitted from non-energy uses of fossil fuels can be found within that section of this chapter.

Various sources of uncertainty surround the estimation of emissions from international bunker fuels, which are subtracted from the U.S. totals (see the detailed discussions on these uncertainties provided in Section 3.9). Another source of uncertainty is fuel consumption by U.S. Territories. The United States does not collect energy statistics for its territories at the same level of detail as for the fifty states and the District of Columbia. Therefore, estimating both emissions and bunker fuel consumption by these territories is difficult.

Uncertainties in the emission estimates presented above also result from the data used to allocate CO_2 emissions from the transportation end-use sector to individual vehicle types and transport modes. In many cases, bottom-up estimates of fuel consumption by vehicle type do not match aggregate fuel-type estimates from EIA. Further research is planned to improve the allocation into detailed transportation end-use sector emissions.

The uncertainty analysis was performed by primary fuel type for each end-use sector, using the IPCC-recommended Approach 2 uncertainty estimation methodology, Monte Carlo stochastic simulation technique, with @RISK software. For this uncertainty estimation, the inventory estimation model for CO_2 from fossil fuel combustion was integrated with the relevant variables from the inventory estimation model for International Bunker Fuels, to realistically characterize the interaction (or endogenous correlation) between the variables of these two models. About 170 input variables were modeled for CO_2 from energy-related fossil fuel combustion (including about 20 for non-energy fuel consumption and about 20 for International Bunker Fuels).

In developing the uncertainty estimation model, uniform distributions were assumed for all activity-related input variables and emission factors, based on the SAIC/EIA (2001) report.[42] Triangular distributions were assigned for the oxidization factors (or combustion efficiencies). The uncertainty ranges were assigned to the input variables based on the data reported in SAIC/EIA (2001) and on conversations with various agency personnel.[43]

---

[42] SAIC/EIA (2001) characterizes the underlying probability density function for the input variables as a combination of uniform and normal distributions (the former to represent the bias component and the latter to represent the random component). However, for purposes of the current uncertainty analysis, it was determined that uniform distribution was more appropriate to characterize the probability density function underlying each of these variables.

[43] In the SAIC/EIA (2001) report, the quantitative uncertainty estimates were developed for each of the three major fossil fuels used within each end-use sector; the variations within the sub-fuel types within each end-use sector were not modeled. However, for purposes of assigning uncertainty estimates to the sub-fuel type categories within each end-use sector in the current uncertainty analysis, SAIC/EIA (2001)-reported uncertainty estimates were extrapolated.

The uncertainty ranges for the activity-related input variables were typically asymmetric around their inventory estimates; the uncertainty ranges for the emissions factors were symmetric. Bias (or systematic uncertainties) associated with these variables accounted for much of the uncertainties associated with these variables (SAIC/EIA 2001).[44] For purposes of this uncertainty analysis, each input variable was simulated 10,000 times through Monte Carlo sampling.

The results of the Approach 2 quantitative uncertainty analysis are summarized in Table 3-17. Fossil fuel combustion CO_2 emissions in 2022 were estimated to be between 4,603.1 and 4,905.2 MMT CO_2 Eq. at a 95 percent confidence level. This indicates a range of 2 percent below to 4 percent above the 2022 emission estimate of 4,699.4 MMT CO_2 Eq.

Table 3-17: Approach 2 Quantitative Uncertainty Estimates for CO_2 Emissions from Energy-Related Fossil Fuel Combustion by Fuel Type and Sector (MMT CO_2 Eq. and Percent)

Fuel/Sector	2022 Emission Estimate (MMT CO_2 Eq.)	Uncertainty Range Relative to Emission Estimate[a] (MMT CO_2 Eq.)		Uncertainty Range Relative to Emission Estimate[a] (%)

NO (Not Occurring)

[a] Range of emission estimates predicted by Monte Carlo stochastic simulation for a 95 percent confidence interval.

[b] The low and high estimates for total emissions were calculated separately through simulations and, hence, the low and high emission estimates for the sub-source categories do not sum to total emissions.

Note: Totals may not sum due to independent rounding.

[44] Although, in general, random uncertainties are the main focus of statistical uncertainty analysis, when the uncertainty estimates are elicited from experts, their estimates include both random and systematic uncertainties. Hence, both these types of uncertainties are represented in this uncertainty analysis.

QA/QC and Verification

In order to ensure the quality of the CO_2 emission estimates from fossil fuel combustion, general (IPCC Tier 1) and category-specific (Tier 2) Quality Assurance/Quality Control (QA/QC) procedures were implemented consistent with the U.S. Inventory QA/QC plan outlined in Annex 8. The Tier 2 procedures that were implemented involved checks specifically focusing on the activity data and methodology used for estimating CO_2 emissions from fossil fuel combustion in the United States. Emission totals for the different sectors and fuels were compared and trends were investigated to determine whether any corrective actions were needed. Minor corrective actions were taken.

One area of QA/QC and verification is to compare the estimates and emission factors used in the *Inventory* with other sources of CO_2 emissions reporting. Two main areas and sources of data were considered. The first is a comparison with the EPA GHGRP combustion data (Subpart C) for stationary combustion sources excluding the electric power sector. This mainly focused on considering carbon factors for natural gas. The second comparison is with the EPA Air Markets Program data for electric power production. This considered carbon factors for coal and natural gas used in electric power production.

The EPA GHGRP collects greenhouse gas emissions data from large emitters including information on fuel combustion. This excludes emissions from mobile sources and smaller residential and commercial sources, those emissions are covered under supplier reporting (Subparts MM and NN) and are areas for further research. Fuel combustion CO_2 data reported in 2022 was 2,082.6 MMT CO_2. Of that, 1,577.7 MMT CO_2 was from electricity production. Therefore, the non-electric power production fuel combustion reporting was a fraction of the total covered by the *Inventory* under fossil fuel combustion. Furthermore, reporters under the GHGRP can use multiple methods of calculating emissions; one method is to use the default emission factors provided in the rule, while another is based on a tier 3 approach using their own defined emission factors. Based on data from reporters on approach used, it was determined that only about 10 percent of natural gas combustion emissions were based on a tier 3 approach. Given the small sample size compared to the overall *Inventory* calculations for natural gas combustion EPA determined it was not reasonable to consider the GHGRP tier 3 natural gas factors at this time. A more detailed analysis was done on upstream oil and gas natural gas combustion emissions using the GHGRP data as discussed in Annex 2.2.

EPA collects detailed sulfur dioxide (SO_2), nitrogen oxides (NO_X), and carbon dioxide (CO_2) emissions data and other information from power plants across the country as part of the Acid Rain Program (ARP), the Cross-State Air Pollution Rule (CSAPR), the CSAPR Update, and the Revised CSAPR Update (RCU). The CO_2 data from these Air Market Programs (AMP) can be compared to the electric power sector emissions calculated from the *Inventory* as shown in Table 3-18 for the three most recent years of data.

Table 3-18: Comparison of Electric Power Sector Emissions (MMT CO_2 Eq. and Percent)

Fuel/Sector	CO_2 Emissions (MMT CO_2 Eq.)			% Change	
	2020	2021	2022	20-21	21-22
Inventory Electric Power Sector	**1,439.6**	**1,540.9**	**1,531.7**	**7.0%**	**-0.6%**
Coal	788.2	910.1	851.5	15.5%	-6.4%
Natural Gas	634.8	612.8	659.3	-3.5%	7.6%
Petroleum	16.2	17.7	20.5	9.6%	15.9%
AMP Electric Power Sector	**1,430.8**	**1,531.7**	**1,520.1**	**7.1%**	**-0.8%**
Coal	792.7	913.4	858.5	15.2%	-6.0%
Natural Gas	629.4	609.6	652.7	-3.1%	7.1%
Petroleum	8.8	8.7	8.9	-0.8%	2.7%

Note: Totals may not sum due to independent rounding.

In general the emissions and trends from the two sources line up well. There are differences expected based on coverage and scope of each source. The *Inventory* covers all emissions from the electric power sector as defined above. The EPA AMP data covers emissions from electricity generating units of a certain size so in some respects it could cover more sources (like electric power units at industrial facilities that would be covered under the industrial sector in the *Inventory*) and not as many sources (since smaller units are excluded). The EPA AMP data also includes heat input for different fuel types. That data can be combined with emissions to calculate implied

emission factors.[45] The following Table 3-19 shows the implied emissions factors for coal and natural gas from the EPA AMP data compared to the factors used in the *Inventory* for the three most recent years of data.

Table 3-19: Comparison of Emissions Factors (MMT Carbon/QBtu)

Fuel Type	2020	2021	2022
EPA AMP			
Coal	25.67	25.66	25.53
Natural Gas	14.56	14.60	14.61
EPA Inventory			
Electric Power Coal	26.12	26.13	26.13
Natural Gas	14.43	14.43	14.43

The factors for natural gas line up reasonably well, the EPA factors are roughly 1 percent lower than those calculated from the EPA AMP data. For coal the EPA emissions factors are roughly 2 percent higher than those calculated from the EPA AMP data. One possible reason for the difference is that the EPA *Inventory* factors are based on all coal used in electric power production while the factors from the EPA AMP data are based on units where coal is the source of fuel used. There are units that use coal and other fuel sources but emissions for each fuel type could not be calculated. This is an area of further research but given current data available the approach to develop carbon factors as outlined in Annex 2 is still felt to be the most appropriate to represent total fuel combustion in the United States.

The Paris Agreement and the UNFCCC reporting guidelines also require countries to complete a "top-down" reference approach for estimating CO_2 emissions from fossil fuel combustion in addition to their "bottom-up" sectoral methodology. The reference approach (detailed in Annex 4) uses alternative methodologies and different data sources than those contained in this section of the report. The reference approach estimates fossil fuel consumption by adjusting national aggregate fuel production data for imports, exports, and stock changes rather than relying on end-user consumption surveys. The reference approach assumes that once carbon-based fuels are brought into a national economy, they are either saved in some way (e.g., stored in products, kept in fuel stocks, or left unoxidized in ash) or combusted, and therefore the carbon in them is oxidized and released into the atmosphere. In the reference approach, accounting for actual consumption of fuels at the sectoral or sub-national level is not required. One difference between the two approaches is that emissions from carbon that was not stored during non-energy use of fuels are subtracted from the sectoral approach and reported separately (see Section 3.2). These emissions, however, are not subtracted in the reference approach. As a result, the reference approach emission estimates are comparable to those of the sectoral approach, with the exception that the non-energy use (NEU) source category emissions are included in the reference approach (see Annex 4 for more details).

Recalculations Discussion

EIA (2024a) updated distillate fuel oil consumed by the transportation sector for 2010 and on. This caused transportation petroleum CO_2 emissions to increase by an average annual amount of 0.2 MMT CO_2 Eq. (less than half a percent) for the years 2010 through 2021.

EIA (2024a) updated propane consumed by the industrial sector for 2010 and on, which is used to calculate HGL (Energy Use) annually variable carbon content coefficients. In addition, EIA (2023b) shifted all 2022 product supplied of natural gasoline and unfinished oils to crude oil transfers. This change was made to reflect that natural gasoline and unfinished oils are used as feedstocks in crude oil production instead of directly consumed as an end-use fuel. EPA made the same adjustment across the timeseries. This change impacted industrial energy

[45] These emission factors can be converted from MMT Carbon/QBtu to MMT CO_2 Eq./QBtu by multiplying the emission factor by 44/12, the molecular-to-atomic weight ratio of CO_2 to C. This would assume the fraction oxidized to be 100 percent, which is the guidance in IPCC (2006) (see Annex 2.1).

consumption across the timeseries as well as non-energy use consumption, which impacts industrial energy consumption values. This change also impacted the HGL carbon content coefficient used to calculate emissions.

To better align with EIA methodology, the non-energy use consumption of HGLs is now calculated for the entire timeseries by assuming that 100 percent of ethane, ethylene, and propylene consumption is for non-combustion use and 85 percent of normal butane, butylene, isobutane, and isobutylene is for non-combustion use. Non-energy use consumption of propane is calculated by subtracting the non-energy consumption of all other HGLs from the total non-combustion consumption of HGLs as published by the EIA. Non-energy use consumption is subtracted from energy consumption, therefore this methodology change impacts industrial petroleum consumption values. Additionally, the energy HGL carbon contents are now calculated following the above methodology and have therefore increased across the timeseries, impacting U.S. Territories petroleum and industrial petroleum CO_2 emissions.

Overall, these four updates to EIA (2024a) data and methodology caused U.S. Territories petroleum CO_2 emissions to decrease by an average annual amount of less than 0.1 MMT CO_2 Eq. (less than half a percent) for the timeseries, and industrial petroleum CO_2 emissions to increase by an average annual amount of 5.0 MMT CO_2 Eq. (1.8 percent) for the timeseries.

EPA revised its calculation of change in total energy use in the industrial sector to include renewable energy and electricity. The value previously included only fossil fuel energy consumption. Additionally, EPA revised power sector carbon intensity data to correct for an error and ensure total renewable energy consumed from EIA's *Monthly Energy Review* (EIA 2024a) was being used. There were also very minor updates associated with changes in residential and commercial petroleum use due to MER updates changes in industrial coal use due to updated data on CO_2 exports.

Overall, these changes resulted in an average annual increase of 5.8 MMT CO_2 Eq. (0.1 percent) in CO_2 emissions from fossil fuel combustion for the period 1990 through 2021, relative to the previous *Inventory*.

Planned Improvements

To reduce the uncertainty of CO_2 from fossil fuel combustion estimates for U.S. Territories, further expert elicitation may be conducted to better quantify the total uncertainty associated with emissions from U.S. Territories. Additionally, although not technically a fossil fuel, since geothermal energy-related CO_2 emissions are included for reporting purposes, further expert elicitation may be conducted to better quantify the total uncertainty associated with CO_2 emissions from geothermal energy use.

EPA will continue to examine the availability of facility-level combustion emissions through EPA's GHGRP to help better characterize the industrial sector's energy consumption in the United States and further classify total industrial sector fossil fuel combustion emissions by business establishments according to industrial economic activity type. Most methodologies used in EPA's GHGRP are consistent with IPCC methodologies, although for EPA's GHGRP, facilities collect detailed information specific to their operations according to detailed measurement standards, which may differ with the more aggregated data collected for the *Inventory* to estimate total national U.S. emissions. In addition, and unlike the reporting requirements for this chapter under the Paris Agreement and UNFCCC reporting guidelines, some facility-level fuel combustion emissions reported under the GHGRP may also include industrial process emissions.[46] In line with the Paris Agreement and UNFCCC reporting guidelines, fuel combustion emissions are included in this chapter, while process emissions are included in the Industrial Processes and Product Use chapter of this report. In examining data from EPA's GHGRP that would be useful to improve the emission estimates for the CO_2 from fossil fuel combustion category, particular attention will also be made to ensure time-series consistency, as the facility-level reporting data from EPA's GHGRP are not available for all inventory years as reported in this *Inventory*.

Additional analyses will be conducted to align reported facility-level fuel types and IPCC fuel types per the national energy statistics. For example, additional work will look at CO_2 emissions from biomass to ensure they are

[46] See https://unfccc.int/resource/docs/2013/cop19/eng/10a03.pdf#page=2.

separated in the facility-level reported data and maintaining consistency with national energy statistics provided by EIA. In implementing improvements and integration of data from EPA's GHGRP, the latest guidance from the IPCC on the use of facility-level data in national inventories will continue to be relied upon.[47]

EPA is also evaluating the methods used to adjust for conversion of fuels and exports of CO_2. EPA is exploring the approach used to account for CO_2 transport, injection, and geologic storage; as part of this there may be changes made to the accounting for CO_2 exports.

Finally, another ongoing planned improvement is to evaluate data availability to update the carbon and heat content of more fuel types accounted for in this *Inventory*. This update will impact consumption and emissions across all sectors and will improve consistency with EIA data as carbon and heat contents of fuels will be accounted for as annually variable and therefore improve accuracy across the time series. Some of the fuels considered in this effort include petroleum coke, residual fuel, and woody biomass.

CH_4 and N_2O from Stationary Combustion

Methodology and Time-Series Consistency

Methane and N_2O emissions from stationary combustion were estimated by multiplying fossil fuel and wood consumption data by emission factors (by sector and fuel type for industrial, residential, commercial, and U.S. Territories; and by fuel and technology type for the electric power sector). The electric power sector utilizes a Tier 2 methodology, whereas all other sectors utilize a Tier 1 methodology in accordance with IPCC methodological decision tree Figure 2.1 in the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (IPCC 2006) and available data. The activity data and emission factors used are described in the following subsections.

More detailed information on the methodology for calculating emissions from stationary combustion, including emission factors and activity data, is provided in Annex 3.1.

Industrial, Residential, Commercial, and U.S. Territories

National coal, natural gas, fuel oil, and wood consumption data were grouped by sector: industrial, commercial, residential, and U.S. Territories. For the CH_4 and N_2O emission estimates, consumption data for each fuel were obtained from EIA's *Monthly Energy Review* (EIA 2024a). Because the United States does not include territories in its national energy statistics, fuel consumption data for territories were provided separately by EIA's International Energy Statistics (EIA 2024b).[48] Fuel consumption for the industrial sector was adjusted to subtract out mobile source construction and agricultural use, which is reported under mobile sources. Construction and agricultural mobile source fuel use was obtained from EPA (2022) and FHWA (1996 through 2023). Estimates for wood biomass consumption for fuel combustion do not include municipal solid waste, tires, etc., that are reported as biomass by EIA. Non-CO_2 emissions from combustion of the biogenic portion of municipal solid waste and tires is included under waste incineration (Section 3.2). Estimates for natural gas combustion do not include biogas, and therefore non-CO_2 emissions from biogas are not included (see the Planned Improvements section, below). Tier 1 default emission factors for the industrial, commercial, and residential end-use sectors were provided by the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (IPCC 2006). U.S. Territories' emission factors were estimated using the U.S. emission factors for the primary sector in which each fuel was combusted.

Electric Power Sector

The electric power sector uses a Tier 2 emission estimation methodology as fuel consumption for the electric

[47] See http://www.ipcc-nggip.iges.or.jp/public/tb/TFI_Technical_Bulletin_1.pdf.

[48] U.S. Territories data also include combustion from mobile activities because data to allocate territories' energy use were unavailable. For this reason, CH_4 and N_2O emissions from combustion by U.S. Territories are only included in the stationary combustion totals.

power sector by control-technology type is based on EPA's Acid Rain Program Dataset (EPA 2024). Total fuel consumption in the electric power sector from EIA (2024a) was apportioned to each combustion technology type and fuel combination using a ratio of fuel consumption by technology type derived from EPA (2024) data. The combustion technology and fuel use data by facility obtained from EPA (2024) were only available from 1996 to 2022 so the consumption estimates from 1990 to 1995 were estimated by applying the 1996 consumption ratio by combustion technology type from EPA (2024) to the total EIA (2024a) consumption for each year from 1990 to 1995.

Emissions were estimated by multiplying fossil fuel and wood consumption by technology-, fuel-, and country-specific Tier 2 emission factors. The Tier 2 emission factors used are based in part on emission factors published by EPA, and EPA's Compilation of Air Pollutant Emission Factors, AP-42 (EPA 1997) for coal wall-fired boilers, residual fuel oil, diesel oil and wood boilers, natural gas-fired turbines, and combined cycle natural gas units.[49]

Methodological recalculations were applied to the entire time series to ensure time-series consistency from 1990 through 2022 as discussed below. As discussed in Annex 5, data are unavailable to include estimates of CH_4 and N_2O emissions from biomass use in Territories, but those emissions are assumed to be insignificant.

Uncertainty

Methane emission estimates from stationary sources exhibit high uncertainty, primarily due to difficulties in calculating emissions from wood combustion (i.e., fireplaces and wood stoves). The estimates of CH_4 and N_2O emissions presented are based on broad indicators of emissions (i.e., fuel use multiplied by an aggregate emission factor for different sectors), rather than specific emission processes (i.e., by combustion technology and type of emission control).

An uncertainty analysis was performed by primary fuel type for each end-use sector, using the IPCC-recommended Approach 2 uncertainty estimation methodology, Monte Carlo stochastic simulation technique, with @RISK software.

The uncertainty estimation model for this source category was developed by integrating the CH_4 and N_2O stationary source inventory estimation models with the model for CO_2 from fossil fuel combustion to realistically characterize the interaction (or endogenous correlation) between the variables of these three models. About 55 input variables were simulated for the uncertainty analysis of this source category (about 20 from the CO_2 emissions from fossil fuel combustion inventory estimation model and about 35 from the stationary source inventory models).

In developing the uncertainty estimation model, uniform distribution was assumed for all activity-related input variables and N_2O emission factors, based on the SAIC/EIA (2001) report.[50] For these variables, the uncertainty ranges were assigned to the input variables based on the data reported in SAIC/EIA (2001).[51] However, the CH_4 emission factors differ from those used by EIA. These factors and uncertainty ranges are based on IPCC default uncertainty estimates (IPCC 2006).

[49] Several of the U.S. Tier 2 emission factors were used in IPCC (2006) as Tier 1 emission factors. See Table A-67 in Annex 3.1 for emission factors by technology type and fuel type for the electric power sector.

[50] SAIC/EIA (2001) characterizes the underlying probability density function for the input variables as a combination of uniform and normal distributions (the former distribution to represent the bias component and the latter to represent the random component). However, for purposes of the current uncertainty analysis, it was determined that uniform distribution was more appropriate to characterize the probability density function underlying each of these variables.

[51] In the SAIC/EIA (2001) report, the quantitative uncertainty estimates were developed for each of the three major fossil fuels used within each end-use sector; the variations within the sub-fuel types within each end-use sector were not modeled. However, for purposes of assigning uncertainty estimates to the sub-fuel type categories within each end-use sector in the current uncertainty analysis, SAIC/EIA (2001)-reported uncertainty estimates were extrapolated.

The results of the Approach 2 quantitative uncertainty analysis are summarized in Table 3-20. Stationary combustion CH_4 emissions in 2022 (including biomass) were estimated to be between 5.9 and 19.1 MMT CO_2 Eq. at a 95 percent confidence level. This indicates a range of 31 percent below to 122 percent above the 2022 emission estimate of 8.6 MMT CO_2 Eq.[52] Stationary combustion N_2O emissions in 2022 (including biomass) were estimated to be between 16.5 and 33.4 MMT CO_2 Eq. at a 95 percent confidence level. This indicates a range of 33 percent below to 35 percent above the 2022 emission estimate of 24.7 MMT CO_2 Eq.

Table 3-20: Approach 2 Quantitative Uncertainty Estimates for CH_4 and N_2O Emissions from Energy-Related Stationary Combustion, Including Biomass (MMT CO_2 Eq. and Percent)

Source	Gas	2022 Emission Estimate (MMT CO_2 Eq.)	Uncertainty Range Relative to Emission Estimate[a] (MMT CO_2 Eq.)		(%)	
			Lower Bound	Upper Bound	Lower Bound	Upper Bound
Stationary Combustion	CH_4	8.6	5.9	19.1	-31%	122%
Stationary Combustion	N_2O	24.7	16.5	33.4	-33%	35%

[a] Range of emission estimates predicted by Monte Carlo stochastic simulation for a 95 percent confidence interval.

The uncertainties associated with the emission estimates of CH_4 and N_2O are greater than those associated with estimates of CO_2 from fossil fuel combustion, which mainly rely on the carbon content of the fuel combusted. Uncertainties in both CH_4 and N_2O estimates are due to the fact that emissions are estimated based on emission factors representing only a limited subset of combustion conditions. For the indirect greenhouse gases, uncertainties are partly due to assumptions concerning combustion technology types, age of equipment, emission factors used, and activity data projections.

QA/QC and Verification

In order to ensure the quality of the non-CO_2 emission estimates from stationary combustion, general (IPCC Tier 1) and category-specific (Tier 2) Quality Assurance/Quality Control (QA/QC) procedures were implemented consistent with the U.S. Inventory QA/QC plan outlined in Annex 8. The Tier 2 procedures that were implemented involved checks specifically focusing on the activity data and emission factor sources and methodology used for estimating CH_4, N_2O, and the greenhouse gas precursors from stationary combustion in the United States. Emission totals for the different sectors and fuels were compared and trends were investigated.

Recalculations Discussion

EIA (2024a) updated industrial HGL statistics, which caused CH_4 and N_2O emissions from industrial fuel oil to decrease slightly for the years 2010 through 2021.

In addition, EIA (2023b) shifted all 2022 product supplied of natural gasoline and unfinished oils to crude oil transfers. This change was made to reflect the fact that these fuels are used as feedstocks in crude oil production instead of directly consumed as end-use fuels. EPA made the change across the time series. This change impacted energy consumption across the timeseries as well as non-energy use consumption, which impacts energy consumption values.

To better align with EIA methodology, the non-energy use consumption of HGLs is now calculated for the entire timeseries by assuming that 100 percent of ethane, ethylene, and propylene consumption is for non-combustion use and 85 percent of normal butane, butylene, isobutane, and isobutylene is for non-combustion use. Non-energy use consumption of propane is calculated by subtracting the non-energy consumption of all other HGLs from the

[52] The low emission estimates reported in this section have been rounded down to the nearest integer values and the high emission estimates have been rounded up to the nearest integer values.

total non-combustion consumption of HGLs as published by the EIA. Non-energy use consumption is subtracted from energy consumption, therefore this methodology change impacts industrial fuel oil consumption values.

Other small updates included changes in residential and commercial/institutional fuel oil are use and changes in industrial coal due to updated CO_2 export data.

Overall, these updates to EIA data and methodology (2024a) caused CH_4 and N_2O emissions from industrial fuel oil to increase by an average annual amount of 0.01 MMT CO_2 Eq. and 0.01 MMT CO_2 Eq. (3 percent and 3 percent), respectively, for the time series. EIA (2024a) updated 2020 and 2021 wood energy consumed by the residential sector due to new underlying data collected by the Residential Energy Consumption Survey (RECS), which collects data about once every 5 years and uses Annual Energy Outlook growth rates to estimate data for other years. This caused CH_4 and N_2O emissions from residential wood consumption to decrease by 0.76 MMT CO_2 Eq. and 0.10 MMT CO_2 Eq. (22 percent and 13 percent) in 2020, respectively, and 0.94 MMT CO_2 Eq. and 0.12 MMT CO_2 Eq. (26 percent and 15 percent) in 2021, respectively.

Planned Improvements

Several items are being evaluated to improve the CH_4 and N_2O emission estimates from stationary combustion and to reduce uncertainty for U.S. Territories. Efforts will be taken to work with EIA and other agencies to improve the quality of the U.S. Territories data. Because these data are not broken out by stationary and mobile uses, further research will be aimed at trying to allocate consumption appropriately. In addition, the uncertainty of biomass emissions will be further investigated because it was expected that the exclusion of biomass from the estimates would reduce the uncertainty; and in actuality the exclusion of biomass increases the uncertainty. These improvements are not all-inclusive but are part of an ongoing analysis and efforts to continually improve these stationary combustion estimates from U.S. Territories.

Other forms of biomass-based gas consumption include biogas. As an additional planned improvement, EPA will examine EIA and GHGRP data on biogas collected and burned for energy use and determine if CH_4 and N_2O emissions from biogas can be included in future Inventories. EIA (2024a) natural gas data already deducts biogas used in the natural gas supply, so no adjustments are needed to the natural gas fuel consumption data to account for biogas.

CH_4 and N_2O from Mobile Combustion

Methodology and Time-Series Consistency

Estimates of CH_4 and N_2O emissions from mobile combustion were calculated by multiplying emission factors by measures of activity for each fuel and vehicle type (e.g., light-duty gasoline trucks). Activity data included vehicle miles traveled (VMT) for on-road vehicles and fuel consumption for non-road mobile sources. The activity data and emission factors used in the calculations are described in the subsections that follow. A complete discussion of the methodology used to estimate CH_4 and N_2O emissions from mobile combustion and the emission factors used in the calculations is provided in Annex 3.2.

On-Road Vehicles

Estimates of CH_4 and N_2O emissions from gasoline and diesel on-road vehicles are based on VMT and emission factors (in grams of CH_4 and N_2O per mile) by vehicle type, fuel type, model year, and emission control technology. Emission estimates for alternative fuel vehicles (AFVs) are based on VMT and emission factors (in grams of CH_4 and N_2O per mile) by vehicle and fuel type.[53]

[53] Alternative fuel and advanced technology vehicles are those that can operate using a motor fuel other than gasoline or diesel. This includes electric or other bi-fuel or dual-fuel vehicles that may be partially powered by gasoline or diesel.

CH_4 and N_2O emissions factors by vehicle type and emission tier for newer (starting with model year 2004) on-road gasoline vehicles were calculated by Browning (2019) from annual vehicle certification data compiled by EPA. CH_4 and N_2O emissions factors for older (model year 2003 and earlier) on-road gasoline vehicles were developed by ICF (2004). These earlier emission factors were derived from EPA, California Air Resources Board (CARB) and Environment and Climate Change Canada (ECCC) laboratory test results of different vehicle and control technology types. The EPA, CARB and ECCC tests were designed following the Federal Test Procedure (FTP). The procedure covers three separate driving segments, since vehicles emit varying amounts of greenhouse gases depending on the driving segment. These driving segments are: (1) a transient driving cycle that includes cold start and running emissions, (2) a cycle that represents running emissions only, and (3) a transient driving cycle that includes hot start and running emissions. For each test run, a bag was affixed to the tailpipe of the vehicle and the exhaust was collected; the content of this bag was then analyzed to determine quantities of gases present. The emissions characteristics of driving segment 2 tests were used to define running emissions. Running emissions were subtracted from the total FTP emissions to determine start emissions. These were then recombined to approximate average driving characteristics, based upon the ratio of start to running emissions for each vehicle class from MOBILE6.2, an EPA emission factor model that predicts grams per mile emissions of CO_2, CO, HC, NO_x, and PM from vehicles under various conditions.[54]

Diesel on-road vehicle emission factors were developed by ICF (2006). CH_4 and N_2O emissions factors for newer (starting with model year 2007) on-road diesel vehicles (those using engine aftertreatment systems) were calculated from annual vehicle certification data compiled by EPA.

CH_4 and N_2O emission factors for AFVs were developed based on the 2022 Greenhouse gases, Regulated Emissions, and Energy use in Transportation (GREET) model (ANL 2022). For light-duty trucks, EPA used travel fractions for LDT1 and LDT2 (MOVES Source Type 31 for LDT1 and MOVES Source Type 32 for LDT2; see Annex 3.2 for information about the MOVES model) to determine emission factors. For medium-duty vehicles, EPA used emission factors for light heavy-duty vocational trucks. For heavy-duty vehicles, EPA used emission factors for long-haul combination trucks. For buses, EPA used emission factors for transit buses. These values represent vehicle operations only (tank-to-wheels); upstream well-to-tank emissions are calculated elsewhere in the Inventory. Biodiesel CH_4 emission factors were corrected from GREET values to be the same as CH_4 emission factors for diesel vehicles. GREET overestimated biodiesel CH_4 emission factors based upon an incorrect CH_4-to-THC ratio for diesel vehicles with aftertreatment technology.

Annual VMT data for 1990 through 2022 were obtained from the Federal Highway Administration's (FHWA) Highway Performance Monitoring System database as reported in Highway Statistics (FHWA 1996 through 2023). VMT estimates were then allocated to vehicle type using ratios of VMT per vehicle type to total VMT, derived from EPA's MOVES3 model (see Annex 3.2 for information about the MOVES model). This corrects time series inconsistencies in FHWA definitions of vehicle types (Browning 2022a). VMT for alternative fuel vehicles (AFVs) were estimated based on Browning (2022b). The age distributions of the U.S. vehicle fleet were obtained from EPA (2004, 2022), and the average annual age-specific vehicle mileage accumulation of U.S. vehicles were obtained from EPA (2022).

Control technology and standards data for on-road vehicles were obtained from EPA's Office of Transportation and Air Quality (EPA 1998, 2022b, and 2023) and Browning (2005). These technologies and standards are defined in Annex 3.2, and were compiled from EPA (1994a, 1994b, 1998, 1999) and IPCC (2006) sources.

Non-Road Mobile Sources

The nonroad mobile category for CH_4 and N_2O includes ships and boats, aircraft, locomotives, and other mobile non-road sources (e.g., construction or agricultural equipment). For locomotives, aircraft, ships, and non-recreational boats, fuel-based emission factors are applied to data on fuel consumption, following the IPCC Tier 1 approach. The Tier 2 approach for these sources would require separate fuel-based emissions factors by

[54] Additional information regarding the MOBILE model can be found at https://www.epa.gov/moves/description-and-history-mobile-highway-vehicle-emission-factor-model.

technology, for which data are not currently available. For other non-road sources, EPA uses the Nonroad component of the MOVES model to estimate fuel use. Emission factors by horsepower bin are estimated from EPA engine certification data. Because separate emission factors are applied to specific engine technologies; these non-road sources utilize a Tier 2 approach.

To estimate CH_4 and N_2O emissions from non-road mobile sources, fuel consumption data were employed as a measure of activity and multiplied by fuel-specific emission factors (in grams of N_2O and CH_4 per kilogram of fuel consumed).[55] Activity data were obtained from AAR (2008 through 2023), APTA (2007 through 2023), Rail Inc (2014 through 2022), APTA (2006), BEA (1991 through 2015), Benson (2002 through 2004), Bureau of Transportation Statistics (BTS; 2023), DLA Energy (2022), DOC (1991 through 2022), DOE (1993 through 2022), DOT (1991 through 2023), EIA (2002, 2007, 2023a, 2023b), EIA (1991 through 2022), EPA (2022), Esser (2003 through 2004), FAA (2024), FHWA (1996 through 2023),[56] Gaffney (2007), FTA (2023), and Whorton (2006 through 2014). Fuel consumption data for boats and vessels in U.S. Territories data and vessel domestic vessel bunkering is proxied from 2021 proxy data. Emission factors for non-road modes were taken from IPCC (2006) and Browning (2020 and 2018).

Uncertainty

A quantitative uncertainty analysis was conducted for the mobile source sector using the IPCC-recommended Approach 2 uncertainty estimation methodology, Monte Carlo stochastic simulation technique, using @RISK software. The uncertainty analysis was performed on 2022 estimates of CH_4 and N_2O emissions, incorporating probability distribution functions associated with the major input variables. For the purposes of this analysis, the uncertainty was modeled for the following four major sets of input variables: (1) VMT data, by on-road vehicle and fuel type, (2) emission factor data, by on-road vehicle, fuel, and control technology type, (3) fuel consumption, data, by non-road vehicle and equipment type, and (4) emission factor data, by non-road vehicle and equipment type.

Uncertainty analyses were not conducted for NO_x, CO, or NMVOC emissions. Emission factors for these gases have been extensively researched because emissions of these gases from motor vehicles are regulated in the United States, and the uncertainty in these emission estimates is believed to be relatively low. For more information, see Section 3.11. However, a much higher level of uncertainty is associated with CH_4 and N_2O emission factors due to limited emission test data, and because, unlike CO_2 emissions, the emission pathways of CH_4 and N_2O are highly complex.

Based on the uncertainty analysis, mobile combustion CH_4 emissions from all mobile sources in 2022 were estimated to be between 2.5 and 3.4 MMT CO_2 Eq. at a 95 percent confidence level. This indicates a range of 4 percent below to 30 percent above the corresponding 2022 emission estimate of 2.6 MMT CO_2 Eq. Mobile combustion N_2O emissions from mobile sources in 2022 were estimated to be between 15.3 and 20.1MMT CO_2 Eq. at a 95 percent confidence level. This indicates a range of 8 percent below to 20 percent above the corresponding 2022 emission estimate of 16.7 MMT CO_2 Eq.

[55] The consumption of international bunker fuels is not included in these activity data, but emissions related to the consumption of international bunker fuels are estimated separately under the International Bunker Fuels source category.

[56] This Inventory uses FHWA's Agriculture, Construction, and Commercial/Industrial MF-24 fuel volumes along with the MOVES model gasoline volumes to estimate non-road mobile source CH_4 and N_2O emissions for these categories. For agriculture, the MF-24 gasoline volume is used directly because it includes both non-road trucks and equipment. For construction and commercial/industrial category gasoline estimates, the 2014 and older MF-24 volumes represented non-road trucks only; therefore, the MOVES gasoline volumes for construction and commercial/industrial categories are added to the respective categories in the Inventory. Beginning in 2015, this addition is no longer necessary since the FHWA updated its methods for estimating on-road and non-road gasoline consumption. Among the method updates, FHWA now incorporates MOVES equipment gasoline volumes in the construction and commercial/industrial categories.

Table 3-21: Approach 2 Quantitative Uncertainty Estimates for CH_4 and N_2O Emissions from Mobile Sources (MMT CO_2 Eq. and Percent)

Source	Gas	2022 Emission Estimate (MMT CO_2 Eq.)	Uncertainty Range Relative to Emission Estimate[a] (MMT CO_2 Eq.)		(%)	
			Lower Bound	Upper Bound	Lower Bound	Upper Bound
Mobile Sources	CH_4	2.6	2.5	3.4	-4%	+30%
Mobile Sources	N_2O	16.7	15.3	20.1	-8%	+20%

[a] Range of emission estimates predicted by Monte Carlo stochastic simulation for a 95 percent confidence interval.

This uncertainty analysis is a continuation of a multi-year process for developing quantitative uncertainty estimates for this source category using the IPCC Approach 2 uncertainty estimation methodology. As a result, as new information becomes available, uncertainty characterization of input variables may be improved and revised. For additional information regarding uncertainty in emission estimates for CH_4 and N_2O please refer to the Uncertainty Annex. As discussed in Annex 5, data are unavailable to include estimates of CH_4 and N_2O emissions from any liquid fuel used in pipeline transport or some biomass used in transportation sources, but those emissions are assumed to be insignificant.

QA/QC and Verification

In order to ensure the quality of the emission estimates from mobile combustion, general (IPCC Tier 1) and category-specific (Tier 2) Quality Assurance/Quality Control (QA/QC) procedures were implemented consistent with the U.S. Inventory QA/QC plan outlined in Annex 8. The specific plan used for mobile combustion was updated prior to collection and analysis of this current year of data. The Tier 2 procedures focused on the emission factor and activity data sources, as well as the methodology used for estimating emissions. These procedures included a qualitative assessment of the emission estimates to determine whether they appear consistent with the most recent activity data and emission factors available. A comparison of historical emissions between the current Inventory and the previous Inventory was also conducted to ensure that the changes in estimates were consistent with the changes in activity data and emission factors.

Recalculations Discussion

In previous *Inventories* (1990 through 2020 *Inventory* and before), on-highway greenhouse gas emissions were calculated using FHWA fuel consumption and vehicle miles traveled (VMT) data delineated by FHWA vehicle classes. These fuel consumption estimates were then combined with estimates of fuel shares by vehicle type from Oak Ridge National Laboratory's Transportation Energy Data Book (TEDB), to develop an estimate of fuel consumption for each vehicle type in the Inventory (i.e., passenger cars, light-duty trucks, buses, medium- and heavy-duty trucks, motorcycles). However, in 2011, FHWA changed its methods for estimating VMT and related data. These methodological changes included how vehicles are classified, moving from a system based on body-type to one that is based on wheelbase. These changes were first incorporated in the 1990 through 2008 *Inventory* and applied to the time series beginning in 2007. The FHWA methodology update resulted in large changes in VMT and fuel consumption by vehicle class, leading to a shift in emissions among vehicle classes. For example, FHWA replaced the vehicle category "Passenger Cars" with "Light-duty Vehicles-Short Wheelbase" and the "Other 2 axle-4 Tire Vehicles" category was replaced by "Light-duty Vehicles, Long Wheelbase." FHWA changed the definition of light-duty vehicles to less than 10,000 lbs. GVWR instead of 8,500 lbs. GVWR category updates pushed some single-unit heavy-duty trucks to the light-duty class. This change in vehicle classification also moved some smaller trucks and sport utility vehicles from the light truck category to the passenger cars category in this *Inventory*. These updates resulted in a disconnect in FHWA VMT and fuel consumption data in the 2006 to 2007 timeframe, generating a large drop in the light-duty truck VMT and fuel consumption trend lines between 2006 and 2007, and a corresponding increase in the passenger cars trend lines.

To address this inconsistency in the time series, EPA updated the methodology (starting with the 1990 through 2021 *Inventory*) to divide FHWA VMT data into vehicle classes and fuel type using distributions from EPA's *MOtor Vehicle Emission Simulator*, MOVES. The MOVES model is a nationally recognized model based on vehicle registration, travel activity, and emission rates that are updated with each model release. MOVES uses forecast growth factors which provide EPA's best estimate of likely future activity based on historical data (see Annex 3.2 for more information about the MOVES model). Thus, dividing FHWA total VMT data into vehicle class and fuel type using MOVES ratios provides a more consistent estimate of vehicle activity over the *Inventory* time series. MOVES ratios are also used to reallocate FHWA gasoline and diesel fuel use data (Browning 2022a). For this update, the MOVES3 model was run for calendar years 1990 and 1999 through 2022 for all vehicle types. Calendar years 1991 through 1998 were linearly interpolated from 1990 and 1999 calendar year MOVES3 outputs. Model outputs of VMT and fuel consumption were binned by calendar year, MOVES vehicle type, and fuel type; MOVES vehicle types were then mapped to the vehicle types used in the *Inventory*. Only outputs of gasoline and diesel fuel consumption from MOVES3 were used; alternative fuel VMT and fuel consumption outputs are ignored because they are calculated for the *Inventory* under a separate methodology. Total gasoline and diesel fuel consumption values from FHWA were then allocated to *Inventory* vehicle types using gasoline and diesel fuel consumption ratios by vehicle type from MOVES3. Similarly, VMT by vehicle type and fuel type was calculated by multiplying the total VMT from FHWA by VMT ratios by vehicle and fuel type generated by MOVES3. Overall, because total fuel consumption and VMT values are conserved, the changes in total emissions are small, within 0.1 percent. Observed differences in total emissions are due to changes in CH_4 and N_2O emissions, as the methodology for calculating these non-CO_2 emissions utilizes more detailed activity data and is therefore sensitive to the re-allocation of activity data. While total emissions estimates are not significantly impacted by this methodology update, there are significant changes in the allocation of emissions by vehicle type. The share of emissions allocated to passenger cars now generally decline through the time series while the share of emissions allocated to light-duty trucks increase over time.

In addition, the latest version of Argonne National Laboratory's *Greenhouse Gas, Regulated Emissions, and Energy Use in Transportation Model (*GREET2022*)* provided updated emission factors for all alternative fuel vehicle classes (ANL 2022). Updated emission factors from GREET2022 were implemented in this *Inventory*, across the entire time series.

Additionally, new data from BTS on Amtrak fuel consumption for the time period 2019 through 2022 were included in this *Inventory* (BTS 2023).

Planned Improvements

While the data used for this report represent the most accurate information available, several areas for improvement have been identified.

- Update emission factors for ships and non-recreational boats using residual fuel and distillate fuel. Develop emission factors for locomotives using ultra-low sulfur diesel and emission factors for aircraft using jet fuel. The Inventory currently uses IPCC default values for these emission factors.
- Continue to explore potential improvements to estimates of domestic waterborne fuel consumption for future Inventories. The *Inventory* estimates for residual and distillate fuel used by ships and boats is based in part on data on bunker fuel use from the U.S. Department of Commerce. Domestic fuel consumption is estimated by subtracting fuel sold for international use from the total sold in the United States. Since 2015, all ships travelling within 200 nautical miles of the U.S. coastlines must use distillate fuels, thereby overestimating the residual fuel used by U.S. vessels and underestimating distillate fuel use in these ships. Additionally, the EIA has stopped publishing the Fuel Oil and Kerosene Sales report, which reported data on distillate marine fuel use in the U.S. and the territories. This affects the volume of fuel and emissions that are allocated to the domestic ships and boats source, although top-down data is still available from the Monthly Energy Review that will be used to estimate total domestic emission from diesel fuel use. New data and methods are being explored to improve the diesel ships and boats emissions estimates going forward.
- Update the analyses to use a forthcoming version of MOVES when it becomes available.

3.2 Carbon Emitted from Non-Energy Uses of Fossil Fuels (CRT Source Category 1A)

In addition to being combusted for energy, fossil fuels are also consumed for non-energy uses (NEU) in the United States. The fuels used for these purposes are diverse, including natural gas, hydrocarbon gas liquids (HGL),[57] asphalt (a viscous liquid mixture of heavy crude oil distillates), petroleum coke (manufactured from heavy oil), and coal (metallurgical) coke (manufactured from coking coal). The non-energy applications of these fuels are equally diverse, including feedstocks for the manufacture of plastics, rubber, synthetic fibers and other materials; reducing agents for the production of various metals and inorganic products; and products such as lubricants, waxes, and asphalt (IPCC 2006). Emissions from non-energy use of lubricants, paraffin waxes, bitumen/asphalt, and solvents are reported in the Energy sector, as opposed to the Industrial Processes and Product Use (IPPU) sector, to reflect national circumstances in its choice of methodology and to increase transparency of this source category's unique country-specific data sources and methodology (see Box 3-5). In addition, estimates of non-energy use emissions included here do not include emissions already reflected in the IPPU sector, e.g., fuels used as reducing agents. To avoid double counting, the "raw" non-energy fuel consumption data reported by EIA are reduced to account for these emissions already included under IPPU.

Carbon dioxide emissions arise from non-energy uses via several pathways. Emissions may occur during the manufacture of a product, as is the case in producing plastics or rubber from fuel-derived feedstocks. Additionally, emissions may occur during the product's lifetime, such as during solvent use. Overall, throughout the time series and across all uses, about 64 percent of the total carbon consumed for non-energy purposes was stored in products (e.g., plastics), and not released to the atmosphere; the remaining 36 percent was emitted.

There are several areas in which non-energy uses of fossil fuels are closely related to other parts of this *Inventory*. For example, some of the non-energy use products release CO_2 at the end of their commercial life when they are combusted after disposal; these emissions are reported separately within the Energy chapter in the Incineration of Waste source category. There are also net exports of petrochemical intermediate products that are not completely accounted for in the EIA data, and the *Inventory* calculations adjust for the effect of net exports on the mass of carbon in non-energy applications.

As shown in Table 3-22, fossil fuel emissions in 2022 from the non-energy uses of fossil fuels were 102.8 MMT CO_2 Eq., which constituted approximately 2.0 percent of overall fossil fuel emissions. In 2022, the consumption of fuels for non-energy uses (after the adjustments described above) was 5,428.2 TBtu (see Table 3-23). A portion of the carbon in the 5,428.2 TBtu of fuels was stored (236.7 MMT CO_2 Eq.), while the remaining portion was emitted (102.8 MMT CO_2 Eq.). Non-energy use emissions decreased by 7.9 percent from 2021 to 2022, primarily due to decreases in industrial coal, natural gas, and HGL fuel consumption. See Annex 2.3 for more details.

[57] HGL (formerly referred to as liquefied petroleum gas, or LPG) are hydrocarbons that occur as gases at atmospheric pressure and as liquids under higher pressures. HGLs include paraffins, such as ethane, propane, butanes, isobutane, and natural gasoline (formerly referred to as pentanes plus), and HGLs include olefins, such as ethylene, propylene, butylene and isobutylene.

Table 3-22: CO_2 Emissions from Non-Energy Use Fossil Fuel Consumption (MMT CO_2 Eq. and Percent C)

Year	1990	2005	2018	2019	2020	2021	2022
Potential Emissions	292.5	357.7	341.5	334.7	328.6	345.0	339.5
C Stored	193.4	232.7	223.2	228.2	230.8	233.4	236.7
Emissions as a % of Potential	34%	35%	35%	32%	30%	32%	30%

Note: NEU emissions presented in this table differ from the NEU emissions presented in CRT Table 1.A(a)s4 as the CRT NEU emissions do not include NEU of lubricants and other petroleum in U.S. Territories. NEU emissions from U.S. Territories are reported under U.S. Territories in the CRT Table 1.A(a)s4.

Methodology and Time-Series Consistency

As per discussion of methodology for estimating CO_2 emissions from fossil fuel combustion, NEU emissions are estimated in line with a Tier 2 method described by the *IPCC in the 2006 IPCC Guidelines for National Greenhouse Gas Inventories* (IPCC 2006) Chapter 2, Figure 2.1 decision tree and available data on energy use and country specific fuel carbon contents. The first step in estimating carbon stored in products was to determine the aggregate quantity of fossil fuels consumed for non-energy uses. The carbon content of these feedstock fuels is equivalent to potential emissions, or the product of consumption and the fuel-specific carbon content values. Both the non-energy fuel consumption and carbon content data were supplied by the EIA (2023) (see Annex 2.1). Consumption values for industrial coking coal, petroleum coke, other oils, and natural gas in Table 3-23 and Table 3-24 have been adjusted to subtract non-energy uses that are included in the source categories of the Industrial Processes and Product Use chapter.[58] Consumption of natural gas, HGL, naphthas, other oils, and special naphtha were adjusted to subtract out net exports of these products that are not reflected in the raw data from EIA. Consumption values were also adjusted to subtract net exports of HGL components (e.g., propylene, ethane).

For the remaining non-energy uses, the quantity of carbon stored was estimated by multiplying the potential emissions by a storage factor.

- For several fuel types—petrochemical feedstocks (including natural gas for non-fertilizer uses, HGL, naphthas, other oils, still gas, special naphtha, and industrial other coal), asphalt and road oil, lubricants, and waxes—U.S. data on carbon stocks and flows were used to develop carbon storage factors, calculated as the ratio of (a) the carbon stored by the fuel's non-energy products to (b) the total carbon content of the fuel consumed. A lifecycle approach was used in the development of these factors in order to account for losses in the production process and during use. Because losses associated with municipal solid waste management are handled separately in the Energy sector under the Incineration of Waste source category, the storage factors do not account for losses at the disposal end of the life cycle.
- For industrial coking coal and distillate fuel oil, storage factors were taken from Marland and Rotty (1984).
- For the remaining fuel types (petroleum coke, miscellaneous products and other petroleum), IPCC (2006) does not provide guidance on storage factors, and assumptions were made based on the potential fate of carbon in the respective non-energy use products. Carbon dioxide emissions from carbide production are implicitly accounted for in the storage factor calculation for the non-energy use of petroleum coke.

[58] These source categories include iron and steel production, lead production, zinc production, ammonia manufacture, carbon black manufacture (included in petrochemical production), titanium dioxide production, ferroalloy production, silicon carbide production, and aluminum production.

[c] Formerly referred to as "pentanes plus." this source has been adjusted and is reported separately from HGL to align with historic data and revised EIA terminology.
Note: Totals may not sum due to independent rounding.

Lastly, emissions were estimated by subtracting the carbon stored from the potential emissions (see Table 3-22). More detail on the methodology for calculating storage and emissions from each of these sources is provided in Annex 2.3.

Where storage factors were calculated specifically for the United States, data were obtained on (1) products such as asphalt, plastics, synthetic rubber, synthetic fibers, cleansers (soaps and detergents), pesticides, food additives, antifreeze and deicers (glycols), and silicones; and (2) industrial releases including energy recovery (waste gas from chemicals), Toxics Release Inventory (TRI) releases, hazardous waste incineration, and volatile organic compound, solvent, and non-combustion CO emissions. Data were taken from a variety of industry sources, government reports, and expert communications. Sources include EPA reports and databases such as compilations of air emission factors (EPA 2001), EPA's Emissions Inventory System (EIS) to National Inventory Report (NIR) Mapping file (EPA 2023), *Toxics Release Inventory, 1998* (EPA 2000b), *Biennial Reporting System* (EPA 2000a, 2009), *Resource Conservation and Recovery Act Information System* (EPA 2013b, 2015, 2016b, 2018b, 2021), pesticide sales and use estimates (EPA 1998, 1999, 2002, 2004, 2011, 2017), and the Chemical Data Access Tool (EPA 2014b); the EIA Manufacturer's Energy Consumption Survey (MECS) (EIA 1994, 1997, 2001, 2005, 2010, 2013, 2017, 2021); the National Petrochemical & Refiners Association (NPRA 2002); the U.S. Census Bureau (1999, 2004, 2009, 2014, 2021); Bank of Canada (2012, 2013, 2014, 2016, 2017, 2018, 2019, 2020, 2021, 2022, 2023); Financial Planning Association (2006); INEGI (2006); the United States International Trade Commission (2023); Gosselin, Smith, and Hodge (1984); EPA's *Municipal Solid Waste (MSW) Facts and Figures* (EPA 2013, 2014a, 2016a, 2018a, 2019); the U.S. Tire Manufacturers Association (USTMA 2012, 2013, 2014, 2016, 2018, 2020, 2022); the International Institute of Synthetic Rubber Products (IISRP 2000, 2003); the Fiber Economics Bureau (FEB 2001, 2003, 2005, 2007, 2009, 2010, 2011, 2012, 2013); the Independent Chemical Information Service (ICIS 2008, 2016); the EPA Chemical Data Access Tool (CDAT) (EPA 2014b); the American Chemistry Council (ACC 2003 through 2011, 2013, 2014, 2015, 2016, 2017, 2018, 2019, 2020, 2021, 2022, 2023a); the *Guide to the Business of Chemistry* (ACC 2023b); and the Chemistry Industry Association of Canada (CIAC 2023). Specific data sources are listed in full detail in Annex 2.3.

Methodological recalculations were applied to the entire time series to ensure time-series consistency from 1990 through 2022 as discussed below.

Box 3-5: Reporting of Lubricants, Waxes, and Asphalt and Road Oil Product Use in Energy Sector

IPCC (2006) provides methodological guidance to estimate emissions from the first use of fossil fuels as a product for primary purposes other than combustion for energy purposes (including lubricants, paraffin waxes, bitumen / asphalt, and solvents) under the IPPU sector.[59] In this *Inventory*, carbon storage and carbon

[59] See for example Volume 3: Industrial Processes and Product Use, and Chapter 5: Non-Energy Products from Fuels and Solvent Use of the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (IPCC 2006).

emissions from product use of lubricants, waxes, and asphalt and road oil are reported under the Energy sector in the Carbon Emitted from Non-Energy Uses of Fossil Fuels source category (CRT Source Category 1A5).[60]

The emissions are reported in the Energy sector, as opposed to the IPPU sector, to reflect national circumstances in its choice of methodology and to increase transparency of this source category's unique country-specific data sources and methodology. Although emissions from these non-energy uses are reported in the Energy chapter the methodologies used to determine emissions are compatible with the *2006 IPCC Guidelines*. The country-specific methodology used for the Carbon Emitted from Non-Energy Uses of Fossil Fuels source category is based on a carbon balance (i.e., carbon inputs-outputs) calculation of the aggregate amount of fossil fuels used for non-energy uses, including inputs of lubricants, waxes, asphalt and road oil (see Table 3-24).

For those inputs, U.S. country-specific data on carbon stocks and flows are used to develop carbon storage factors, which are calculated as the ratio of the carbon stored by the fossil fuel non-energy products to the total carbon content of the fuel consumed, taking into account losses in the production process and during product use.[61] The country-specific methodology to reflect national circumstances starts with the aggregate amount of fossil fuels used for non-energy uses and applies a carbon balance calculation, breaking out the carbon emissions from non-energy use of lubricants, waxes, and asphalt and road oil. The emissions are reported under the Energy chapter to improve transparency, report a more complete carbon balance and to avoid double counting. Due to U.S. national circumstances, reporting these carbon emissions separately under IPPU would involve making artificial adjustments to allocate both the carbon inputs and carbon outputs of the non-energy use carbon balance. For example, only the emissions from the first use of lubricants and waxes are to be reported under the IPPU sector, emissions from use of lubricants in 2-stroke engines and emissions from secondary use of lubricants and waxes in waste incineration with energy recovery are to be reported under the Energy sector. Reporting these non-energy use emissions from only first use of lubricants and waxes under IPPU would involve making artificial adjustments to the non-energy use carbon balance and could potentially result in double counting of emissions. These artificial adjustments would also be required for asphalt and road oil and solvents (which are captured as part of petrochemical feedstock emissions) and could also potentially result in double counting of emissions. To avoid presenting an incomplete carbon balance and a less transparent approach for the Carbon Emitted from Non-Energy Uses of Fossil Fuels source category calculation, the entire calculation of carbon storage and carbon emissions is therefore conducted in the Non-Energy Uses of Fossil Fuels category calculation methodology, and both the carbon storage and carbon emissions for lubricants, waxes, and asphalt and road oil are reported under the Energy sector.

However, emissions from non-energy uses of fossil fuels as feedstocks or reducing agents (e.g., petrochemical production, aluminum production, titanium dioxide, and zinc production) are reported in the IPPU chapter, unless otherwise noted due to specific national circumstances.

Uncertainty

An uncertainty analysis was conducted to quantify the uncertainty surrounding the estimates of emissions and storage factors from non-energy uses. This analysis, performed using @RISK software and the IPCC-recommended Approach 2 methodology (Monte Carlo stochastic simulation technique), provides for the specification of probability density functions for key variables within a computational structure that mirrors the calculation of the

[60] Non-methane volatile organic compound (NMVOC) emissions from solvent use are reported separately in the IPPU sector, following Chapter 5 of the *2006 IPCC Guidelines*.

[61] Data and calculations for lubricants and waxes and asphalt and road oil are in Annex 2.3 – Methodology for Estimating Carbon Emitted from Non-Energy Uses of Fossil Fuels.

inventory estimate. The results presented below provide the 95 percent confidence interval, the range of values within which emissions are likely to fall, for this source category.

As noted above, the non-energy use analysis is based on U.S.-specific storage factors for (1) feedstock materials (natural gas, HGL, natural gasoline, naphthas, other oils, still gas, special naphthas, and other industrial coal), (2) asphalt, (3) lubricants, and (4) waxes. For the remaining fuel types (the "other" category in Table 3-23 and Table 3-24) the storage factors were taken directly from IPCC (2006), where available, and otherwise assumptions were made based on the potential fate of carbon in the respective NEU products. To characterize uncertainty, five separate analyses were conducted, corresponding to each of the five categories. In all cases, statistical analyses or expert judgments of uncertainty were not available directly from the information sources for all the activity variables; thus, uncertainty estimates were determined using assumptions based on source category knowledge.

The results of the Approach 2 quantitative uncertainty analysis are summarized in Table 3-25 (emissions) and Table 3-26 (storage factors). Carbon emitted from non-energy uses of fossil fuels in 2022 was estimated to be between 71.0 and 166.6 MMT CO_2 Eq. at a 95 percent confidence level. This indicates a range of 31 percent below to 62 percent above the 2022 emission estimate of 102.8 MMT CO_2 Eq. The uncertainty in the emission estimates is a function of uncertainty in both the quantity of fuel used for non-energy purposes and the storage factor.

Table 3-25: Approach 2 Quantitative Uncertainty Estimates for CO_2 Emissions from Non-Energy Uses of Fossil Fuels (MMT CO_2 Eq. and Percent)

Source	Gas	2022 Emission Estimate (MMT CO_2 Eq.)	Uncertainty Range Relative to Emission Estimate[a] (MMT CO_2 Eq.)		(%)	
			Lower Bound	Upper Bound	Lower Bound	Upper Bound
Feedstocks	CO_2	81.4	51.7	146.6	-37%	+80%
Asphalt	CO_2	0.3	0.1	0.7	-58%	+119%

[a] Range of emission estimates predicted by Monte Carlo stochastic simulation for a 95 percent confidence interval.

Note: Totals may not sum due to independent rounding.

Table 3-26: Approach 2 Quantitative Uncertainty Estimates for Storage Factors of Non-Energy Uses of Fossil Fuels (Percent)

Source	Gas	2022 Storage Factor (%)	Uncertainty Range Relative to Emission Estimate[a] (%)		(%, Relative)	
			Lower Bound	Upper Bound	Lower Bound	Upper Bound
Feedstocks	CO_2	67.0%	52.3%	73.5%	-22%	+10%
Asphalt	CO_2	99.6%	99.1%	99.8%	0.5%	0.3%
Lubricants	CO_2	9.2%	3.9%	17.5%	-57%	+91%
Waxes	CO_2	57.8%	47.4%	67.5%	-18%	+17%
Other	CO_2	13.6%	8.1%	83.0%	-41%	+511%

[a] Range of emission estimates predicted by Monte Carlo stochastic simulation for a 95 percent confidence interval, as a percentage of the inventory value (also expressed in percent terms).

As shown in Table 3-26, waxes and asphalt contribute least to overall storage factor uncertainty on a percentage basis. Although the feedstocks category—the largest use category in terms of total carbon flows—also appears to have relatively tight confidence limits, this is to some extent an artifact of the way the uncertainty analysis was structured. As discussed in Annex 2.3, the storage factor for feedstocks is based on an analysis of six fates that result in long-term storage (e.g., plastics production), and eleven that result in emissions (e.g., volatile organic compound emissions). Rather than modeling the total uncertainty around all of these fate processes, the current analysis addresses only the storage fates, and assumes that all carbon that is not stored is emitted. As the

production statistics that drive the storage values are relatively well-characterized, this approach yields a result that is probably biased toward understating uncertainty.

As is the case with the other uncertainty analyses discussed throughout this document, the uncertainty results above address only those factors that can be readily quantified. More details on the uncertainty analysis are provided in Annex 2.3.

QA/QC and Verification

In order to ensure the quality of the emission estimates from non-energy uses of fossil fuels, general (IPCC Tier 1) and category-specific (Tier 2) Quality Assurance/Quality Control (QA/QC) procedures were implemented consistent with the U.S. Inventory QA/QC plan outlined in Annex 8. This effort included a general analysis, as well as portions of a category specific analysis for non-energy uses involving petrochemical feedstocks and for imports and exports. The Tier 2 procedures that were implemented involved checks specifically focusing on the activity data and methodology for estimating the fate of carbon (in terms of storage and emissions) across the various end-uses of fossil C. Emission and storage totals for the different subcategories were compared, and trends across the time series were analyzed to determine whether any corrective actions were needed. Corrective actions were taken to rectify minor errors and to improve the transparency of the calculations, facilitating future QA/QC.

For petrochemical import and export data, special attention was paid to NAICS numbers and titles to verify that none had changed or been removed. Import and export totals were compared with 2021 totals as well as their trends across the time series.

It is important to ensure no double counting of emissions between fuel combustion, non-energy use of fuels and industrial process emissions. For petrochemical feedstock production, our review of the categories suggests this is not a significant issue since the non-energy use industrial release data includes different categories of sources and sectors than those included in the Industrial Processes and Product Use (IPPU) emissions category for petrochemicals. Further data integration is not available at this time because feedstock data from the EIA used to estimate non-energy uses of fuels are aggregated by fuel type, rather than disaggregated by both fuel type and particular industries. Also, GHGRP-reported data on quantities of fuel consumed as feedstocks by petrochemical producers are unable to be used due to the data failing GHGRP CBI aggregation criteria. This country-specific approach taken is better able to reflect the national situation because it is accounting for secondary product imports and exports that are not included directly in the national energy statistics. Furthermore, it is compatible with the *2006 IPCC Guidelines* as discussed in Box 3-5 above, but also as the NEU emissions are here represent different emissions from those covered in the IPPU petrochemical production category.

Recalculations Discussion

Several updates to activity data factors lead to recalculations of previous year results. The major updates are as follows:

- U.S. International Trade Commission (2023) made changes to the classification of certain cleanser types, which doubled the historic emissions data for cleanser imports while exports remained constant.
- ACC (2023b) updated polyester, polyolefin and nylon fiber, ethylene glycol, maleic anhydride, adipic acid, and acetic acid production in 2021 which resulted in a slight decrease in emissions relative to the previous *Inventory*.
- U.S. International Trade Commission (2023) updated historical import and export data from 1996 to 2021, resulting in greater net exports relative to the previous *Inventory*.
- EIA (2024) shifted all 2022 product supplied of natural gasoline and unfinished oils to crude oil transfers, reflecting that, in actuality, nearly the full volume of these fuels is used as a feedstock in crude oil production, instead of directly consumed as an end-use fuel. Under EIA's guidance, EPA shifted all product supplied of natural gasoline to crude oil transfers for the time series. Natural gasoline was entirely

recategorized, which resulted in zero emissions for the time series from 1990 to 2022. Natural gasoline previously made up 1.7 percent of total emissions on average across the time series for non-energy uses of fossil fuels.

- To better align with EIA methodology, the non-energy use consumption of HGLs is now calculated for the entire timeseries by assuming that 100 percent of ethane, ethylene, and propylene consumption is for non-combustion use and 85 percent of normal butane, butylene, isobutane, and isobutylene is for non-combustion use. Non-energy use consumption of propane is calculated by subtracting the non-energy consumption of all other HGLs from the total non-combustion consumption of HGLs as published by the EIA. A further adjustment is made to natural gas, HGL, naphtha, other oil, and special naphtha consumption to account for exports of organic chemicals, cleansers, and pesticides. Because this adjustment is apportioned based on the relative ratios of each fuel, the emissions from these fuels have also changed slightly across the time series. Additionally, to better align with EIA methodology, the non-combustion and energy HGL carbon contents are now calculated for the entire timeseries following the above methodology. Overall, this update caused emissions from the non-energy use of natural gas to decrease an average of 27 MMT CO_2 Eq. annually, or 23 percent.

Overall, these changes resulted in an average annual decrease of 10.1 MMT CO_2 Eq. (8.2 percent) in carbon emissions from non-energy uses of fossil fuels for the period 1990 through 2021, relative to the previous *Inventory*.

Planned Improvements

There are several future improvements planned:

- More accurate accounting of carbon in petrochemical feedstocks. EPA has worked with EIA to determine the cause of input/output discrepancies in the carbon mass balance contained within the NEU model. In the future, two strategies to reduce or eliminate this discrepancy will continue to be pursued as part of quality control procedures. First, accounting of carbon in imports and exports will be improved. The import/export adjustment methodology will be examined to ensure that net exports of intermediaries such as ethylene and propylene are fully accounted for. Second, the use of top-down carbon input calculation in estimating emissions will be reconsidered. Alternative approaches that rely more substantially on the bottom-up carbon output calculation will be considered instead.
- Improving the uncertainty analysis. Most of the input parameter distributions are based on professional judgment rather than rigorous statistical characterizations of uncertainty.
- Better characterizing flows of fossil carbon. Additional fates may be researched, including the fossil carbon load in organic chemical wastewaters, plasticizers, adhesives, films, paints, and coatings. There is also a need to further clarify the treatment of fuel additives and backflows (especially methyl tert-butyl ether, MTBE).
- Reviewing the trends in fossil fuel consumption for non-energy uses. Annual consumption for several fuel types is highly variable across the time series, including industrial coking coal and other petroleum. A better understanding of these trends will be pursued to identify any mischaracterized or misreported fuel consumption for non-energy uses.
- Updating the average carbon content of solvents was researched, since the entire time series depends on one year's worth of solvent composition data. The data on carbon emissions from solvents that were readily available do not provide composition data for all categories of solvent emissions and also have conflicting definitions for volatile organic compounds, the source of emissive carbon in solvents. Additional sources of solvents data will be investigated in order to update the carbon content assumptions.
- Updating the average carbon content of cleansers (soaps and detergents) was researched; although production and consumption data for cleansers are published every 5 years by the Census Bureau, the composition (C content) of cleansers has not been recently updated. Recently available composition data

sources may facilitate updating the average carbon content for this category.

- Revising the methodology for consumption, production, and carbon content of plastics was researched; because of recent changes to the type of data publicly available for plastics, the NEU model for plastics applies data obtained from personal communications. Potential revisions to the plastics methodology to account for the recent changes in published data will be investigated.
- Although U.S.-specific storage factors have been developed for feedstocks, asphalt, lubricants, and waxes, default values from IPCC are still used for two of the non-energy fuel types (industrial coking coal, distillate oil), and broad assumptions are being used for miscellaneous products and other petroleum. Over the long term, there are plans to improve these storage factors by analyzing carbon fate similar to those described in Annex 2.3 or deferring to more updated default storage factors from IPCC where available.
- Reviewing the storage of carbon black across various sectors in the *Inventory*; in particular, the carbon black abraded and stored in tires.
- Assess the current method and/or identify new data sources (e.g., EIA) for estimating emissions from ammonia/fertilizer use of natural gas.
- Investigate EIA NEU and MECS data to update, as needed, adjustments made for ammonia production and "natural gas to chemical plants, other uses" and "natural gas to other" non-energy uses, including iron and steel production, in energy uses and IPPU.

3.3 Incineration of Waste (CRT Source Category 1A)

Combustion is used to manage about 7 to 19 percent of the solid wastes generated in the United States, depending on the source of the estimate and the scope of materials included in the definition of solid waste (EPA 2000; EPA 2020; Goldstein and Madtes 2001; Kaufman et al. 2004; Simmons et al. 2006; van Haaren et al. 2010). In the context of this section, waste includes all municipal solid waste (MSW) as well as scrap tires. In the United States, combustion of MSW tends to occur at waste-to-energy facilities or industrial facilities where useful energy is recovered, and thus emissions from waste combustion are accounted for in the Energy chapter. Similarly, scrap tires are combusted for energy recovery in industrial and utility boilers, pulp and paper mills, and cement kilns. Combustion of waste results in conversion of the organic inputs to CO_2. According to the *2006 IPCC Guidelines*, when the CO_2 emitted is of fossil origin, it is counted as a net anthropogenic emission of CO_2 to the atmosphere. Thus, the emissions from waste combustion are calculated by estimating the quantity of waste combusted and the fraction of the waste that is carbon derived from fossil sources.

Most of the organic materials in MSW are of biogenic origin (e.g., paper, yard trimmings), and have their net carbon flows accounted for under the Land Use, Land-Use Change, and Forestry chapter. However, some components of MSW and scrap tires—plastics, synthetic rubber, synthetic fibers, and carbon black—are of fossil origin. Plastics in the U.S. waste stream are primarily in the form of containers, packaging, and durable goods. Rubber is found in durable goods, such as carpets, and in non-durable goods, such as clothing and footwear. Fibers in MSW are predominantly from clothing and home furnishings. As noted above, scrap tires (which contain synthetic rubber and carbon black) are also considered a "non-hazardous" waste and are included in the waste combustion estimate, though waste disposal practices for tires differ from MSW. Estimates on emissions from hazardous waste combustion can be found in Annex 2.3 and are accounted for as part of the carbon mass balance for non-energy uses of fossil fuels.

Approximately 26.3 million metric tons of MSW were combusted in 2022 (EPA 2022). Carbon dioxide emissions from combustion of waste decreased 4.2 percent since 1990, to an estimated 12.4 MMT CO_2 (12,357 kt) in 2022. Emissions across the time series are shown in Table 3-27 and Table 3-28.

Waste combustion is also a source of CH_4 and N_2O emissions (De Soete 1993; IPCC 2006). Methane emissions from the combustion of waste were estimated to be less than 0.05 MMT CO_2 Eq. (less than 0.05 kt CH_4) in 2022 and have remained steady since 1990. Nitrous oxide emissions from the combustion of waste were estimated to be 0.3 MMT CO_2 Eq. (1.3 kt N_2O) in 2022 and have decreased by 18 percent since 1990. This decrease is driven by the decrease in total MSW combusted.

Table 3-27: CO_2, CH_4, and N_2O Emissions from the Combustion of Waste (MMT CO_2 Eq.)

Gas	1990	2005	2018	2019	2020	2021	2022
CO_2	12.9	13.3	13.3	12.9	12.9	12.5	12.4
CH_4	+	+	+	+	+	+	+
N_2O	0.4	0.3	0.4	0.4	0.3	0.4	0.3
Total	**13.3**	**13.6**	**13.7**	**13.3**	**13.3**	**12.8**	**12.7**

+ Does not exceed 0.05 MMT CO_2 Eq.
Note: Totals may not sum due to independent rounding.

Table 3-28: CO_2, CH_4, and N_2O Emissions from the Combustion of Waste (kt)

Gas	1990	2005	2018	2019	2020	2021	2022
CO_2	12,900	13,254	13,339	12,948	12,921	12,476	12,357
CH_4	+	+	+	+	+	+	+
N_2O	2	1	1	1	1	1	1

+ Does not exceed 0.05 kt.

Methodology and Time-Series Consistency

Municipal Solid Waste Combustion

To determine both CO_2 and non-CO_2 emissions from the combustion of waste, the tonnage of waste combusted and an estimated emissions factor are needed. Emission estimates from the combustion of tires are discussed separately. Data for total waste combusted was derived from *BioCycle* (van Haaren et al. 2010), EPA Facts and Figures Report, Energy Recovery Council (ERC), EPA's Greenhouse Gas Reporting Program (GHGRP), and the U.S. Energy Information Administration (EIA). Multiple sources were used to ensure a complete, quality dataset, as each source encompasses a different timeframe.

EPA determined the MSW tonnages based on data availability and accuracy throughout the time series.

- 1990-2006: MSW combustion tonnages are from Biocycle combustion data. Tire combustion data from the U.S. Tire Manufacturers Association (USTMA) are removed to arrive at MSW combusted without tires.
- 2006-2010: MSW combustion tonnages are an average of Biocycle (with USTMA tire data tonnage removed), U.S. EPA Facts and Figures, EIA, and Energy Recovery Council data (with USTMA tire data tonnage removed).
- 2011-2022: MSW combustion tonnages are from EPA's GHGRP data.

Table 3-29 provides the estimated tons of MSW combusted including and excluding tires.

Table 3-29: Municipal Solid Waste Combusted (Short Tons)

	1990	2005	2018	2019	2020	2021	2022
Waste Combusted *(excluding tires)*	33,344,839	26,486,414	29,162,364	28,174,311	27,586,271	27,867,446	26,338,130
Waste Combusted *(including tires)*	33,766,239	28,631,054	30,853,949	29,821,141	29,106,686	29,261,446	27,732,130

Sources: BioCycle, EPA Facts and Figures, ERC, GHGRP, EIA, USTMA.

CO_2 Emissions from MSW Excluding Scrap Tires

Fossil CO_2 emission factors were calculated from EPA's GHGRP data for non-biogenic sources. Using GHGRP-reported emissions for CH_4 and N_2O and assumed emission factors, the tonnage of waste combusted, excluding tires, was derived. Methane and N_2O emissions and assumed emission factors were used to estimate the amount of MSW combusted in terms of energy content. The energy content of MSW combusted was then converted into tonnage based on assumed MSW heating value. Two estimates were generated (one for CH_4 and one for N_2O) and the two were averaged together. Dividing fossil CO_2 emissions from GHGRP FLIGHT data for MSW combustors by this estimated tonnage yielded an annual CO_2 emission factor. As this data was only available following 2011, all years prior use an average of the emission factors from 2011 through 2015. See Annex 3.7 for more detail on how MSW carbon factors were calculated.

Finally, CO_2 emissions were calculated by multiplying the annual tonnage estimates, excluding tires, by the calculated emissions factor. Calculated fossil CO_2 emission factors are shown in Table 3-30.

Table 3-30: Calculated Fossil CO_2 Content per Ton Waste Combusted (kg CO_2/Short Ton Combusted)

Year	1990	2005	2018	2019	2020	2021	2022
CO_2 Emission Factors	366	366	361	363	377	365	382

CO_2 Emissions from Scrap Tires

Scrap tires contain several types of synthetic rubber, carbon black, and synthetic fibers. Each type of synthetic rubber has a discrete carbon content, and carbon black is 100 percent C. For synthetic rubber and carbon black in scrap tires, information on average weight, disposal percentage, and total tires incinerated for energy was obtained biannually from U.S. Scrap Tire Management Summary for 2005 through 2022 data (USTMA 2022). Information about scrap tire composition was taken from the Rubber Manufacturers' Association internet site (USTMA 2012a). Emissions of CO_2 were calculated based on the amount of scrap tires used for fuel and the synthetic rubber and carbon black content of scrap tires. The mass of combusted material is multiplied by its carbon content to calculate the total amount of carbon stored. 2022 values are proxied from 2021 data. More detail on the methodology for calculating emissions from each of these waste combustion sources is provided in Annex 3.7. Table 3-31 provides CO_2 emissions from combustion of waste tires.

Table 3-31: CO_2 Emissions from Combustion of Tires (MMT CO_2 Eq.)

Year	1990	2005	2018	2019	2020	2021	2022
Synthetic Rubber	0.3	1.6	1.3	1.2	1.1	1.0	1.0
C Black	0.4	2.0	1.5	1.5	1.4	1.3	1.3
Total	**0.7**	**3.6**	**2.8**	**2.7**	**2.5**	**2.3**	**2.3**

Non-CO_2 Emissions

Combustion of waste also results in emissions of CH_4 and N_2O. These emissions were calculated by multiplying the total estimated mass of waste combusted, including tires, by the respective emission factors. The emission factors for CH_4 and N_2O emissions per quantity of MSW combusted are default emission factors for the default continuously-fed stoker unit MSW combustion technology type and were taken from IPCC (2006).

Uncertainty

An Approach 2 Monte Carlo analysis was performed to determine the level of uncertainty surrounding the estimates of CO_2 emissions and N_2O emissions from the incineration of waste (given the very low emissions for CH_4, no uncertainty estimate was derived). IPCC Approach 2 analysis allows the specification of probability density functions for key variables within a computational structure that mirrors the calculation of the *Inventory* estimate. Statistical analyses or expert judgments of uncertainty were not available directly from the information sources for most variables; thus, uncertainty estimates for these variables were determined using assumptions based on source category knowledge and the known uncertainty estimates for the waste generation variables.

The uncertainties in the waste incineration emission estimates arise from both the assumptions applied to the data and from the quality of the data. Key factors include reported CO_2 emissions; N_2O and CH_4 emissions factors, and tire synthetic rubber and black carbon contents. The highest levels of uncertainty surround the reported emissions from GHGRP; the lowest levels of uncertainty surround variables that were determined by quantitative measurements (e.g., combustion efficiency, carbon content of carbon black).

The results of the Approach 2 quantitative uncertainty analysis are summarized in Table 3-32. Waste incineration CO_2 emissions in 2022 were estimated to be between 10.3 and 14.4 MMT CO_2 Eq. at a 95 percent confidence level. This indicates a range of 17 percent below to 16 percent above the 2022 emission estimate of 12.4 MMT CO_2 Eq. Also at a 95 percent confidence level, waste incineration N_2O emissions in 2022 were estimated to be between 0.2 and 0.9 MMT CO_2 Eq. This indicates a range of 54 percent below to 164 percent above the 2022 emission estimate of 0.3 MMT CO_2 Eq.

Table 3-32: Approach 2 Quantitative Uncertainty Estimates for CO_2 and N_2O from the Incineration of Waste (MMT CO_2 Eq. and Percent)

Source	Gas	2022 Emission Estimate (MMT CO_2 Eq.)	Uncertainty Range Relative to Emission Estimate[a] (MMT CO_2 Eq.)		(%)	
			Lower Bound	Upper Bound	Lower Bound	Upper Bound
Incineration of Waste	CO_2	12.4	10.3	14.4	-17%	16%
Incineration of Waste	N_2O	0.3	0.2	0.9	-54%	164%

[a] Range of emission estimates predicted by Monte Carlo Simulation for a 95 percent confidence interval.

QA/QC and Verification

In order to ensure the quality of the emission estimates from waste combustion, general (IPCC Tier 1) and category-specific (Tier 2) Quality Assurance/Quality Control (QA/QC) procedures were implemented consistent with the U.S. Inventory QA/QC plan outlined in Annex 8. The Tier 2 procedures that were implemented involved checks specifically focusing on the activity data and specifically focused on the emission factor and activity data sources and methodology used for estimating emissions from combustion of waste. Trends across the time series were analyzed to determine whether any corrective actions were needed. Corrective actions were taken to rectify minor errors in the use of activity data.

Recalculations Discussion

No recalculations were performed for the current *Inventory*.

Planned Improvements

Research was conducted to review the composition of carbon black abraded and stored in tires. No definitive sources were found that support updating the current factor of 28 percent carbon black for commercial and light duty tires. This factor was not updated, but additional research can be completed in future *Inventory* cycles.

3.4 Coal Mining (CRT Source Category 1B1a)

Three types of coal mining-related activities release CH_4 and CO_2 to the atmosphere: underground mining, surface mining, and post-mining (i.e., coal-handling) activities. While surface coal mines account for the majority of U.S. coal production, underground coal mines contribute the largest share of fugitive CH_4 emissions (see Table 3-34 and Table 3-35) due to the higher CH_4 content of coal in the deeper underground coal seams. In 2022, 185 underground coal mines and 354 surface mines were operating in the United States (EIA 2023). In recent years, the total number of active coal mines in the United States has declined. In 2022, the United States was the fourth largest coal producer in the world, after China, India, and Indonesia (IEA 2022).

Table 3-33: Coal Production (kt)

Year	1990	2005	2018	2019	2020	2021	2022
Underground							
Number of Mines	1,683	586	236	226	196	174	185
Production	384,244	334,399	249,804	242,557	177,380	200,122	201,525

Production	**931,052**	**1,025,846**	**685,325**	**640,307**	**485,324**	**523,264**	**538,515**

Fugitive CH_4 Emissions

Underground coal mines liberate CH_4 from ventilation systems and from degasification systems. Ventilation systems pump air through the mine workings to dilute noxious gases and ensure worker safety; these systems can exhaust significant amounts of CH_4 to the atmosphere in low concentrations. Degasification systems are wells drilled from the surface or boreholes drilled inside the mine that remove large, often highly concentrated volumes of CH_4 before, during, or after mining. Some mines recover and use CH_4 generated from ventilation and degasification systems, thereby reducing emissions to the atmosphere.

Surface coal mines liberate CH_4 as the overburden is removed and the coal is exposed to the atmosphere. Methane emissions are normally a function of coal rank (a classification related to the percentage of carbon in the coal) and depth. Surface coal mines typically produce lower-rank coals and remove less than 250 feet of overburden, so their level of emissions is much lower than from underground mines.

In addition, CH_4 is released during post-mining activities, as the coal is processed, transported, and stored for use.

Total CH_4 emissions in 2022 were estimated to be 1,558 kt (43.6 MMT CO_2 Eq.), a decline of approximately 60 percent since 1990 (see Table 3-34 and Table 3-35). In 2022, underground mines accounted for approximately 72 percent of total emissions, surface mines accounted for 14 percent, and post-mining activities accounted for 14 percent. In 2022, total CH_4 emissions from coal mining decreased by approximately 2 percent relative to the previous year. Total coal production in 2022 increased by 3 percent compared to 2021. This resulted in an increase of 4 percent in CH_4 emissions from surface mining and post-mining activities in 2022. However, surface mining and post-mining activities have a lower impact on total CH_4 compared to underground mining (72 percent of total emissions in 2022). The number of operating underground mines increased in 2022 and the amount of CH_4 recovered and used in 2022 increased by 25 percent compared to 2021. This resulted in a slight decrease in overall CH_4 emissions in 2022 (2 percent), compared to 2021.

Methodology and Time-Series Consistency

EPA uses an IPCC Tier 3 method for estimating CH_4 emissions from underground coal mining and an IPCC Tier 2 method for estimating CH_4 emissions from surface mining and post-mining activities (for coal production from both underground mines and surface mines) in accordance with methodological decisions trees in IPCC guidelines (Volume 2, Chapter 4, Figure 4.1.1 and 4.1.2) and available data (IPCC 2006). The methodology for estimating CH_4 emissions from coal mining consists of two steps:

- Estimate CH_4 emissions from underground mines. These emissions have two sources: ventilation systems and degasification systems. They are estimated using mine-specific data, then summed to determine total CH_4 liberated. The CH_4 recovered and used is then subtracted from this total, resulting in an estimate of net emissions to the atmosphere.
- Estimate CH_4 emissions from surface mines and post-mining activities. Unlike the methodology for underground mines, which uses mine-specific data, the methodology for estimating emissions from surface mines and post-mining activities consists of multiplying basin-specific coal production by basin-specific gas content and an emission factor.

Step 1: Estimate CH_4 Liberated and CH_4 Emitted from Underground Mines

Underground mines generate CH_4 from ventilation systems and degasification systems. Some mines recover and

use the liberated CH_4, thereby reducing emissions to the atmosphere. Total CH_4 emitted from underground mines equals the CH_4 liberated from ventilation systems, plus the CH_4 liberated from degasification systems, minus the CH_4 recovered and used.

Step 1.1: Estimate CH_4 Liberated from Ventilation Systems

To estimate CH_4 liberated from ventilation systems, EPA uses data collected through its Greenhouse Gas Reporting Program (GHGRP)[62] (Subpart FF, "Underground Coal Mines"), data provided by the U.S. Mine Safety and Health Administration (MSHA) (MSHA 2023), and occasionally data collected from other sources on a site-specific level (e.g., state gas production databases). Since 2011, the nation's "gassiest" underground coal mines—those that liberate more than 36,500,000 actual cubic feet of CH_4 per year (about 17,525 MT CO_2 Eq.)—have been required to report to EPA's GHGRP (EPA 2023).[63] Mines that report to EPA's GHGRP must report quarterly measurements of CH_4 emissions from ventilation systems; they have the option of recording and reporting their own measurements, or using the measurements taken by MSHA as part of that agency's quarterly safety inspections of all mines in the United States with detectable CH_4 concentrations.[64]

Since 2013, ventilation CH_4 emission estimates have been calculated based on both quarterly GHGRP data submitted by underground mines and on quarterly measurement data obtained directly from MSHA. Because not all mines report under EPA's GHGRP, the emissions of the mines that do not report must be calculated using MSHA data. The MSHA data also serves as a quality assurance tool for validating GHGRP data. For GHGRP data, reported quarterly ventilation methane emissions (metric tons) are summed for each mine to develop mine-specific annual ventilation emissions. For MSHA data, the average daily CH_4 emission rate for each mine is determined using the CH_4 total for all data measurement events conducted during the calendar year and total duration of all data measurement events (in days). The calculated average daily CH_4 emission rate is then multiplied by 365 days to estimate annual ventilation CH_4 emissions for the MSHA dataset.

Step 1.2: Estimate CH_4 Liberated from Degasification Systems

Particularly gassy underground mines also use degasification systems (e.g., wells or boreholes) to remove CH_4 before, during, or after mining. This CH_4 can then be collected for use or vented to the atmosphere. Nineteen mines used degasification systems in 2022 and all of these mines reported the CH_4 removed through these systems to EPA's GHGRP under Subpart FF (EPA 2023). Based on the weekly measurements reported to EPA's GHGRP, degasification data summaries for each mine are added to estimate the CH_4 liberated from degasification systems. Twelve of the 19 mines with degasification systems had operational CH_4 recovery and use projects, including two mines with two recovery and use projects each (see step 1.3 below).[65]

Degasification data reported to EPA's GHGRP by underground coal mines is the primary source of data used to develop estimates of CH_4 liberated from degasification systems. Data reported to EPA's GHGRP were used exclusively to estimate CH_4 liberated from degasification systems at 13 of the 19 mines that used degasification systems in 2022. Data from state gas well production databases were used to supplement GHGRP degasification data for the remaining six mines (DMME 2023; GSA 2023; WVGES 2023; McElroy OVS 2013).

---

[62] In implementing improvements and integrating data from EPA's GHGRP, EPA followed the latest guidance from the IPCC on the use of facility-level data in national inventories (IPCC 2011).

[63] Underground coal mines report to EPA under Subpart FF of the GHGRP (40 CFR Part 98). In 2022, 61 underground coal mines reported to the program.

[64] MSHA records coal mine CH_4 readings with concentrations of greater than 50 ppm (parts per million) CH_4. Readings below this threshold are considered non-detectable.

[65] Several of the mines venting CH_4 from degasification systems use a small portion of the gas to fuel gob well blowers in remote locations where electricity is not available. However, this CH_4 use is not considered to be a formal recovery and use project.

For pre-mining wells, cumulative degasification volumes that occur prior to the well being mined through are attributed to the mine in the inventory year in which the well is mined through.[66] EPA's GHGRP does not require gas production from virgin coal seams (coalbed methane) to be reported by coal mines under Subpart FF.[67] Most pre-mining wells drilled from the surface are considered coalbed methane wells prior to mine-through and associated CH_4 emissions are reported under another subpart of the GHGRP (Subpart W, "Petroleum and Natural Gas Systems"). As a result, GHGRP data must be supplemented to estimate cumulative degasification volumes that occurred prior to well mine-through. There were four mines with degasification systems that include pre-mining wells that were mined through in 2022. For all of these mines, GHGRP data were supplemented with historical data from state gas well production databases (ERG 2023; GSA 2023), as well as with mine-specific information regarding the locations and dates on which the pre-mining wells were mined through (JWR 2010; El Paso 2009; ERG 2023).

Step 1.3: Estimate CH_4 Recovered from Ventilation and Degasification Systems, and Utilized or Destroyed (Emissions Avoided)

Twelve mines had a total of fourteen CH_4 recovery and use projects in place in 2022, including two mines that each have two recovery and use projects. Thirteen of these projects involved degasification systems with one mine having a ventilation air methane abatement project (VAM). Eleven of these mines sold the recovered CH_4 to a pipeline, including one that also used CH_4 to fuel a thermal coal dryer. One mine destroyed the recovered CH_4 (VAM) using regenerative thermal oxidation (RTO) without energy recovery and using enclosed flares.

The CH_4 recovered and used (or destroyed) at the twelve mines described above are estimated using the following methods:

- EPA's GHGRP data was exclusively used to estimate the CH_4 recovered and used from six of the 12 mines that deployed degasification systems in 2022. Based on quarterly measurements, the GHGRP degasification destruction data summaries for each mine are added together to estimate the CH_4 recovered and used from degasification systems.
- State sales data were used to supplement GHGRP data to estimate CH_4 recovered and used from five mines that deployed degasification systems in 2022 (DMME 2023, ERG 2023, GSA 2023, and WVGES 2023). Four of these mines intersected pre-mining wells in 2022. Supplemental information is used for these mines because estimating CH_4 recovery and use from pre-mining wells requires additional data not reported under Subpart FF of EPA's GHGRP (see discussion in step 1.2 above) to account for the emissions avoided prior to the well being mined through. The supplemental data is obtained from state gas production databases as well as mine-specific information on the location and timing of mined-through pre-mining wells.
- For the single mine that employed VAM for CH_4 recovery and use, the estimates of CH_4 recovered and used were obtained from the mine's offset verification statement (OVS) submitted to the California Air Resources Board (CARB) (McElroy OVS 2023). This mine also reported CH_4 reductions from flaring. GHGRP data were used to estimate CH_4 recovered and flared in 2022.

Step 2: Estimate CH_4 Emitted from Surface Mines and Post-Mining Activities

Mine-specific data are not available for estimating CH_4 emissions from surface coal mines or for post-mining activities. For surface mines, basin-specific coal production obtained from the Energy Information Administration's *Annual Coal Report* (EIA 2023) is multiplied by basin-specific CH_4 contents (EPA 1996, 2005) and a 150 percent emission factor (to account for CH_4 from over- and under-burden) to estimate CH_4 emissions (King 1994; Saghafi

[66] A well is "mined through" when coal mining development or the working face intersects the borehole or well.

[67] This applies for pre-drainage in years prior to the well being mined through. Beginning with the year the well is mined through, the annual volume of CH_4 liberated from a pre-drainage well is reported under Subpart FF of EPA's GHGRP.

2013). For post-mining activities, basin-specific coal production is multiplied by basin-specific CH_4 contents and a mid-range 32.5 percent emission factor for CH_4 desorption during coal transportation and storage (Creedy 1993). Basin-specific in situ gas content data were compiled from AAPG (1984) and USBM (1986).

Fugitive CO_2 Emissions

Methane and CO_2 are naturally occurring in coal seams and are collectively referred to as coal seam gas. These gases remain trapped in the coal seam until coal is mined (i.e., coal seam is exposed and fractured during mining operations). Fugitive CO_2 emissions occur during underground coal mining, surface coal mining, and post-mining activities. Methods and data to estimate fugitive CO_2 emissions from underground and surface coal mining are presented in the sections below. Fugitive CO_2 emissions from post-mining activities were not estimated due to the lack of an IPCC method and unavailability of data.

Total fugitive CO_2 emissions in 2022 were estimated to be 2,474 kt (2.5 MMT CO_2 Eq.), a decline of approximately 46 percent since 1990. In 2022, underground mines accounted for approximately 89 percent of total fugitive CO_2 emissions. In 2022, total fugitive CO_2 emissions from coal mining increased by approximately 1 percent relative to the previous year. This increase was due to an increase in annual coal production.

Methodology and Time-Series Consistency

EPA uses an IPCC Tier 1 method for estimating fugitive CO_2 emissions from underground coal mining and surface mining in accordance with methodological decisions trees in IPCC guidelines (Volume 2, Chapter 4, Figure 4.1.1a) and available data (IPCC 2019). IPCC methods and data to estimate fugitive CO_2 emissions from post-mining activities (for both underground and surface coal mining) are currently not available.

Step 1: Underground Mining

EPA used the following overarching IPCC equation to estimate fugitive CO_2 emissions from underground coal mines (IPCC 2019):

Equation 3-1: Estimating Fugitive CO_2 Emissions from Underground Mines

$$Total\ CO_2\ from\ Underground\ Mines = CO_2\ from\ underground\ mining - Amount\ of\ CO_2\ in\ gas\ recovered + CO_2\ from\ methane\ flaring$$

Step 1.1: Estimate Fugitive CO_2 Emissions from Underground Mining

EPA estimated fugitive CO_2 emissions from underground mining using the IPCC Tier 1 emission factor (5.9 m^3/metric ton) and annual coal production from underground mines (EIA 2023). The underground mining default emission factor accounts for all the fugitive CO_2 likely to be emitted from underground coal mining. Therefore, the amount of CO_2 from coal seam gas recovered and utilized for energy is subtracted from underground mining estimates in Step 2, below. Under IPCC methods, the CO_2 emissions from gas recovered and utilized for energy use (e.g., injected into a natural gas pipeline) are reported under other sectors of the *Inventory* (e.g., stationary combustion of fossil fuel or oil and natural gas systems) and not under the coal mining sector.

Step 1.2: Estimate Amount of CO_2 In Coal Seam Gas Recovered for Energy Purposes

EPA estimated fugitive CO_2 emissions from coal seam gas recovered and utilized for energy purposes by using the IPCC Tier 1 default emission factor (19.57 metric tons CO_2/million cubic meters of coal bed methane (CBM) produced) and quantity of coal seam gas recovered and utilized. Data on annual quantity of coal seam gas recovered and utilized are available from GHGRP and state sales data (GHGRP 2023; DMME 2023; ERG 2023; GSA 2023; WVGES 2023). The quantity of coal seam gas recovered and destroyed without energy recovery (e.g., VAM projects with RTO) is deducted from the total coal seam gas recovered quantity (McElroy OVS 2023).

Step 1.3: Estimate Fugitive CO_2 Emissions from Flaring

The IPCC method includes combustion CO_2 emissions from gas recovered for non-energy uses (i.e., flaring, or catalytic oxidation) under fugitive CO_2 emission estimates for underground coal mining. In effect, these emissions, though occurring through stationary combustion, are categorized as fugitive emissions in the *Inventory*. EPA estimated CO_2 emissions from methane flaring using the following equation:

Equation 3-2: Estimating CO_2 Emissions from Drained Methane Flared or Catalytically Oxidized

$$CO_2\ from\ flaring = 0.98 \times Volume\ of\ methane\ flared \times Conversion\ Factor \times Stoichiometric\ Mass\ Factor$$

Currently there are three mines that report destruction of recovered methane through flaring without energy use. Annual data for 2022 were obtained from one mine's offset verification statement (OVS) submitted to the California Air Resources Board (CARB) and the GHGRP for the remaining two mines (McElroy OVS 2023; GHGRP 2023).

Step 2: Surface Mining

EPA estimated fugitive CO_2 emissions from surface mining using the IPCC Tier 1 emission factor (0.44 m^3/metric ton) and annual coal production from surface mines (EIA 2023).

Uncertainty

A quantitative uncertainty analysis was conducted for the coal mining source category using the IPCC-recommended Approach 2 uncertainty estimation methodology. Because emission estimates of CH_4 from underground ventilation systems were based on actual measurement data from EPA's GHGRP or from MSHA, uncertainty is relatively low. A degree of imprecision was introduced because the ventilation air measurements

used were not continuous but rather quarterly instantaneous readings that were used to determine the average annual emission rates. Additionally, the measurement equipment used can be expected to have resulted in an average of 10 percent overestimation of annual CH_4 emissions (Mutmansky & Wang 2000). Equipment measurement uncertainty is applied to GHGRP data.

Estimates of CH_4 liberated and recovered by degasification systems are relatively certain for utilized CH_4 because of the availability of EPA's GHGRP data and state gas sales information. Many of the liberation and recovery estimates use data on wells within 100 feet of a mined area. However, uncertainty exists concerning the radius of influence of each well. The number of wells counted, and thus the liberated CH_4 and avoided emissions, may vary if the drainage area is found to be larger or smaller than estimated.

EPA's GHGRP requires weekly CH_4 monitoring of mines that report degasification systems, and continuous CH_4 monitoring is required for CH_4 utilized on- or off-site. Since 2012, GHGRP data have been used to estimate CH_4 emissions from vented degasification wells, reducing the uncertainty associated with prior MSHA estimates used for this sub-source. Beginning in 2013, GHGRP data were also used for determining CH_4 recovery and use at mines without publicly available gas usage or sales records, which has reduced the uncertainty from previous estimation methods that were based on information from coal industry contacts.

Surface mining and post-mining emissions are associated with considerably more uncertainty than underground mines, because of the difficulty in developing accurate emission factors from field measurements. However, since underground coal mining, as a general matter, results in significantly larger CH_4 emissions due to production of higher-rank coal and greater depth, and estimated emissions from underground mining constitute the majority of estimated total coal mining CH_4 emissions, the uncertainty associated with underground emissions is the primary factor that determines overall uncertainty.

The major sources of uncertainty for estimates of fugitive CO_2 emissions are the Tier 1 IPCC default emission factors used for underground mining (-50 percent to +100 percent) and surface mining (-67 percent to +200 percent) (IPCC 2019). Additional sources of uncertainty for fugitive CO_2 emission estimates include EIA's annual coal production data and data used for gas recovery projects, such as GHGRP data, state gas sales data, and VAM estimates for the single mine that operates an active VAM project. Uncertainty ranges for these additional data sources are already available, as these are the same data sources used for CH_4 emission estimates.

The results of the Approach 2 quantitative uncertainty analysis are summarized in Table 3-38. Coal mining CH_4 emissions in 2022 were estimated to be between 34.8 and 47.8 MMT CO_2 Eq. at a 95 percent confidence level. This indicates a range of 20.3 percent below to 9.5 percent above the 2022 emission estimate of 43.6 MMT CO_2 Eq. Coal mining fugitive CO_2 emissions in 2022 were estimated to be between 0.8 and 4.3 MMT CO_2 Eq. at a 95 percent confidence level. This indicates a range of 68.5 percent below to 75.4 percent above the 2022 emission estimate of 2.5 MMT CO_2 Eq.

Table 3-38: Approach 2 Quantitative Uncertainty Estimates for CH_4 and CO_2 Emissions from Coal Mining (MMT CO_2 Eq. and Percent)

Source	Gas	2022 Emission Estimate (MMT CO_2 Eq.)	Uncertainty Range Relative to Emission Estimate[a] (MMT CO_2 Eq.)		(%)	
			Lower Bound	Upper Bound	Lower Bound	Upper Bound
Coal Mining	CH_4	43.6	34.8	47.8	-20%	+9%
Coal Mining	CO_2	2.5	0.8	4.3	-69%	+75%

[a] Range of emission estimates predicted by Monte Carlo stochastic simulation for a 95 percent confidence interval.

QA/QC and Verification

In order to ensure the quality of the emission estimates for coal mining, general (IPCC Tier 1) and category-specific (Tier 2) Quality Assurance/Quality Control (QA/QC) procedures were implemented consistent with the U.S. Inventory QA/QC plan outlined in Annex 8. The Tier 2 procedures that were implemented involved checks specifically focusing on the activity data and reported emissions data used for estimating fugitive emissions from

coal mining. Trends across the time series were analyzed to determine whether any corrective actions were needed.

Emission estimates for coal mining rely in large part on data reported by coal mines to EPA's GHGRP. EPA verifies annual facility-level reports through a multi-step process to identify potential errors and ensure that data submitted to EPA are accurate, complete, and consistent. All reports submitted to EPA are evaluated by electronic validation and verification checks. If potential errors are identified, EPA will notify the reporter, who can resolve the issue either by providing an acceptable response describing why the flagged issue is not an error or by correcting the flagged issue and resubmitting their annual report. Additional QA/QC and verification procedures occur for each GHGRP subpart. No QA/QC issues or errors were identified in the 2022 Subpart FF data.

Recalculations Discussion

Time series recalculations were performed due to revised historical data from state natural gas sales databases for five mines, which are used to estimate avoided CH_4 emissions. Additionally, calculation errors were identified and corrected for CH_4 emissions avoided from two mines. As a result of recalculations, CH_4 emissions decreased by an average of 0.03 percent across the time series, compared to the previous *Inventory*. The biggest increase in CH_4 emissions was in 1991 where emissions increased by 0.14 percent, compared to the previous *Inventory*. The biggest decrease in CH_4 emissions was in 2006 (0.6 percent). As a result of recalculations, there was a very minor decrease in CH_4 emissions in 2021 (less than 0.005 percent), compared to the previous *Inventory*.

Planned Improvements

EPA is assessing planned improvements for future reports, but at this time has no specific planned improvements for estimating CH_4 and CO_2 emissions from underground and surface mining and CH_4 emissions from post-mining.

3.5 Abandoned Underground Coal Mines (CRT Source Category 1B1a)

Underground coal mines contribute the largest share of coal mine methane (CMM) emissions, with active underground mines the leading source of underground emissions. However, mines also continue to release CH_4 after closure. As mines mature and coal seams are mined through, mines are closed and abandoned. Many are sealed and some flood through intrusion of groundwater or surface water into the void. Shafts or portals are generally filled with gravel and capped with a concrete seal, while vent pipes and boreholes are plugged in a manner similar to oil and gas wells. Some abandoned mines are vented to the atmosphere to prevent the buildup of CH_4 that may find its way to surface structures through overburden fractures. As work stops within the mines, CH_4 liberation decreases but it does not stop completely. Following an initial decline, abandoned mines can liberate CH_4 at a near-steady rate over an extended period of time, or if flooded, produce gas for only a few years. The gas can migrate to the surface through the conduits described above, particularly if they have not been sealed adequately. In addition, diffuse emissions can occur when CH_4 migrates to the surface through cracks and fissures in the strata overlying the coal mine. The following factors influence abandoned mine emissions:

- Time since abandonment;
- Gas content and adsorption characteristics of coal;
- CH_4 flow capacity of the mine;
- Mine flooding;
- Presence of vent holes; and
- Mine seals.

Annual gross abandoned mine CH_4 emissions ranged from 8.1 to 12.1 MMT CO_2 Eq. from 1990 to 2022, varying, in general, by less than 1 percent to approximately 19 percent from year to year. Fluctuations were due mainly to the number of mines closed during a given year as well as the magnitude of the emissions from those mines when active. Gross abandoned mine emissions peaked in 1996 (12.1 MMT CO_2 Eq.) due to the large number of gassy mine[68] closures from 1994 to 1996 (72 gassy mines closed during the three-year period). In spite of this rapid rise, abandoned mine emissions have been generally on the decline since 1996. Since 2002, there have been fewer than twelve gassy mine closures each year. In 2022 there was one gassy mine closure. Gross abandoned mine emissions decreased slightly from 9.2 MMT CO_2 Eq. (330 kt CH_4) in 2021 to 9.1 (324 kt CH_4) MMT CO_2 Eq. in 2022 (see Table 3-39 and Table 3-40). Gross emissions are reduced by CH_4 recovered and used at 51 mines, resulting in net emissions in 2022 of 6.3 MMT CO_2 Eq. (225 kt CH_4).

Table 3-39: CH_4 Emissions from Abandoned Coal Mines (MMT CO_2 Eq.)

Activity	1990	2005	2018	2019	2020	2021	2022

Methodology and Time-Series Consistency

Estimating CH_4 emissions from an abandoned coal mine requires predicting the emissions of a mine from the time of abandonment through the inventory year of interest. The flow of CH_4 from the coal to the mine void is primarily dependent on the mine's emissions when active and the extent to which the mine is flooded or sealed. The CH_4 emission rate before abandonment reflects the gas content of the coal, the rate of coal mining, and the flow capacity of the mine in much the same way as the initial rate of a water-free conventional gas well reflects the gas content of the producing formation and the flow capacity of the well. A well or a mine that produces gas from a coal seam and the surrounding strata will produce less gas through time as the reservoir of gas is depleted. Depletion of a reservoir will follow a predictable pattern depending on the interplay of a variety of natural physical conditions imposed on the reservoir. The depletion of a reservoir is commonly modeled by mathematical equations and mapped as a type curve. Type curves, which are referred to as decline curves, have been developed for abandoned coal mines. Existing data on abandoned mine emissions through time, although sparse, appear to fit the hyperbolic type of decline curve used in forecasting production from natural gas wells.

There are sufficient mine level data available to establish decline curves for individual gassy mines abandoned since 1972. For mines abandoned prior to 1972, county level data are available. Mine status information (i.e., whether a mine is sealed, venting, or flooded) is not available for all the abandoned gassy mines. Therefore, a hybrid Tier 2/Tier 3 method was developed to model abandoned gassy mine emissions using Monte Carlo simulations. Tier 3 calculations are used for mines with known status information where decline curves can be used to directly estimate abandoned mine emissions. For mines with unknown status, a Tier 2 approach that estimates basin level emissions is used. This Tier 2 approach relies on data from other mines with known status

[68] A mine is considered a "gassy" mine if it emits more than 100 thousand cubic feet of CH_4 per day (100 Mcfd).

and located within the same basin as the unknown status mines. This approach is consistent with the IPCC 2006 Guidelines as underground mines can be considered point sources and measurement methods are available.

To estimate CH_4 emissions over time for a given abandoned mine, it is necessary to apply a decline function, initiated upon abandonment, to that mine. In the analysis, mines were grouped by coal basin with the assumption that they will generally have the same initial pressures, permeability, and isotherm. As CH_4 leaves the system, the reservoir pressure (Pr) declines as described by the isotherm's characteristics. The emission rate declines because the mine pressure (Pw) is essentially constant at atmospheric pressure for a vented mine, and the productivity index (PI), which is expressed as the flow rate per unit of pressure change, is essentially constant at the pressures of interest (atmospheric to 30 psia). The CH_4 flow rate is determined by the laws of gas flow through porous media, such as Darcy's Law. A rate-time equation can be generated that can be used to predict future emissions. This decline through time is hyperbolic in nature and can be empirically expressed as:

Equation 3-3: Decline Function to Estimate Venting Abandoned Mine Methane Emissions

$$q = q_i \left(1 + bD_i t\right)^{\left(-\frac{1}{b}\right)}$$

where,

q = Gas flow rate at time t in million cubic feet per day (mmcfd)

q_i = Initial gas flow rate at time zero (t_o), mmcfd

b = The hyperbolic exponent, dimensionless

D_i = Initial decline rate, 1/year

t = Elapsed time from t_o (years)

This equation is applied to mines of various initial emission rates that have similar initial pressures, permeability, and adsorption isotherms (EPA 2004).

The decline curves created to model the gas emission rate of coal mines must account for factors that decrease the rate of emissions after mining activities cease, such as sealing and flooding. Based on field measurement data, it was assumed that most U.S. mines prone to flooding will become completely flooded within eight years and therefore will no longer have any measurable CH_4 emissions. Based on this assumption, an average decline rate for flooded mines was established by fitting a decline curve to emissions from field measurements. An exponential equation was developed from emissions data measured at eight abandoned mines known to be filling with water located in two of the five basins. Using a least squares, curve-fitting algorithm, emissions data were matched to the exponential equation shown below. For this analysis of flooded abandoned mines, there was not enough data to establish basin-specific equations, as was done with the vented, non-flooding mines (EPA 2004). This decline through time can be empirically expressed as:

Equation 3-4: Decline Function to Estimate Flooded Abandoned Mine Methane Emissions

$$q = q_i e^{(-Dt)}$$

where,

q = Gas flow rate at time t in mmcfd

q_i = Initial gas flow rate at time zero (t_o), mmcfd

D = Decline rate, 1/year

t = Elapsed time from t_o (years)

Seals have an inhibiting effect on the rate of flow of CH_4 into the atmosphere compared to the flow rate that would exist if the mine had an open vent. The total volume emitted will be the same, but emissions will occur over a longer period of time. The methodology, therefore, treats the emissions prediction from a sealed mine similarly to the emissions prediction from a vented mine, but uses a lower initial rate depending on the degree of sealing. A

computational fluid dynamics simulator was used with the conceptual abandoned mine model to predict the decline curve for inhibited flow. The percent sealed is defined as 100 × (1 – [initial emissions from sealed mine / emission rate at abandonment prior to sealing]). Significant differences are seen between 50 percent, 80 percent, and 95 percent closure. These decline curves were therefore used as the high, middle, and low values for emissions from sealed mines (EPA 2004).

For active coal mines, those mines producing over 100 thousand cubic feet per day (Mcfd) of CH_4 account for about 98 percent of all CH_4 emissions. This same relationship is assumed for abandoned mines. It was determined that the 531 abandoned mines closed since 1972 produced CH_4 emissions greater than 100 Mcfd when active. Further, the status of 307 of the 531 mines (or 58 percent) is known to be either: 1) vented to the atmosphere; 2) sealed to some degree (either earthen or concrete seals); or 3) flooded (enough to inhibit CH_4 flow to the atmosphere). The remaining 42 percent of the mines whose status is unknown were placed in one of these three categories by applying a probability distribution analysis based on the known status of other mines located in the same coal basin (EPA 2004). Table 3-41 presents the count of mines by post-abandonment state, based on EPA's probability distribution analysis.

Table 3-41: Number of Gassy Abandoned Mines Present in U.S. Basins in 2022, Grouped by Class According to Post-Abandonment State

Basin	Sealed	Vented	Flooded	Total Known	Unknown	Total Mines
Central Appl.	43	25	50	118	144	262
Illinois	35	3	14	52	31	83
Northern Appl.	49	23	15	87	39	126
Warrior Basin	0	0	16	16	0	16
Western Basins	28	4	2	34	10	44
Total	**155**	**55**	**97**	**307**	**224**	**531**

Note: Totals may not sum due to independent rounding.

Inputs to the decline equation require the average CH_4 emission rate prior to abandonment and the date of abandonment. Generally, these data are available for mines abandoned after 1971; however, such data are largely unknown for mines closed before 1972. Information that is readily available, such as coal production by state and county, is helpful but does not provide enough data to directly employ the methodology used to calculate emissions from mines abandoned before 1972. It is assumed that pre-1972 mines are governed by the same physical, geologic, and hydrologic constraints that apply to post-1971 mines; thus, their emissions may be characterized by the same decline curves.

During the 1970s, 78 percent of CH_4 emissions from coal mining came from seventeen counties in seven states. Mine closure dates were obtained for two states, Colorado and Illinois, for the hundred-year period extending from 1900 through 1999. The data were used to establish a frequency of mine closure histogram (by decade) and applied to the other five states with gassy mine closures. As a result, basin-specific decline curve equations were applied to the 145 gassy coal mines estimated to have closed between 1920 and 1971 in the United States, representing 78 percent of the emissions. State-specific, initial emission rates were used based on average coal mine CH_4 emission rates during the 1970s (EPA 2004).

Abandoned mine emission estimates are based on all closed mines known to have active mine CH_4 ventilation emission rates greater than 100 Mcfd at the time of abandonment. For example, for 1990 the analysis included 145 mines closed before 1972 and 258 mines closed between 1972 and 1990. Initial emission rates based on MSHA reports, time of abandonment, and basin-specific decline curves influenced by a number of factors were used to calculate annual emissions for each mine in the database (MSHA 2023). Coal mine degasification data are not available for years prior to 1990, thus the initial emission rates used reflect only ventilation emissions for pre-1990 closures. Methane degasification amounts were added to the quantity of CH_4 vented to determine the total CH_4 liberation rate for all mines that closed between 1992 and 2022. Since the sample of gassy mines described above is assumed to account for 78 percent of the pre-1972 and 98 percent of the post-1971 abandoned mine emissions, the modeled results were multiplied by 1.22 and 1.02, respectively, to account for all U.S. abandoned mine emissions.

From 1993 through 2022, emission totals were downwardly adjusted to reflect CH_4 emissions avoided from abandoned mines with CH_4 recovery and use or destruction systems. Currently, there are 51 abandoned mines with recovery projects, including 11 projects at mines abandoned before 1972 (pre-1972 mines) (EPA 2004, CMOP 2022). Because CH_4 recovered by these projects is expected to decline with the age of the mine, CH_4 recovery is assumed to be the total estimated CH_4 liberated based on the mine's decline function except for three recovery projects where additional data are available (COGIS 2018, MSHA 2023).[69]

The *Inventory* totals were not adjusted for abandoned mine CH_4 emissions avoided from 1990 through 1992 due to unavailability of data. Avoided CH_4 emissions from pre-1972 abandoned mines are estimated by multiplying the total estimated emissions from these mines in each decade by the fraction of mines with recovery projects in that decade. For recovery projects at pre-1972 abandoned mines, four projects are at mines abandoned in the 1920s, three in the 1930s, two in the 1950s, and two in the 1960s (EPA 2004).

Reviewing Coalbed Methane Outreach Program data (CMOP 2023) revealed four additional recovery projects starting in 2021. In addition to reviewing CMOP data, the recovery project list was checked against the International Coal Mine Methane Database (GMI 2021). Of the 24 operational recovery projects for U.S. abandoned coal mines currently available in the GMI dataset, 18 are already included in the AMM model. The remaining six projects in the GMI dataset are for mines that are not yet abandoned according to MSHA records (MSHA 2023). Therefore, no new recovery projects were added from the GMI database for the 1990 through 2022 *Inventory*.

Uncertainty

A quantitative uncertainty analysis was conducted for the abandoned coal mine source category using the IPCC-recommended Approach 2 uncertainty estimation methodology. The uncertainty analysis provides for the specification of probability density functions for key variables within a computational structure that mirrors the calculation of the *Inventory* estimate. The results provide the range within which, with 95 percent certainty, emissions from this source category are likely to fall.

As discussed above, the parameters for which values must be estimated for each mine to predict its decline curve are: 1) the coal's adsorption isotherm; 2) CH_4 flow capacity as expressed by permeability; and 3) pressure at abandonment. Because these parameters are not available for each mine, a methodological approach to estimating emissions was used that generates a probability distribution of potential outcomes based on the most likely value and the probable range of values for each parameter. The range of values is not meant to capture the extreme values, but rather values that represent the highest and lowest quartile of the cumulative probability density function of each parameter. Once the low, mid, and high values are selected, they are applied to a probability density function.

The results of the Approach 2 quantitative uncertainty analysis are summarized in Table 3-42. Annual abandoned coal mine CH_4 emissions in 2022 were estimated to be between 5.0 and 7.5 MMT CO_2 Eq. at a 95 percent confidence level. This indicates a range of 21 percent below to 20 percent above the 2022 emission estimate of 6.3 MMT CO_2 Eq. One of the reasons for the relatively narrow range is that mine-specific data is available for use in the methodology for mines closed in 1972 and later years. Emissions from mines closed prior to 1972 have the largest degree of uncertainty because no mine-specific CH_4 liberation rates at the time of abandonment exist.

[69] Data from a state oil and gas database (COGIS) is used for one project and the mine status information from MSHA for two mines (sealed and flooded) indicate zero recovery emissions for these projects.

Table 3-42: Approach 2 Quantitative Uncertainty Estimates for CH_4 Emissions from Abandoned Underground Coal Mines (MMT CO_2 Eq. and Percent)

Source	Gas	2022 Emission Estimate (MMT CO_2 Eq.)	Uncertainty Range Relative to Emission Estimate[a] (MMT CO_2 Eq.)		(%)	
			Lower Bound	Upper Bound	Lower Bound	Upper Bound
Abandoned Underground Coal Mines	CH_4	6.3	5.0	7.5	-21%	+20%

[a] Range of emission estimates predicted by Monte Carlo Simulation for a 95 percent confidence interval.

QA/QC and Verification

In order to ensure the quality of the emission estimates for abandoned coal mines, general (IPCC Tier 1) and category-specific (Tier 2) Quality Assurance/Quality Control (QA/QC) procedures were implemented consistent with the U.S. Inventory QA/QC plan outlined in Annex 8. The Tier 2 procedures that were implemented involved checks specifically focusing on the activity data and reported emissions data used for estimating emissions from abandoned coal mines. Trends across the time series were analyzed to determine whether any corrective actions were needed.

Recalculations Discussion

Four new abandoned mine methane recovery projects were added to the AMM model during the current *Inventory* (CMOP 2023). CMOP data indicate these recovery projects were started in 2021. Time series recalculations were performed for 2021. As a result of recalculations, CH_4 emissions decreased by 2 percent in 2021, compared to the previous *Inventory*.

3.6 Petroleum Systems (CRT Source Category 1B2a)

This category (1B2a) is defined in the IPCC methodological guidance as fugitive emissions from petroleum systems, which per IPCC guidelines include emissions from leaks, venting, and flaring. Methane emissions from petroleum systems are primarily associated with onshore and offshore crude oil exploration, production, transportation, and refining operations. During these activities, CH_4 is released to the atmosphere as emissions from leaks, venting (including emissions from operational upsets), and flaring. Carbon dioxide emissions from petroleum systems are primarily associated with onshore and offshore crude oil production and refining operations. Note, CO_2 emissions in petroleum systems exclude all combustion emissions (e.g., engine combustion) except for flaring CO_2 emissions. All combustion CO_2 emissions (except for flaring) are accounted for in the fossil fuel combustion chapter (see Section 3.1). Emissions of N_2O from petroleum systems are primarily associated with flaring. Total greenhouse gas emissions (CH_4, CO_2, and N_2O) from petroleum systems in 2022 were 61.6 MMT CO_2 Eq., an increase of 4 percent from 1990, primarily due to increases in CO_2 emissions. Total emissions decreased by 6 percent from 2010 levels and have decreased by 15 percent since 2021. Total CO_2 emissions from petroleum systems in 2022 were 21.97 MMT CO_2 (21,967 kt CO_2), 2.3 times higher than in 1990. Total CO_2 emissions in 2022 were 1.6 times higher than in 2010 and 9 percent lower than in 2021. Total CH_4 emissions from petroleum systems in 2022 were 39.6 MMT CO_2 Eq. (1,415 kt CH_4), a decrease of 20 percent from 1990. Since 2010, total CH_4 emissions decreased by 24 percent; and since 2021, CH_4 emissions decreased by 19 percent. Total N_2O emissions from petroleum systems in 2022 were 0.048 MMT CO_2 Eq. (0.179 kt N_2O), 3.8 times higher than in 1990, 2.8 times higher than in 2010, and 142 percent higher than in 2021. Since 1990, U.S. oil production has increased by 56 percent. In 2022, U.S. oil production was 163 percent higher than in 2010 and 7 percent higher than in 2021.

Each year, some estimates in the *Inventory* are recalculated with improved methods and/or data. These improvements are implemented consistently across the entire *Inventory's* time series (i.e., 1990 to 2022) to ensure that the trend is representative of changes in emissions levels. Recalculations in petroleum systems in this year's *Inventory* include:

- Updates to oil and gas production volumes, produced water production volumes, and well counts using the most recent data from Enverus.
- Updates to oil and gas production volumes using the most recent data from the United States Energy Information Administration (EIA)
- Recalculations due to Greenhouse Gas Reporting Program (GHGRP) submission revisions
- Recalculations due to methodological updates to completions and workovers.

The Recalculations Discussion section below provides more details on the updated methods.

Exploration. Exploration includes well drilling, testing, and completions. Exploration accounts for less than 0.5 percent of total CH_4 emissions (including leaks, vents, and flaring) from petroleum systems in 2022. The predominant sources of CH_4 emissions from exploration are hydraulically fractured oil well completions. Other sources include well testing, well drilling, and well completions without hydraulic fracturing. Since 1990, exploration CH_4 emissions have decreased 96 percent, and while the number of hydraulically fractured wells completed increased 64 percent, there were decreases in the fraction of such completions without reduced emissions completions (RECs) or flaring. Emissions of CH_4 from exploration were highest in 2008, over 70 times higher than in 2022; and lowest in 2022. Emissions of CH_4 from exploration decreased 39 percent from 2021 to 2022, due to a decrease in emissions from hydraulically fractured oil well completions with RECs. Exploration accounts for 1 percent of total CO_2 emissions (including leaks, vents, and flaring) from petroleum systems in 2022. Emissions of CO_2 from exploration in 2022 were 25 percent lower than in 1990, and decreased by 50 percent from 2021, largely due to a decrease in emissions from hydraulically fractured oil well completions with REC and flaring (by 58 percent from 2021). Emissions of CO_2 from exploration were highest in 2014, over 13 times higher than in 2022. Exploration accounts for less than 0.5 percent of total N_2O emissions from petroleum systems in 2022. Emissions of N_2O from exploration in 2022 are 29 percent lower than in 1990, and 56 percent lower than in 2021, due to hydraulically fractured oil well completions with flaring.

Production. Production accounts for 97 percent of total CH_4 emissions (including leaks, vents, and flaring) from petroleum systems in 2022. The predominant sources of emissions from production field operations are pneumatic controllers, offshore oil platforms, equipment leaks, produced water, gas engines, chemical injection pumps, and associated gas flaring. In 2022, these seven sources together accounted for 93 percent of the CH_4 emissions from production. Since 1990, CH_4 emissions from production have decreased by 15 percent primarily due to decreases in emissions from offshore production. Overall, production segment CH_4 emissions decreased by 19 percent from 2021 levels due primarily to lower pneumatic controller emissions. Production emissions account for 86 percent of the total CO_2 emissions (including leaks, vents, and flaring) from petroleum systems in 2022. The principal sources of CO_2 emissions are associated gas flaring, miscellaneous production flaring, and oil tanks with flares. In 2022, these three sources together accounted for 96 percent of the CO_2 emissions from production. In 2022, CO_2 emissions from production were 3.1 times higher than in 1990, due to increases in flaring emissions from associated gas flaring, miscellaneous production flaring, and tanks. Overall, in 2022, production segment CO_2 emissions decreased by 8 percent from 2021 levels primarily due to decreases in associated gas flaring in the Williston Basin and oil tanks with flares. Production emissions accounted for 84 percent of the total N_2O emissions from petroleum systems in 2022. The principal sources of N_2O emissions are oil tanks with flares and associated gas flaring, accounting for 90% of N_2O emissions from the production segment in 2022. In 2022, N_2O emissions from production were 8.0 times higher than in 1990 and were 3.5 times higher than in 2021.

Crude Oil Transportation. Emissions from crude oil transportation account for a very small percentage of the total emissions (including leaks, vents, and flaring) from petroleum systems. Crude oil transportation activities account for 0.6 percent of total CH_4 emissions from petroleum systems. Emissions from tanks, marine loading, and truck loading operations accounted for 81 percent of CH_4 emissions from crude oil transportation in 2022. Since 1990,

CH_4 emissions from transportation have increased by 27 percent. In 2022, CH_4 emissions from transportation increased by 6 percent from 2021 levels. Crude oil transportation activities account for less than 0.01 percent of total CO_2 emissions from petroleum systems. Emissions from tanks, marine loading, and truck loading operations account for 81 percent of CO_2 emissions from crude oil transportation.

Crude Oil Refining. Crude oil refining processes and systems account for 2 percent of total fugitive (including leaks, vents, and flaring) CH_4 emissions from petroleum systems in 2022. This low share is because most of the CH_4 in crude oil is removed or escapes before the crude oil is delivered to the refineries. There is a negligible amount of CH_4 in all refined products. Within refineries, flaring accounts for 42 percent of the CH_4 emissions, while delayed cokers, uncontrolled blowdowns, and equipment leaks account for 19, 14 and 11 percent, respectively. Fugitive CH_4 emissions from refining of crude oil have decreased by 4 percent since 1990, and decreased by 3 percent from 2021; however, like the transportation subcategory, this increase has had little effect on the overall emissions of CH_4 from petroleum systems. Crude oil refining processes and systems account for 13 percent of total fugitive (including leaks, vents, and flaring) CO_2 emissions from petroleum systems. Of the total fugitive CO_2 emissions from refining, almost all (about 99 percent) of it comes from flaring.[70] Since 1990, refinery fugitive CO_2 emissions decreased by 10 percent and have decreased by 5 percent from 2021 levels, due to a decrease in flaring. Flaring occurring at crude oil refining processes and systems accounts for 16 percent of total fugitive N_2O emissions from petroleum systems. In 2022, refinery fugitive N_2O emissions increased by 4 percent since 1990 and decreased by 5 percent from 2021 levels.

[70] Petroleum Systems includes fugitive emissions (leaks, venting, and flaring). In many industries, including petroleum refineries, the largest source of onsite CO_2 emissions is often fossil fuel combustion, which is covered in Section 3.1 of this chapter.

Methodology and Time-Series Consistency

See Annex 3.5 for the full time series of emissions data, activity data, emission factors, and additional information on methods and data sources.

Petroleum systems includes emission estimates for activities occurring in petroleum systems from the oil wellhead through crude oil refining, including activities for crude oil exploration, production field operations, crude oil transportation activities, and refining operations. Generally, emissions are estimated for each activity by multiplying emission factors (e.g., emission rate per equipment or per activity) by corresponding activity data (e.g., equipment count or frequency of activity). Certain sources within petroleum refineries are developed using an IPCC Tier 3 approach (i.e., all refineries in the nation report facility-level emissions data to the GHGRP, which are included directly in the national emissions estimates here). Other estimates are developed with a Tier 2 approach. Tier 1 approaches are not used.

EPA did not receive stakeholder feedback on updates in the *Inventory* through EPA's stakeholder process on oil and gas in the *Inventory*. More information on the stakeholder process can be found online.[71]

Emission Factors. Key references for emission factors include *Methane Emissions from the Natural Gas Industry by the Gas Research Institute and EPA* (GRI/EPA 1996), *Estimates of Methane Emissions from the U.S. Oil Industry* (EPA 1999), *Compilation of Air Pollutant Emission Factors, AP-42* (EPA 1997), *Global Emissions of Methane from Petroleum Sources* (API 1992), consensus of industry peer review panels, Bureau of Ocean Energy Management (BOEM) reports, *Nonpoint Oil and Gas Emission Estimation Tool* (EPA 2017), and analysis of GHGRP data (EPA 2023).

Emission factors for hydraulically fractured (HF) oil well completions and workovers (in four control categories) were developed at the basin level using EPA's GHGRP data; year-specific data were used to calculate basin-specific emission factors from 2016-forward and the year 2016 emission factors were applied to all prior years in the time series. For basins not reporting to the GHGRP, Subpart W average emission factors were used. For more information, please see the 2023 memoranda available online.[72]

The emission factors for well testing and associated gas venting and flaring were developed using year-specific GHGRP data for years 2015 forward; earlier years in the time series use 2015 emission factors. For miscellaneous production flaring, year-specific emission factors were developed for years 2015 forward from GHGRP data, an emission factor of 0 (assumption of no flaring) was assumed for 1990 through 1992, and linear interpolation was applied to develop emission factors for 1993 through 2014. For more information, please see memoranda available online.[73] For offshore oil production, emission factors were calculated using BOEM data for offshore facilities in federal waters of the Gulf of Mexico (and these data were also applied to facilities located in state waters of the Gulf of Mexico) and GHGRP data for offshore facilities off the coasts of California and Alaska. For

[71] See https://www.epa.gov/ghgemissions/natural-gas-and-petroleum-systems.

[72] See https://www.epa.gov/ghgemissions/natural-gas-and-petroleum-systems.

[73] See https://www.epa.gov/ghgemissions/natural-gas-and-petroleum-systems.

many other sources, emission factors were held constant for the period 1990 through 2022, and trends in emissions reflect changes in activity levels. Emission factors from EPA 1999 are used for all other production and transportation activities.

For associated gas venting and flaring and miscellaneous production flaring, emission factors were developed on a production basis (i.e., emissions per unit oil produced). Additionally, for these two sources, basin-specific activity and emission factors were developed for each basin that in any year from 2011 forward contributed at least 10 percent of total source emissions (on a CO_2 Eq. basis) in the GHGRP. For associated gas venting and flaring, basin-specific factors were developed for four basins: Williston, Permian, Gulf Coast, and Anadarko. For miscellaneous production flaring, basin-specific factors were developed for three basins: Williston, Permian, and Gulf Coast. For each source, data from all other basins were combined, and activity and emission factors were developed for the other basins as a single group.

For pneumatic controllers and tanks, basin-specific emission factors were calculated for all the basins reporting to the GHGRP. These emission factors were calculated for all the years with applicable GHGRP data (i.e., 2011 - 2022 or 2015 - 2022). For the remaining basins (i.e., basins not reporting to the GHGRP), Subpart W average emission factors were used. For more information, please see memoranda available online.[3]

For the exploration and production segments, in general, CO_2 emissions for each source were estimated with GHGRP data or by multiplying CO_2 content factors by the corresponding CH_4 data, as the CO_2 content of gas relates to its CH_4 content. Sources with CO_2 emission estimates calculated using GHGRP data include HF completions and workovers, associated gas venting and flaring, tanks, well testing, pneumatic controllers, chemical injection pumps, miscellaneous production flaring, and certain offshore production facilities (those located off the coasts of California and Alaska). For these sources, CO_2 was calculated using the same methods as used for CH_4. Carbon dioxide emission factors for offshore oil production in the Gulf of Mexico were derived using data from BOEM, following the same methods as used for CH_4 estimates. For other sources, the production field operations emission factors for CO_2 are generally estimated by multiplying the CH_4 emission factors by a conversion factor, which is the ratio of CO_2 content and CH_4 content in produced associated gas.

For the exploration and production segments, N_2O emissions were estimated for flaring sources using GHGRP or BOEM OGOR-B data and the same method used for CO_2. Sources with N_2O emissions in the exploration segment include well testing and HF completions with flaring. Sources with N_2O emissions in the production segment include associated gas flaring, tank flaring, miscellaneous production flaring, HF workovers with flaring, and flaring from offshore production sources.

For crude oil transportation, emission factors for CH_4 were largely developed using data from EPA (1997), API (1992), and EPA (1999). Emission factors for CO_2 were estimated by multiplying the CH_4 emission factors by a conversion factor, which is the ratio of CO_2 content and CH_4 content in whole crude post-separator.

For petroleum refining activities, year-specific emissions from 2010 forward were directly obtained from EPA's GHGRP. All U.S. refineries have been required to report CH_4, CO_2, and N_2O emissions for all major activities starting with emissions that occurred in 2010. The reported total CH_4, CO_2, and N_2O emissions for each activity was used for the emissions in each year from 2010 forward. To estimate emissions for 1990 to 2009, the 2010 to 2013 emissions data from GHGRP along with the refinery feed data for 2010 to 2013 were used to derive CH_4 and CO_2 emission factors (i.e., sum of activity emissions/sum of refinery feed) and 2010 to 2017 data were used to derive N_2O emission factors; these emission factors were then applied to the annual refinery feed in years 1990 to 2009. GHGRP delayed coker CH_4 emissions for 2010 through 2017 were increased using the ratio of certain reported emissions for 2018 to 2017, to account for a more accurate GHGRP calculation methodology that was implemented starting in reporting year 2018.

A complete list of references for emission factors and activity data by emission source is provided in Annex 3.5.

Activity Data. References for activity data include Enverus data (Enverus 2023), Energy Information Administration (EIA) reports, *Methane Emissions from the Natural Gas Industry by the Gas Research Institute and EPA* (EPA/GRI 1996), *Estimates of Methane Emissions from the U.S. Oil Industry* (EPA 1999), consensus of industry peer review panels, BOEM reports, the Oil & Gas Journal, the Interstate Oil and Gas Compact Commission, the United States Army Corps of Engineers, and analysis of GHGRP data (EPA 2023).

For HF oil well completions and workovers, pneumatic controllers, equipment leaks, chemical injection pumps, and tanks, basin-specific activity factors were calculated for all the basins reporting to the GHGRP. These factors were calculated for all the years with applicable GHGRP data (i.e., 2011 through 2022, 2016 through 2022, or 2015 through 2022). For the remaining basins (i.e., basins not reporting to the GHGRP), GHGRP average activity factors were used. For more information, please see memoranda available online.[74]

For many sources, complete activity data were not available for all years of the time series. In such cases, one of three approaches was employed to estimate values, consistent with IPCC good practice. Where appropriate, the activity data were calculated from related statistics using ratios developed based on EPA/GRI (1996) and/or GHGRP data. In some cases, activity data are developed by interpolating between recent data points (such as from GHGRP) and earlier data points, such as from EPA/GRI (1996). Lastly, in limited instances the previous year's data were used if current year data were not yet available.

A complete list of references for emission factors and activity data by emission source is provided in Annex 3.5. The United States reports data to the UNFCCC using this *Inventory* report along with Common Reporting Tables (CRTs). This note is provided for those reviewing the CRTs: The notation key "IE" is used for CO_2 and CH_4 emissions from venting and flaring in CRT 1.B.2. Disaggregating flaring and venting estimates across the Inventory would involve the application of assumptions and could result in inconsistent reporting and, potentially, decreased transparency. Data availability varies across segments within oil and gas activities systems, and emission factor data available for activities that include flaring can include emissions from multiple sources (flaring, venting and leaks).

As noted above, EPA's GHGRP data, available starting in 2010 for refineries and in 2011 for other sources, have improved estimates of emissions from petroleum systems. Many of the previously available datasets were collected in the 1990s. To develop a consistent time series for sources with new data, EPA reviewed available information on factors that may have resulted in changes over the time series (e.g., regulations, voluntary actions) and requested stakeholder feedback on trends as well. For most sources, EPA developed annual data for 1993 through 2009 or 2014 by interpolating activity data or emission factors or both between 1992 (when GRI/EPA data are available) and 2010 or 2015 data points. Information on time-series consistency for sources updated in this year's *Inventory* can be found in the Recalculations Discussion below, with additional detail provided in supporting memos (relevant memos are cited in the Recalculations Discussion). For information on other sources, please see the Methodology and Time-Series Consistency discussion above and Annex 3.5.

Methodological recalculations were applied to the entire time series to ensure time-series consistency from 1990 through 2022.

Uncertainty

EPA conducted a quantitative uncertainty analysis using the IPCC Approach 2 methodology (Monte Carlo Simulation technique) to characterize uncertainty for petroleum systems. For more information on the approach, please see the memoranda *Inventory of U.S. Greenhouse Gas Emissions and Sinks 1990-2016: Natural Gas and Petroleum Systems Uncertainty Estimates* (*2018 uncertainty memo)* and *Inventory of U.S. Greenhouse Gas Emissions and Sinks 1990-2019: Update for Natural Gas and Petroleum Systems CO_2 Uncertainty Estimates (2021 uncertainty memo)*.[75]

EPA used Microsoft Excel's @RISK add-in tool to estimate the 95 percent confidence bound around CH_4 and CO_2 emissions from petroleum systems for the current *Inventory*. For the CH_4 uncertainty analysis, EPA focused on the eight highest methane-emitting sources for the year 2022, which together emitted 75 percent of methane from petroleum systems in 2022, and extrapolated the estimated uncertainty for the remaining sources. For the CO_2 uncertainty analysis, EPA focused on the five highest-emitting sources for the year 2022 which together emitted 81 percent of CO_2 from petroleum systems in 2022, and extrapolated the estimated uncertainty for the remaining

[74] See https://www.epa.gov/ghgemissions/natural-gas-and-petroleum-systems.

[75] See https://www.epa.gov/ghgemissions/natural-gas-and-petroleum-systems.

sources. The @RISK add-in provides for the specification of probability density functions (PDFs) for key variables within a computational structure that mirrors the calculation of the inventory estimate. For emission factors that are derived from methane emissions measurement studies, the PDFs are commonly determined to be lognormally distributed (GRI/EPA 1996; EPA 1999). For activity data that are derived from national datasets, the PDFs are set to a uniform distribution (see 2018 and 2021 uncertainty memos). Many emission factors and activity factors are calculated using subpart W data, and for these, the @RISK add-in determines the best fitting PDF (e.g., lognormal, gaussian), based on bootstrapping of the underlying data (see 2018 and 2021 uncertainty memos). The IPCC guidance notes that in using this Approach 2 method, "some uncertainties that are not addressed by statistical means may exist, including those arising from omissions or double counting, or other conceptual errors, or from incomplete understanding of the processes that may lead to inaccuracies in estimates developed from models." As a result, the understanding of the uncertainty of emission estimates for this category evolves and improves as the underlying methodologies and datasets improve. The uncertainty bounds reported below only reflect those uncertainties that EPA has been able to quantify and do not incorporate considerations such as modeling uncertainty, data representativeness, measurement errors, misreporting or misclassification. To estimate uncertainty for N_2O, EPA applied the uncertainty bounds calculated for CO_2. EPA will seek to refine this estimate in future *Inventories*.

The results presented below provide the 95 percent confidence bound within which actual emissions from this source category are likely to fall for the year 2022, using the recommended IPCC methodology. The results of the Approach 2 uncertainty analysis are summarized in Table 3-50. Petroleum systems CH_4 emissions in 2022 were estimated to be between 32.7 and 48.6 MMT CO_2 Eq., while CO_2 emissions were estimated to be between 17.9 and 27.4 MMT CO_2 Eq. at a 95 percent confidence level. Petroleum systems N_2O emissions in 2022 were estimated to be between 0.039 and 0.059 MMT CO_2 Eq. at a 95 percent confidence level.

Uncertainty bounds for other years of the time series have not been calculated, but uncertainty is expected to vary over the time series. For example, years where many emission sources are calculated with interpolated data would likely have higher uncertainty than years with predominantly year-specific data. In addition, the emission sources that contribute the most to CH_4 and CO_2 emissions are different over the time series, particularly when comparing recent years to early years in the time series. For example, associated gas venting emissions were higher and flaring emissions were lower in early years of the time series, compared to recent years. Technologies also changed over the time series (e.g., reduced emissions completions were not used early in the time series).

Table 3-50: Approach 2 Quantitative Uncertainty Estimates for CH_4 and CO_2 Emissions from Petroleum Systems (MMT CO_2 Eq. and Percent)

Source	Gas	2022 Emission Estimate (MMT CO_2 Eq.)[b]	Uncertainty Range Relative to Emission Estimate[a] (MMT CO_2 Eq.)		(%)	
			Lower Bound	Upper Bound	Lower Bound	Upper Bound
Petroleum Systems	CH_4	39.6	32.7	48.6	-18%	+23%
Petroleum Systems	CO_2	22.0	17.9	27.4	-19%	+25%
Petroleum Systems	N_2O	0.048	0.039	0.059	-19%	+25%

[a] Range of emission estimates estimated by applying the 95 percent confidence intervals obtained from the Monte Carlo Simulation analysis conducted for the year 2022 CH_4 and CO_2 emissions.

[b] All reported values are rounded after calculation. As a result, lower and upper bounds may not be duplicable from other rounded values as shown in table.

QA/QC and Verification Discussion

In order to ensure the quality of the emission estimates for petroleum systems, general (IPCC Tier 1) Quality Assurance/Quality Control (QA/QC) procedures were implemented consistent with the U.S. Inventory QA/QC plan outlined in Annex 8.

The petroleum systems emission estimates in the *Inventory* are continually being reviewed and assessed to determine whether emission factors and activity factors accurately reflect current industry practices. A QA/QC analysis was performed for data gathering and input, documentation, and calculation. QA/QC checks are consistently conducted to minimize human error in the emission calculations. EPA performs a thorough review of information associated with new studies, GHGRP data, regulations, public webcasts, and the Natural Gas STAR Program to assess whether the assumptions in the *Inventory* are consistent with current industry practices. EPA has a multi-step data verification process for GHGRP data, including automatic checks during data-entry, statistical analyses on completed reports, and staff review of the reported data. Based on the results of the verification process, EPA follows up with facilities to resolve mistakes that may have occurred.[76]

As in previous years, EPA conducted early engagement and communication with stakeholders on updates prior to public review of the current *Inventory*. EPA held a stakeholder webinar on greenhouse gas data for oil and gas in October of 2023. EPA released memos detailing updates under consideration and requesting stakeholder feedback. EPA did not receive stakeholder feedback for the updates under consideration for the current *Inventory*.

In recent years, several studies have measured emissions at the source level and at the national or regional level and calculated emission estimates that may differ from the *Inventory*. There are a variety of potential uses of data from new studies, including replacing a previous estimate or factor, verifying or QA of an existing estimate or factor, and identifying areas for updates. In general, there are two major types of studies related to oil and gas greenhouse gas data: studies that focus on measurement or quantification of emissions from specific activities, processes, and equipment, and studies that use tools such as inverse modeling to estimate the level of overall emissions needed to account for measured atmospheric concentrations of greenhouse gases at various scales. The first type of study can lead to direct improvements to or verification of *Inventory* estimates. In the past few years, EPA has reviewed, and in many cases, incorporated data from these data sources. The second type of study can provide general indications on potential over- and under-estimates.

A key challenge in using these types of studies to assess *Inventory* results is having a relevant basis for comparison (e.g., the two data sets should have comparable time frames and geographic coverage, and the independent study should assess data from the *Inventory* and not another data set, such as the Emissions Database for Global Atmospheric Research, or "EDGAR"). In an effort to improve the ability to compare the national-level *Inventory* with measurement results that may be at other spatial and temporal scales, EPA has developed a gridded inventory of U.S. anthropogenic methane emissions with 0.1 degree x 0.1 degree spatial resolution, monthly temporal resolution, and detailed scale-dependent error characterization.[77] The most recent version of the gridded methane inventory is designed to be consistent with the U.S. EPA's *Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2018* estimates for the years 2012 through 2018. The gridded inventory improves efforts to compare results of this *Inventory* with atmospheric studies.

As discussed above, refinery emissions are quantified by using the total emissions reported to GHGRP for the refinery emission categories included in petroleum systems. Subpart Y has provisions that refineries are not required to report under Subpart Y if their emissions fall below certain thresholds. Each year, a review is conducted to determine whether an adjustment is needed to the Inventory emissions to include emissions from refineries that stopped reporting to the GHGRP. Based on the review of the most recent GHGRP data, EPA did not identify any additional refineries that would require gap filling. There are a total of 7 refineries that EPA previously identified (i.e., during the 1990 through 2021 *Inventory* and prior versions) as not reporting to the GHGRP and continued to gap fill annual emissions for these refineries. EPA used the last reported emissions (by source) for these refineries as proxy to gap fill annual emissions.

Recalculations Discussion

EPA received information and data related to the emission estimates through GHGRP reporting and presented information to stakeholders regarding the updates under consideration. In November 2023, EPA released draft memoranda that discussed changes under consideration and requested stakeholder feedback on those changes. EPA then released final memoranda documenting the methodology implemented in the current Inventory.[78] The memorandum cited in the Recalculations Discussion below is: Inventory of U.S. Greenhouse Gas Emissions and Sinks 1990-2022: Updates for Completion and Workover Emissions (*Completions and Workovers* memo).

EPA evaluated relevant information available and made an updates to the *Inventory* for hydraulically fractured (HF) oil well completions and workovers. General information for these source specific recalculations are presented below and details are available in the *Completions and Workovers* memo.

In addition to the updates to the sources mentioned above, for certain sources, CH_4 and/or CO_2 emissions changed by greater than 0.05 MMT CO_2 Eq., comparing the previous estimate for 2021 to the current (recalculated) estimate for 2021. The emissions changes were mostly due to GHGRP data submission revisions. These sources are discussed below and include associated gas flaring, miscellaneous production flaring, pneumatic controllers, oil tanks, chemical injection pumps, produced water, offshore production (in Gulf of Mexico federal waters), gas engines, and refinery flaring.

The combined impact of revisions to 2021 petroleum systems CH_4 emission estimates on a CO_2-equivalent basis, compared to the previous *Inventory*, is a decrease from 50.2 to 48.6 MMT CO_2 Eq. (1.5 MMT CO_2 Eq., or 3 percent). The recalculations resulted in lower CH_4 emission estimates on average across the 1990 through 2021 time series, compared to the previous *Inventory*, by 2.5 MMT CO_2 Eq., or 5 percent.

The combined impact of revisions to 2021 petroleum systems CO_2 emission estimates, compared to the previous *Inventory*, is a decrease from 24.7 to 24.1 MMT CO_2 (0.5 MMT CO_2, or 2 percent). The recalculations resulted in lower emission estimates on average across the 1990 through 2021 time series, compared to the previous *Inventory*, by 0.1 MMT CO_2 Eq., or 0.2 percent.

The combined impact of revisions to 2021 petroleum systems N_2O emission estimates on a CO_2-equivalent basis, compared to the previous *Inventory*, is a decrease of 0.002 MMT CO_2, Eq. or 10.2 percent. The recalculations resulted in an average decrease in emission estimates across the 1990 through 2021 time series, compared to the previous *Inventory*, of 0.001 MMT CO_2 Eq., or 7.4 percent.

In Table 3-51 and Table 3-52 below are categories in petroleum systems with updated methodologies or with recalculations resulting in a change of greater than 0.05 MMT CO_2 Eq., comparing the previous estimate for 2021 to the current (recalculated) estimate for 2021. For more information, please see the discussion below.

Exploration

HF Completions (Methodological Update)

EPA updated the calculation methodology for HF completions to use basin-level HF completion counts from Enverus and basin-specific activity factors and emission factors calculated from Subpart W data for each control category (i.e., non-reduced emission completion (REC) with venting, non-REC with flaring, REC with venting, REC with flaring). Previously, national annual average activity and emission factors calculated using Subpart W data were applied to national activity data counts to estimate HF gas well completion emissions. In this update, EPA developed national emission estimates by summing calculated basin-level total emission estimates. The *Completions and Workovers* memo presents additional information and considerations for this update.

EPA calculated basin-specific activity factors and CH_4 and CO_2 emission factors for all basins that reported Subpart W data. The factors were year-specific for reporting year (RY) 2011 (first year of GHGRP data for this source) through RY2022. For basin-level HF completion event counts, EPA used Enverus data for 1990 to 2010 and Subpart W for 2011 forward. For the fraction of completions in each control subcategory, EPA retained the previous *Inventory's* assumption that all HF gas well completions were non-REC for 1990 to 2000. The previous *Inventory* also assumed that 10 percent of HF completions were non-REC with flaring from 1990 to 2010 (based on national Subpart W data for RY2011 and RY2012); EPA updated this value using basin-specific Subpart W data for RY2011 and RY2012. For 2011 to 2022, EPA determined the percent contribution of each control category directly from Subpart W data and used linear interpolation between 2000 and 2011 to determine the percent of gas wells with RECs. EPA developed year- and basin-specific Subpart W EFs for 2011 forward. Year 2011 emission factors were applied to all prior years for each basin. For basins without Subpart W data available, EPA applied national average activity and emission factors (unweighted average of all Subpart W reported data).

Comparing the final completion emissions and those presented at the October 2023 webinar and in the November 2023 *Completions and Workovers* memo, the final estimates are higher for certain completion categories. These emissions increases are due not to the basin-level methodology changes discussed here but rather to changes in the Enverus dataset. EPA applied the same data processing steps to Enverus data in the fall of 2023 as it did for the previous Enverus data analysis (conducted in 2021) and data changes led to many more completions being classified as HF completions.

As a result of this methodological update, CH_4 emissions estimates are on average 10 percent lower across the time series than in the previous *Inventory*. The 2021 CH_4 emissions estimate is 41 percent higher than in the previous *Inventory*. The largest increase in the CH_4 emissions estimates compared to the previous *Inventory* is 42 percent in 2016, and the largest decrease is 35 percent in 1999. The decrease in CH_4 emissions is predominantly due to HF completions that were non-REC with venting. Basins such as the Permian basin (basin 430), Williston basin (basin 395), and Denver basin (basin 540) had a high number of HF oil well completion events over the time series. However, they had low EFs for non-REC with venting, decreasing the overall CH_4 emissions. The update resulted in CO_2 emissions estimates that are on average 33 percent higher across the time series than in the previous *Inventory*. The 2021 CO_2 emissions estimate is 29 percent higher than in the previous *Inventory*. The largest increase in CO_2 emissions estimates compared to the previous *Inventory* is 80 percent in 2000, and the largest decrease is 17 percent in 2018. The increase in CO_2 emissions is due to HF completions that were non-REC with flaring and REC with flaring. The Permian basin (basin 430) had the highest emissions across the time series for completions that were non-REC with flaring and REC with flaring. The Permian basin had the highest number of HF oil well completions and high EFs for both control categories.

Production

HF Workovers (Methodological Update)

EPA updated the activity data source and calculation methodology for HF workovers to use basin-specific activity factors and emission factors, calculated from Subpart W data for each control category (i.e., non-reduced emission completion (REC) with venting, non-REC with flaring, REC with venting, REC with flaring). Previously, national HF workover counts calculated using analyses for NSPS OOOO (i.e., 1 percent of HF oil wells were worked over annually) and national annual average emission factors calculated using Subpart W data were applied to estimate HF oil well workover emissions. In this update, EPA developed national emission estimates by summing calculated basin-level total emission estimates. The *Completions and Workovers* memo presents additional information and considerations for this update.

EPA calculated basin-specific activity factors (AFs) and CH_4 and CO_2 emission factors for all basins that reported Subpart W data. For basin-level workover counts, instead of applying a 1 percent workover rate to HF oil wells, EPA developed year- and basin-specific Subpart W AFs for 2016 (the first year of GHGRP data for this source) forward that represent the number of HF workovers per oil well. Year 2016 Subpart W AFs were applied to all prior years for each basin. For the fraction of workovers in each control subcategory, EPA retained the previous *Inventory's* assumption that all HF oil well workovers were non-REC for 1990 to 2007 and 10 percent flaring from 1990 to 2007. For 2016 to 2022, EPA determined the percent contribution of each control category directly from Subpart W data at the basin level and used linear interpolation between 2008 and 2015 to determine the percent of oil wells with RECs and the percent flaring. EPA developed year- and basin-specific Subpart W EFs for 2016 forward. Year 2016 emission factors were applied to all prior years for each basin. For basins without Subpart W data available, EPA applied national average activity and emission factors (unweighted average of all Subpart W reported data).

As a result of this methodological update, CH_4 emissions estimates are on average 62 percent lower across the time series than in the previous *Inventory*. The largest decrease in CH_4 emissions estimates compared to the previous *Inventory* is 97 percent in 2021 and the smallest decrease is 39 percent in 2018. The 2021 CH_4 emissions estimate is 97 percent lower than in the previous *Inventory*. The update resulted in CO_2 emissions estimates that are on average 51 percent lower than in the previous *Inventory*. The 2021 CO_2 emissions estimate is 97 percent lower than in the previous *Inventory*. The largest decrease in CO_2 emissions estimates compared to the previous *Inventory* is 97 percent in 2021 and the smallest decrease is 26 percent in 1990. The decrease in emissions for both CH_4 and CO_2 was primarily due to the change in calculation method for workover counts. HF oil well workover counts decreased by an average of 52 percent across the 1990 to 2021 time series compared to the previous *Inventory*.

Pneumatic Controllers (Methodological Update)

In the previous *Inventory*, EPA updated the CH_4 emissions calculation methodology for pneumatic controllers to use basin-specific activity factors and emission factors by bleed type (i.e., low, high, intermittent bleed) from GHGRP data. However, the CO_2 emissions calculation methodology was not updated and instead the previous *Inventory* still relied on a national-level methodology to estimate CO_2 emissions. For this year's *Inventory*, EPA calculated pneumatic controller CO_2 emissions using basin-specific emissions data such that the CO_2 emissions reflect the unique CO_2 composition of the gas in a basin.

The update for pneumatic controller CO_2 emission estimates resulted in an average increase of 61 percent across the time series and an increase of 57 percent in 2021, compared to the previous *Inventory*.

In addition, methane emissions for pneumatic controllers were impacted due to recalculations with updated data. Methane emissions from onshore production pneumatic controllers are an average of 2 percent lower across the time series and 1 percent lower in 2021, compared to the previous *Inventory*. The emission changes were due to GHGRP data submission revisions.

Equipment Leaks (Methodological Update)

In the previous *Inventory*, EPA updated the CH_4 emissions calculation methodology for onshore production equipment leaks to use basin-specific equipment-level activity factors (e.g., separators per well) from GHGRP data. However, the CO_2 emissions calculation methodology was not updated and instead the previous *Inventory* still relied on a national-level methodology to estimate CO_2 emissions. For this year's *Inventory*, EPA calculated

equipment leak CO_2 emissions in the same manner as CH_4 emissions. EPA calculated CO_2 estimates using the basin-specific equipment-level activity factors for RY2015 through RY2022 from GHGRP, consistent with the methodology used to calculate the CH_4 activity factors, and the CO_2 emissions factors for onshore production segment equipment leaks. Note, this methodological update applies only for activity factors. The previous *Inventory's* CO_2 emission factors for onshore production segment equipment leaks (by equipment type) were retained and used to develop CO_2 estimates.

The update for CO_2 emission estimates resulted in an average increase of 7 percent across the time series and an increase of 18 percent in 2021, compared to the previous *Inventory*. Years 2015 to 2021 were impacted more by the update, with an average increase of 28 percent compared to the previous *Inventory*.

Table 3-59: Equipment Leaks National CO_2 Emissions (Metric Tons CO_2)

Chemical Injection Pumps (Methodological Update)

In the previous *Inventory*, EPA updated the CH_4 emissions calculation methodology for chemical injection pumps to use basin-specific equipment-level activity factors (e.g., pumps per well) from GHGRP data. However, the CO_2 emissions calculation methodology was not updated and instead the previous *Inventory* still relied on a national-level methodology to estimate CO_2 emissions. For this year's *Inventory*, EPA calculated chemical injection pump CO_2 emissions in the same manner as CH_4 emissions. EPA calculated CO_2 estimates using the basin-specific equipment-level activity factors for RY2015 through RY2022 from GHGRP, consistent with the methodology used to calculate the CH_4 activity factors, and the CO_2 emission factor. Note, this methodological update applies only for activity factors. The previous *Inventory's* chemical injection pumps CO_2 emission factor was retained and used to develop CO_2 estimates. The update for CO_2 emission estimates resulted in an average decrease of 29 percent across the time series and a decrease of 35 percent in 2021, compared to the previous *Inventory*.

Table 3-60: Chemical Injection Pump National CO_2 Emissions (Metric Tons CO_2)

Storage Tanks (Recalculation with Updated Data)

Carbon dioxide emissions from production storage tanks are on average 0.9 percent higher across the time series compared to the previous *Inventory*. Emissions estimates for 2021 are 4 percent higher than in the previous *Inventory*, which is primarily due to large tanks with flares. The emission changes were due to GHGRP data submission revisions.

Table 3-61: Storage Tanks National CO_2 Emissions (kt CO_2)

Associated Gas Flaring (Recalculation with Updated Data)

Associated gas flaring CH_4 emission estimates increased by an average of 2 percent across the time series and increased by 23 percent in 2021, compared to the previous *Inventory*. The emission changes were due to GHGRP data submission revisions.

Miscellaneous Production Flaring (Recalculation with Updated Data)

Miscellaneous production flaring CO_2 emission estimates are on average 1 percent higher across the time series compared to the previous *Inventory*. Carbon dioxide emissions estimates for 2021 increased by 12 percent compared to the previous *Inventory*. The emission changes were due to GHGRP data submission revisions.

Offshore Production – GOM Federal Waters (Recalculation with Updated Data)

Vented and leak CH_4 emission estimates from offshore production in GOM federal waters decreased by an average of 0.4 percent across the time series and decreased by 8 percent in 2021, compared to the previous *Inventory*. The emission changes were due to updated offshore complex counts from BOEM.

Transportation

Recalculations for the transportation segment have resulted in calculated CH_4 and CO_2 emissions over the time series from this segment that are lower (by less than 0.05 percent) than in the previous *Inventory*.

Refining

Recalculations due to resubmitted GHGRP data in the refining segment have resulted in a decrease in calculated CH_4 emissions by an average of 4.5 percent across the time series and a decrease of 14 percent in 2021, compared to the previous *Inventory*.

Refining CO_2 emission estimates decreased by an average of 8 percent across the time series and decreased by 28 percent in 2021, compared to the previous *Inventory*. This change in emissions is due to GHGRP resubmissions and was largely due to a change in reported flaring CO_2 emissions.

Planned Improvements

Planned Improvements for 2025 *Inventory*

EPA updated the Enverus data and there were notable increases in the number of wells and completions identified as being hydraulically fractured compared with previous versions of the database. EPA will assess the underlying Enverus data to determine the cause of these changes.

Upcoming Data, and Additional Data that Could Inform the *Inventory*

EPA will assess new data received by the Greenhouse Gas Reporting Program, the Methane Challenge Program, and other relevant programs on an ongoing basis, which may be used to confirm or improve existing estimates and assumptions.

EPA continues to track studies that contain data that may be used to update the *Inventory*. EPA will also continue to assess studies that include and compare both top-down and bottom-up estimates, and which could lead to improved understanding of unassigned high emitters (e.g., identification of emission sources and information on frequency of high emitters) as recommended in previous stakeholder comments.

Box 3-6: Carbon Dioxide Transport, Injection, and Geological Storage

Carbon dioxide is produced, captured, transported, and used for Enhanced Oil Recovery (EOR) as well as commercial and non-EOR industrial applications, or is stored geologically. This CO_2 is produced from both naturally-occurring CO_2 reservoirs and from industrial sources such as natural gas processing plants and ammonia plants. In the *Inventory*, emissions of CO_2 from naturally-occurring CO_2 reservoirs are estimated based

on the specific application.

In the *Inventory*, CO_2 that is used in non-EOR industrial and commercial applications (e.g., food processing, chemical production) is assumed to be emitted to the atmosphere during its industrial use. These emissions are discussed in the Carbon Dioxide Consumption section, 4.15.

For EOR CO_2, as noted in the *2006 IPCC Guidelines*, "At the Tier 1 or 2 methodology levels [EOR CO_2 is] indistinguishable from fugitive greenhouse gas emissions by the associated oil and gas activities." In the U.S. estimates for oil and gas fugitive emissions, the Tier 2 emission factors for CO_2 include CO_2 that was originally injected and is emitted along with other gas from leak, venting, and flaring pathways, as measurement data used to develop those factors would not be able to distinguish between CO_2 from EOR and CO_2 occurring in the produced natural gas. Therefore, EOR CO_2 emitted through those pathways is included in CO_2 estimates in 1B2.

IPCC includes methodological guidance to estimate emissions from the capture, transport, injection, and geological storage of CO_2. The methodology is based on the principle that the carbon capture and storage system should be handled in a complete and consistent manner across the entire Energy sector. The approach accounts for CO_2 captured at natural and industrial sites as well as emissions from capture, transport, and use. For storage specifically, a Tier 3 methodology is outlined for estimating and reporting emissions based on site-specific evaluations. However, IPCC (IPCC 2006) notes that if a national regulatory process exists, emissions information available through that process may support development of CO_2 emission estimates for geologic storage.

In the United States, facilities that produce CO_2 for various end-use applications (including capture facilities such as acid gas removal plants and ammonia plants), importers of CO_2, exporters of CO_2, facilities that conduct geologic sequestration of CO_2, and facilities that inject CO_2 underground, are required to report greenhouse gas data annually to EPA through its GHGRP. Facilities reporting geologic sequestration of CO_2 to the GHGRP develop and implement an EPA-approved site-specific monitoring, reporting and verification plan, and report the amount of CO_2 sequestered using a mass balance approach.

GHGRP data relevant for this *Inventory* estimate consists of national-level annual quantities of CO_2 captured and extracted for EOR applications for 2010 to 2022 and data reported for geologic sequestration from 2016 to 2022.

The amount of CO_2 captured and extracted from natural and industrial sites for EOR applications in 2022 is 36,680 kt (36.7 MMT CO_2 Eq.) 6. The quantity of CO_2 captured and extracted is noted here for information purposes only; CO_2 captured and extracted from industrial and commercial processes is generally assumed to be emitted and included in emissions totals from those processes.

Table 3-70: Quantity of CO_2 Captured and Extracted for EOR Operations (kt CO_2)

Stage	2018	2019	2020	2021	2022
Quantity of CO_2 Captured and Extracted for EOR Operations	48,400	52,100	35,210	35,090	36,680

Several facilities are reporting under GHGRP Subpart RR (Geologic Sequestration of Carbon Dioxide). See Table 3-71 for the number of facilities reporting under Subpart RR, the reported CO_2 sequestered in subsurface geologic formations in each year, and of the quantity of CO_2 emitted from equipment leaks in each year. The quantity of CO_2 sequestered and emitted is noted here for information purposes only; EPA is considering updates to its approach for this source and is seeking feedback as part of this public review draft on potential updates that could be incorporated in future *Inventories*.

Table 3-71: Geologic Sequestration Information Reported Under GHGRP Subpart RR

Stage	2018	2019	2020	2021	2022
Number of Reporting Facilities	5	5	6	9	13
Reported Annual CO_2 Sequestered (kt)	7,662	8,332	6,802	6,947	7,953

Reported Annual CO_2 Emissions from Equipment Leaks (kt)	11	16	13	37	27

3.7 Natural Gas Systems (CRT Source Category 1B2b)

The U.S. natural gas system encompasses hundreds of thousands of wells, hundreds of processing facilities, and over a million miles of transmission and distribution pipelines. This category (1B2b) as defined in the IPCC methodological guidance is for fugitive emissions from natural gas systems, which per IPCC guidelines include emissions from leaks, venting, and flaring. Total greenhouse gas emissions (CH_4, CO_2, and N_2O) from natural gas systems in 2022 were 209.7 MMT CO_2 Eq., a decrease of 17 percent from 1990 and a decrease of 0.3 percent from 2021, both primarily due to decreases in CH_4 emissions. From 2011, emissions decreased by 5 percent, primarily due to decreases in CH_4 emissions. National total dry gas production in the United States increased by 104 percent from 1990 to 2022, increased by 5 percent from 2021 to 2022, and increased by 59 percent from 2011 to 2022. Of the overall greenhouse gas emissions (209.7 MMT CO_2 Eq.), 83 percent are CH_4 emissions (173.1 MMT CO_2 Eq.), 17 percent are CO_2 emissions (36.5 MMT), and less than 0.1 percent are N_2O emissions (0.15 MMT CO_2 Eq.).

Overall, natural gas systems emitted 173.1 MMT CO_2 Eq. (6,183 kt CH_4) of CH_4 in 2022, a 21 percent decrease compared to 1990 emissions, and 1 percent decrease compared to 2021 emissions (see Table 3-72 and Table 3-73). For non-combustion CO_2, a total of 36.5 MMT CO_2 Eq. (36,470 kt) was emitted in 2022, a 12 percent increase compared to 1990 emissions, and a 2 percent increase compared to 2021 levels. The 2022 N_2O emissions were estimated to be 0.15 MMT CO_2 Eq. (0.57 kt N_2O), a 3205 percent increase compared to 1990 emissions, and a 1104 percent increase compared to 2021 levels.

The 1990 to 2022 emissions trend is not consistent across segments or gases. Overall, the 1990 to 2022 decrease in CH_4 emissions is due primarily to the decrease in emissions from the following segments: distribution (70 percent decrease), transmission and storage (38 percent decrease), processing (37 percent decrease), and exploration (97 percent decrease). Over the same time period, the production segment saw increased CH_4 emissions of 38 percent (with onshore production emissions increasing 16 percent, offshore production emissions decreasing 86 percent, and gathering and boosting [G&B] emissions increasing 108 percent), and post-meter emissions increasing by 65 percent. The 1990 to 2022 increase in CO_2 emissions is primarily due to an increase in CO_2 emissions in the production segment, where emissions from flaring have increased over time.

Methane and CO_2 emissions from natural gas systems include those resulting from normal operations, routine maintenance, and system upsets. Emissions from normal operations include natural gas engine and turbine uncombusted exhaust, flaring, and leak emissions from system components. Routine maintenance emissions originate from pipelines, equipment, and wells during repair and maintenance activities. Pressure surge relief systems and accidents can lead to system upset emissions. Emissions of N_2O from flaring activities are included in the *Inventory*, with most of the emissions occurring in the processing and production segments. Note, CO_2 emissions exclude all combustion emissions (e.g., engine combustion) except for flaring CO_2 emissions. All combustion CO_2 emissions (except for flaring) are accounted for in Section 3.1.

Each year, some estimates in the *Inventory* are recalculated with improved methods and/or data. These improvements are implemented consistently across the previous *Inventory's* time series (i.e., 1990 to 2022) to ensure that the trend is representative of changes in emissions. Recalculations in natural gas systems in this year's *Inventory* include:

- Methodological updates to transmission compressor station activity data, completions and workovers, and underground natural gas storage well events.
- Recalculations due to Greenhouse Gas Reporting Program (GHGRP) submission revisions.
- Recalculations due to updated well counts and production data from Enverus.

The Recalculations Discussion section below provides more details on the updated methods.

Below is a characterization of the six emission subcategories of natural gas systems: exploration, production (including gathering and boosting), processing, transmission and storage, distribution, and post-meter. Each of the segments is described and the different factors affecting CH_4, CO_2, and N_2O emissions are discussed.

Exploration. Exploration includes well drilling, testing, and completion. Emissions from exploration accounted for 0.1 percent of CH_4 emissions and 0.1% of CO_2 emissions from natural gas systems in 2022. Well completions accounted for approximately 90 percent of CH_4 emissions from the exploration segment in 2022, with the rest resulting from well testing and drilling. Well completion flaring emissions account for most of the CO_2 emissions. Methane emissions from exploration decreased by 97 percent from 1990 to 2022, with the largest decreases coming from hydraulically fractured gas well completions without reduced emissions completions (RECs). Methane emissions from exploration increased 58 percent from 2021 to 2022 due to increases in emissions from hydraulically fractured well completions (both non-REC with flaring and REC with venting). Methane emissions from exploration were highest from 2006 to 2008. Carbon dioxide emissions from exploration decreased by 94 percent from 1990 to 2022 primarily due to decreases in hydraulically fractured gas well completions. Carbon dioxide emissions from exploration increased by 14 percent from 2020 to 2021 due to increases in emissions from hydraulically fractured gas well completions (REC with flaring). Carbon dioxide emissions from exploration were highest from 2006 to 2008. Nitrous oxide emissions from exploration decreased 95 percent from 1990 to 2022 and increased 74 percent from 2021 to 2022.

Production (including gathering and boosting). In the production segment, wells are used to withdraw raw gas from underground formations. Emissions arise from the wells themselves, and from well-site equipment and activities such as pneumatic controllers, tanks and separators, and liquids unloading. Gathering and boosting emission sources are included within the production sector. The gathering and boosting sources include gathering and boosting stations (with multiple emission sources on site) and gathering pipelines. The gathering and boosting stations receive natural gas from production sites and transfer it, via gathering pipelines, to transmission pipelines or processing facilities (custody transfer points are typically used to segregate sources between each segment). Boosting processes include compression, dehydration, and transport of gas to a processing facility or pipeline. Emissions from production (including gathering and boosting) accounted for 52 percent of CH_4 emissions and 23 percent of CO_2 emissions from natural gas systems in 2022. Emissions from gathering and boosting and pneumatic controllers in onshore production accounted for most of the production segment CH_4 emissions in 2022. Within gathering and boosting, the largest sources of CH_4 are compressor exhaust slip, compressor venting and leaks, and tanks. Flaring emissions account for most of the CO_2 emissions from production, with the highest emissions coming from flare stacks at gathering stations, miscellaneous onshore production flaring, and tank flaring. Methane emissions from production increased by 38 percent from 1990 to 2022, due primarily to increases in emissions from pneumatic controllers (due to an increase in the number of controllers, particularly in the number of intermittent bleed controllers) and increases in emissions from compressor exhaust slip in gathering and boosting. Methane emissions from production decreased 3 percent from 2021 to 2022 due to decreases in emissions from pneumatic controllers and liquids unloading. Carbon dioxide emissions from production increased by approximately a factor of 2.6 from 1990 to 2022 due to increases in emissions at flare stacks in gathering and boosting and miscellaneous onshore production flaring and decreased 8 percent from 2021 to 2022 due primarily to decreases in emissions at flare stacks in miscellaneous onshore production flaring and tank venting. Nitrous oxide emissions from production were 36.9 times higher in 2022 than in 1990 and 17.5 times higher in 2022 than in 2021. The increase in N_2O emissions from 1990 to 2022 and from 2021 to 2022 is primarily due to increases in emissions from condensate tank flaring.

Processing. In the processing segment, natural gas liquids and various other constituents from the raw gas are removed, resulting in "pipeline quality" gas, which is injected into the transmission system. Methane emissions from compressors, including compressor seals, are the primary emission source from this stage. Most of the CO_2 emissions come from acid gas removal (AGR) units, which are designed to remove CO_2 from natural gas. Processing plants accounted for 9 percent of CH_4 emissions and 73 percent of CO_2 emissions from natural gas systems. Methane emissions from processing decreased by 37 percent from 1990 to 2022 as emissions from compressors (leaks and venting) and equipment leaks decreased; and increased 7 percent from 2021 to 2022 due to increased emissions from gas engines. Carbon dioxide emissions from processing decreased by 6 percent from 1990 to 2022,

due to a decrease in AGR, and increased 4 percent from 2021 to 2022 due to increased emissions from flaring emissions at processing plants. Nitrous oxide emissions increased 116 percent from 2021 to 2022.

Transmission and Storage. Natural gas transmission involves high pressure, large diameter pipelines that transport gas long distances from field production and processing areas to distribution systems or large volume customers such as power plants or chemical plants. Compressor station facilities are used to move the gas throughout the U.S. transmission system. Leak CH_4 emissions from these compressor stations and venting from pneumatic controllers account for most of the emissions from this stage. Uncombusted compressor engine exhaust and pipeline venting are also sources of CH_4 emissions from transmission. Natural gas is also injected and stored in underground formations, or liquefied and stored in above ground tanks, during periods of low demand (e.g., summer), and withdrawn, processed, and distributed during periods of high demand (e.g., winter). Leak and venting emissions from compressors are the primary contributors to CH_4 emissions from storage. Emissions from liquefied natural gas (LNG) stations and terminals are also calculated under the transmission and storage segment. Methane emissions from the transmission and storage segment accounted for approximately 23 percent of methane emissions from natural gas systems, while CO_2 emissions from transmission and storage accounted for 3 percent of the CO_2 emissions from natural gas systems. CH_4 emissions from this source decreased by 38 percent from 1990 to 2022 due to reduced pneumatic device and compressor station emissions (including emissions from compressors and leaks) and decreased 1 percent from 2021 to 2022 due to decreased emissions from pipeline venting transmission compressors. CO_2 emissions from transmission and storage were 6.6 times higher in 2022 than in 1990, due to increased emissions from LNG export terminals, and increased by 36 percent from 2021 to 2022, also due to LNG export terminals and flaring (both transmission and storage). The quantity of LNG exported from the United States increased by a factor of 74 from 1990 to 2022, and by 9 percent from 2021 to 2022. LNG emissions are about 1 percent of CH_4 and 86 percent of CO_2 emissions from transmission and storage in year 2022. Nitrous oxide emissions from transmission and storage increased by 405 percent from 1990 to 2022 and increased by 177 percent from 2021 to 2022.

Distribution. Distribution pipelines take the high-pressure gas from the transmission system at "city gate" stations, reduce the pressure and distribute the gas through primarily underground mains and service lines to individual end users. There were 1,352,384 miles of distribution mains in 2022, an increase of 408,227 miles since 1990 (PHMSA 2022). Distribution system emissions, which accounted for 9 percent of CH_4 emissions from natural gas systems and less than 0.1 percent of CO_2 emissions from natural gas systems, result mainly from leak emissions from pipelines and stations. An increased use of plastic piping, which has lower emissions than other pipe materials, has reduced both CH_4 and CO_2 emissions from this stage, as have station upgrades at metering and regulating (M&R) stations. Distribution system CH_4 emissions in 2022 were 70 percent lower than 1990 levels and 1 percent lower than 2021 emissions. Distribution system CO_2 emissions in 2022 were 70 percent lower than 1990 levels and 1 percent lower than 2021 emissions. Annual CO_2 emissions from this segment are less than 0.1 MMT CO_2 Eq. across the time series.

Post-Meter. Post-meter includes leak emissions from residential and commercial appliances, industrial facilities and power plants, and natural gas fueled vehicles. Leak emissions from residential appliances and industrial facilities and power plants account for the majority of post-meter CH_4 emissions. Methane emissions from the post-meter segment accounted for approximately 8 percent of emissions from natural gas systems in 2022. Post-meter CH_4 emissions increased by 65 percent from 1990 to 2022 and increased by 3 percent from 2021 to 2022, due to increases in the number of residential houses using natural gas and increased natural gas consumption at industrial facilities and power plants. CO_2 emissions from post-meter account for less than 0.01 percent of total CO_2 emissions from natural gas systems.

Total greenhouse gas emissions from the six subcategories within natural gas systems are shown in MMT CO_2 Eq. in Table 3-72. Total CH_4 emissions for these same segments of natural gas systems are shown in MMT CO_2 Eq. (Table 3-73) and kt (Table 3-74). Most emission estimates are calculated using a net emission approach. However, a few sources are still calculated with a potential emission approach. Reductions data are applied to those sources. In 2022, 2.6 MMT CO_2 Eq. CH_4 is subtracted from production segment emissions, 4.3 MMT CO_2 Eq. CH_4 is subtracted from the transmission and storage segment, and 0.1 MMT CO_2 Eq. CH_4 is subtracted from the distribution segment to calculate net emissions. More disaggregated information on potential emissions, net

emissions, and reductions data is available in Annex 3.6, Methodology for Estimating CH_4 and CO_2 Emissions from Natural Gas Systems.

Table 3-72: Total Greenhouse Gas Emissions (CH_4, CO_2, and N_2O) from Natural Gas Systems (MMT CO_2 Eq.)

Segment	1990	2005	2018	2019	2020	2021	2022

Methodology and Time-Series Consistency

See Annex 3.6 for the full time series of emissions data, activity data, and emission factors, and additional information on methods and data sources—for example, the specific years of reporting data from EPA's GHGRP that are used to develop certain factors.

This section provides a general overview of the methodology for natural gas system emission estimates in the *Inventory*, which involves the calculation of CH_4, CO_2, and N_2O emissions for over 100 emissions sources (i.e., equipment types or processes), and then the summation of emissions for each natural gas segment.

The approach for calculating emissions for natural gas systems generally involves the application of emission factors to activity data. For most sources, the approach uses technology-specific emission factors or emission factors that vary over time and take into account changes to technologies and practices, which are used to calculate net emissions directly. For others, the approach uses what are considered "potential methane factors" and emission reduction data to calculate net emissions. The estimates are developed with an IPCC Tier 2 approach. Tier 1 approaches are not used.

Emission Factors. Key references for emission factors for CH_4 and CO_2 emissions from the U.S. natural gas industry include a 1996 study published by the Gas Research Institute (GRI) and EPA (GRI/EPA 1996), EPA's GHGRP (EPA 2023b), and others.

The 1996 GRI/EPA study developed over 80 CH_4 emission factors to characterize emissions from the various components within the operating segments of the U.S. natural gas system. The GRI/EPA study was based on a combination of process engineering studies, collection of activity data, and measurements at representative natural gas facilities conducted in the early 1990s. Year-specific natural gas CH_4 compositions are calculated using U.S. Department of Energy's Energy Information Administration (EIA) annual gross production data for National Energy Modeling System (NEMS) oil and gas supply module regions in conjunction with data from the Gas Technology Institute (GTI, formerly GRI) Unconventional Natural Gas and Gas Composition Databases (GTI 2001). These year-specific CH_4 compositions are applied to emission factors, which therefore may vary from year to year due to slight changes in the CH_4 composition of natural gas for each NEMS region.

GHGRP Subpart W data were used to develop CH_4, CO_2, and N_2O emission factors for many sources in the *Inventory*. In the exploration and production segments, GHGRP data were used to develop emission factors used for all years of the time series for well testing, gas well completions and workovers with and without hydraulic fracturing, pneumatic controllers and chemical injection pumps, condensate tanks, liquids unloading, miscellaneous flaring, gathering and boosting pipelines, and certain sources at gathering and boosting stations. In the processing segment, for recent years of the time series, GHGRP data were used to develop emission factors for leaks, compressors, flares, dehydrators, and blowdowns/venting. In the transmission and storage segment, GHGRP data were used to develop factors for all years of the time series for LNG stations and terminals and transmission pipeline blowdowns, and for pneumatic controllers for recent years of the time series.

Other data sources used for CH_4 emission factors include Zimmerle et al. (2015) for transmission and storage station leaks and compressors, GTI (2009 and 2019) for commercial and industrial meters, Lamb et al. (2015) for recent years for distribution pipelines and meter/regulator stations, Zimmerle et al. (2019) for gathering and boosting stations, Bureau of Ocean Energy Management (BOEM) reports, and Fischer et al. (2019) and IPCC (2019) for post-meter emissions.

For CO_2 emissions from sources in the exploration, production, and processing segments that use emission factors not directly calculated from GHGRP data, data from the 1996 GRI/EPA study and a 2001 GTI publication were used to adapt the CH_4 emission factors into related CO_2 emission factors. For sources in the transmission and storage segment that use emission factors not directly calculated from GHGRP data, and for sources in the distribution segment, data from the 1996 GRI/EPA study and a 1993 GTI publication were used to adapt the CH_4 emission factors into non-combustion related CO_2 emission factors. CO_2 emissions from post-meter sources (commercial, industrial and vehicles) were estimated using default emission factors from IPCC (2019). Carbon dioxide emissions from post-meter residential sources are included in fossil fuel combustion data.

Flaring N_2O emissions were estimated for flaring sources using GHGRP data.

See Annex 3.6 for more detailed information on the methodology and data used to calculate CH_4, CO_2, and N_2O emissions from natural gas systems.

Activity Data. Activity data were taken from various published data sets, as detailed in Annex 3.6. Key activity data sources include data sets developed and maintained by EPA's GHGRP (EPA 2023b); Enverus (Enverus 2023); BOEM; Federal Energy Regulatory Commission (FERC); EIA; the Natural Gas STAR and Methane Challenge Programs annual data; Oil and Gas Journal; and PHMSA.

For a few sources, recent direct activity data are not available. For these sources, either 2021 data were used as a proxy for 2022 data, or a set of industry activity data drivers was developed and used to calculate activity data over the time series. Drivers include statistics on gas production, number of wells, system throughput, miles of various kinds of pipe, and other statistics that characterize the changes in the U.S. natural gas system infrastructure and operations. More information on activity data and drivers is available in Annex 3.6.

A complete list of references for emission factors and activity data by emission source is provided in Annex 3.6.

Calculating Net Emissions. For most sources, net emissions are calculated directly by applying emission factors to activity data. Emission factors used in net emission approaches reflect technology-specific information and take into account regulatory and voluntary reductions. However, for production, transmission and storage, and distribution, some sources are calculated using potential emission factors, and CH_4 that is not emitted is deducted from the total CH_4 potential estimates. To account for use of such technologies and practices that result in lower emissions but are not reflected in "potential" emission factors, data are collected on both regulatory and voluntary reductions. Regulatory actions addressed using this method include EPA National Emission Standards for Hazardous Air Pollutants (NESHAP) regulations for dehydrator vents. Voluntary reductions included in the *Inventory* are those reported to Natural Gas STAR and Methane Challenge for certain sources.

Methodological recalculations were applied to the entire time series to ensure time-series consistency from 1990 through 2022. GHGRP data available (starting in 2011) and other recent data sources have improved estimates of emissions from natural gas systems. To develop a consistent time series, for sources with new data, EPA reviewed available information on factors that may have resulted in changes over the time series (e.g., regulations, voluntary actions) and requested stakeholder feedback on trends as well. For most sources, EPA developed annual data for 1993 through 2010 by interpolating activity data or emission factors or both between 1992 and 2011 data points. Information on time-series consistency for sources updated in this year's *Inventory* can be found in the Recalculations Discussion below, with additional detail provided in supporting memos (relevant memos are cited in the Recalculations Discussion). For detailed documentation of methodologies, please see Annex 3.5.

The United States reports data to the UNFCCC using this *Inventory* report along with Common Reporting Tables (CRTs). This note is provided for those reviewing the CRTs: The notation key "IE" is used for CO_2 and CH_4 emissions from venting and flaring in CRT 1.B.2. Disaggregating flaring and venting estimates across the *Inventory* would involve the application of assumptions and could result in inconsistent reporting and, potentially, decreased transparency. Data availability varies across segments within oil and gas activities systems, and emission factor data available for activities that include flaring can include emissions from multiple sources (flaring, venting and leaks).

Uncertainty

EPA has conducted a quantitative uncertainty analysis using the IPCC Approach 2 methodology (Monte Carlo Simulation technique) to characterize the uncertainty for natural gas systems. For more information on the approach, please see the memoranda *Inventory of U.S. Greenhouse Gas Emissions and Sinks 1990-2016: Natural Gas and Petroleum Systems Uncertainty Estimates* (*2018 uncertainty memo*) and *Inventory of U.S. Greenhouse Gas Emissions and Sinks 1990-2019: Update for Natural Gas and Petroleum Systems CO_2 Uncertainty Estimates* (*2021*

uncertainty memo).[79]

EPA used Microsoft Excel's @RISK add-in tool to estimate the 95 percent confidence bound around CH_4 and CO_2 emissions from natural gas systems for the current *Inventory*. For the CH_4 uncertainty analysis, EPA focused on the 17 highest-emitting sources for the year 2022, which together emitted 75 percent of methane from natural gas systems in 2022, and extrapolated the estimated uncertainty for the remaining sources. For the CO_2 uncertainty analysis, EPA focused on the three highest-emitting sources for the year 2022, which together emitted 81 percent of CO_2 from natural gas systems in 2022, and extrapolated the estimated uncertainty for the remaining sources. To estimate uncertainty for N_2O, EPA applied the uncertainty bounds calculated for CO_2. EPA will seek to refine this estimate in future Inventories. The @RISK add-in provides for the specification of probability density functions (PDFs) for key variables within a computational structure that mirrors the calculation of the inventory estimate. For emission factors that are derived from methane emissions measurement studies, the PDFs are commonly determined to be lognormally distributed (GRI/EPA 1996; GTI 2001; GTI 2009; Lamb et al. 2015; Zimmerle et al. 2015; Fischer et al. 2018; GTI 2019). For activity data that are derived from national datasets, the PDFs are set to a uniform distribution (see 2018 and 2021 uncertainty memos). Many emission factors and activity factors are calculated using Subpart W data, and for these, the @RISK add-in determines the best fitting PDF (e.g., lognormal, gaussian), based on bootstrapping of the underlying data (see 2018 and 2021 uncertainty memos). The IPCC guidance notes that in using this Approach 2 method, "some uncertainties that are not addressed by statistical means may exist, including those arising from omissions or double counting, or other conceptual errors, or from incomplete understanding of the processes that may lead to inaccuracies in estimates developed from models." The uncertainty bounds reported below only reflect those uncertainties that EPA has been able to quantify and do not incorporate considerations such as modeling uncertainty, data representativeness, measurement errors, misreporting or misclassification. The understanding of the uncertainty of emission estimates for this category evolves and improves as the underlying methodologies and datasets improve.

The results presented below provide the 95 percent confidence bound within which actual emissions from this source category are likely to fall for the year 2022, using the IPCC methodology. The results of the Approach 2 uncertainty analysis are summarized in Table 3-79. Natural gas systems CH_4 emissions in 2022 were estimated to be between 141.2 and 203.0 MMT CO_2 Eq. at a 95 percent confidence level. Natural gas systems CO_2 emissions in 2022 were estimated to be between 31.9 and 42.1 MMT CO_2 Eq. at a 95 percent confidence level. Natural gas systems N_2O emissions in 2022 were estimated to be between 0.13 and 0.18 MMT CO_2 Eq. at a 95 percent confidence level.

Uncertainty bounds for other years of the time series have not been calculated, but uncertainty is expected to vary over the time series. For example, years where many emission sources are calculated with interpolated data would likely have higher uncertainty than years with predominantly year-specific data. In addition, the emission sources that contribute the most to CH_4 and CO_2 emissions are different over the time series, particularly when comparing recent years to early years in the time series. For example, venting emissions were higher and flaring emissions were lower in early years of the time series, compared to recent years. Technologies also changed over the time series (e.g., liquids unloading with plunger lifts and reduced emissions completions were not used early in the time series and cast iron distribution mains were more prevalent than plastic mains in early years). Transmission and gas processing compressor leak and vent emissions were also higher in the early years of the time series.

Table 3-79: Approach 2 Quantitative Uncertainty Estimates for CH_4 and Non-combustion CO_2 Emissions from Natural Gas Systems (MMT CO_2 Eq. and Percent)

Source	Gas	2022 Emission Estimate (MMT CO_2 Eq.)[b]	Uncertainty Range Relative to Emission Estimate[a]			
			(MMT CO_2 Eq.)		(%)	
			Lower Bound[b]	Upper Bound[b]	Lower Bound[b]	Upper Bound[b]
Natural Gas Systems	CH_4	173.1	141.2	203.0	-18%	+17%

Natural Gas Systems	CO_2	36.5	31.9	42.1	-12%	+15%
Natural Gas Systems	N_2O	0.15	0.13	0.18	-12%	+15%

[a] Range of emission estimates estimated by applying the 95 percent confidence intervals obtained from the Monte Carlo simulation analysis conducted for the year 2022 CH_4 and CO_2 emissions.

[b] All reported values are rounded after calculation. As a result, lower and upper bounds may not be duplicable from other rounded values as shown in Table 3-73 and Table 3-74.

QA/QC and Verification Discussion

In order to ensure the quality of the emission estimates for natural gas systems, general (IPCC Tier 1) Quality Assurance/Quality Control (QA/QC) procedures were implemented consistent with the U.S. Inventory QA/QC plan outlined in Annex 8.

The natural gas systems emission estimates in the *Inventory* are continually being reviewed and assessed to determine whether emission factors and activity factors accurately reflect current industry practices. A QA/QC analysis was performed for data gathering and input, documentation, and calculation. QA/QC checks are consistently conducted to minimize human error in the model calculations. EPA performs a thorough review of information associated with new studies, GHGRP data, regulations, public webcasts, and the Natural Gas STAR Program to assess whether the assumptions in the *Inventory* are consistent with current industry practices. The EPA has a multi-step data verification process for GHGRP data, including automatic checks during data-entry, statistical analyses on completed reports, and staff review of the reported data. Based on the results of the verification process, the EPA follows up with facilities to resolve mistakes that may have occurred.[80]

As in previous years, EPA conducted early engagement and communication with stakeholders on updates prior to public review of the current *Inventory*. EPA held a stakeholder webinar in October of 2023. EPA released memos detailing updates under consideration and requesting stakeholder feedback.

In recent years, several studies have measured emissions at the source level and at the national or regional level and calculated emission estimates that may differ from the *Inventory*. There are a variety of potential uses of data from new studies, including replacing a previous estimate or factor, verifying or QA of an existing estimate or factor, and identifying areas for updates. In general, there are two major types of studies related to oil and gas greenhouse gas data: studies that focus on measurement or quantification of emissions from specific activities, processes and equipment, and studies that use tools such as inverse modeling to estimate the level of overall emissions needed to account for measured atmospheric concentrations of greenhouse gases at various scales. The first type of study can lead to direct improvements to or verification of *Inventory* estimates. In the past few years, EPA has reviewed and, in many cases, incorporated data from these data sources. The second type of study can provide general indications of potential over- and under-estimates. In addition, in recent years information from top-down studies has been directly incorporated to quantify emissions from well blowouts.

A key challenge in using these types of studies to assess *Inventory* results is having a relevant basis for comparison (e.g., the two data sets should have comparable time frames and geographic coverage, and the independent study should assess data from the *Inventory* and not another data set, such as the Emissions Database for Global Atmospheric Research, or "EDGAR"). In an effort to improve the ability to compare the national-level *Inventory* with measurement results that may be at other spatial and temporal scales, EPA has developed a gridded inventory of U.S. anthropogenic methane emissions with 0.1 degree x 0.1 degree spatial resolution, monthly temporal resolution, and detailed scale-dependent error characterization.[81] The most recent version of the gridded methane inventory is designed to be consistent with the U.S. EPA's *Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2018* estimates for the years 2012 to 2018. The gridded inventory improves efforts to compare results of this *Inventory* with atmospheric studies.

[80] See https://www.epa.gov/sites/production/files/2015-07/documents/ghgrp_verification_factsheet.pdf.

[81] See https://www.epa.gov/ghgemissions/us-gridded-methane-emissions.

Recalculations Discussion

EPA received information and data related to the emission estimates through GHGRP reporting and presented information to stakeholders regarding the updates under consideration. In November 2023, EPA released draft memoranda that discussed changes under consideration and requested stakeholder feedback on those changes. EPA then released final memoranda documenting the methodology implemented in the current Inventory.[82] Memoranda cited in the Recalculations Discussion below are: Inventory of U.S. Greenhouse Gas Emissions and Sinks 1990-2022: Updates for Transmission Compressor Station Activity (*Transmission Station Activity* memo), Inventory of U.S. Greenhouse Gas Emissions and Sinks 1990-2022: Updates for Completion and Workover Emissions (*Completions and Workovers* memo), and Inventory of U.S. Greenhouse Gas Emissions and Sinks 1990-2022: Updates for Underground Natural Gas Storage Well Emission Events (*Storage Well Events* memo).

EPA evaluated relevant information available and made several updates to the *Inventory*, including for transmission compressor stations, completions and workovers, and underground natural gas storage wells. General information for these source specific recalculations are presented below and details are available in the *Transmission Station Activity*, *Completions and Workovers*, and *Storage Well Events* memos, including additional considerations for the updates.

In addition to the updates to the sources mentioned above, for certain sources, CH_4 and/or CO_2 emissions changed by greater than 0.05 MMT CO_2 Eq., comparing the previous estimate for 2021 to the current (recalculated) estimate for 2021. The emissions changes were mostly due to GHGRP data submission revisions. These sources are discussed below and include pneumatic controllers, well pad equipment leaks, condensate tanks, liquids unloading, gas engines (in production segment), miscellaneous production flaring, gathering and boosting (G&B) station blowdowns, G&B pneumatic controllers, G&B yard piping, G&B acid gas removal units (AGRU), natural gas processing flares, and transmission pipeline venting.

The combined impact of revisions to 2021 natural gas systems CH_4 emissions, compared to the previous *Inventory*, is a decrease from 181.4 to 174.6 MMT CO_2 Eq. (6.8 MMT CO_2 Eq., or 4 percent). The recalculations resulted in an average increase in the annual CH_4 emission estimates across the 1990 through 2021 time series, compared to the previous *Inventory*, of 1.9 MMT CO_2 Eq., or 0.8 percent.

The combined impact of revisions to 2021 natural gas systems CO_2 emissions, compared to the previous *Inventory*, is a decrease from 36.2 MMT to 35.8 MMT, or 1.1 percent. The recalculations resulted in an average increase in emission estimates across the 1990 through 2021 time series, compared to the previous *Inventory*, of 0.4 MMT CO_2 Eq., or 1.5 percent.

The combined impact of revisions to 2021 natural gas systems N_2O emissions, compared to the previous *Inventory*, is an increase from 7.6 kt CO_2 Eq. to 12.6 kt CO_2 Eq., or 65 percent. The recalculations resulted in an average increase in emission estimates across the 1990 through 2021 time series, compared to the previous *Inventory*, of 10.4 percent.

In Table 3-80 and Table 3-81 below are categories in natural gas systems with recalculations resulting in a change of greater than 0.05 MMT CO_2 Eq., comparing the previous estimate for 2021 to the current (recalculated) estimate for 2021. No changes made to N_2O estimates resulted in a change greater than 0.05 MMT CO_2 Eq. For more information, please see the Recalculations Discussion below.

[82] Stakeholder materials including draft and final memoranda for the current (i.e., 1990 to 2022) *Inventory* are available at https://www.epa.gov/ghgemissions/natural-gas-and-petroleum-systems.

Exploration

HF Completions (Methodological Update)

EPA updated the calculation methodology for HF completions to use basin-level HF completion counts from Enverus and basin-specific activity factors and emission factors calculated from Subpart W data for each control category (i.e., non-reduced emission completion (REC) with venting, non-REC with flaring, REC with venting, REC with flaring). Previously, national annual average activity and emission factors calculated using Subpart W data were applied to national completion counts to estimate HF gas well completion emissions. In this update, EPA developed national emission estimates by summing calculated basin-level total emission estimates. The *Completions and Workovers* memo presents additional information and considerations for this update.

EPA calculated basin-specific activity factors and CH_4 and CO_2 emission factors for all basins that reported Subpart W data. The factors were year-specific for reporting year (RY) 2011 through RY2022. For basin-level HF completion event counts, EPA used Enverus data for 1990 to 2010 and Subpart W for 2011 forward. For the fraction of completions in each control subcategory, EPA retained the previous *Inventory's* assumption that all HF gas well completions were non-REC for 1990 to 2000. The previous *Inventory* also assumed that 10 percent of HF completions were non-REC with flaring from 1990 to 2010 (based on national Subpart W data for RY2011 and RY2012); EPA updated this value using basin-specific Subpart W data for RY2011 and RY2012. For 2011 to 2022, EPA determined the percent contribution of each control category directly from Subpart W data and used linear interpolation between 2000 and 2011 to determine the percent of gas wells with RECs. EPA developed year- and basin-specific Subpart W EFs for 2011 forward. Year 2011 emission factors were applied to all prior years for each basin. For basins without Subpart W data available, EPA applied national average activity and emission factors (unweighted average of all Subpart W reported data).

Comparing the final completion emissions and those presented at the October 2023 webinar and in the November 2023 *Completions and Workovers* memo, the final estimates are higher for certain completion categories. These emissions increases are due not to the basin-level methodology changes discussed here but rather to changes in the Enverus dataset. EPA applied the same data processing steps to Enverus data in the fall of 2023 as it did for the previous Enverus data analysis (conducted in 2021) and data changes led to many more completions being classified as HF completions.

As a result of this methodological update, CH_4 emissions estimates for HF completions are on average 55 percent higher across the time series than in the previous *Inventory*. The 2021 CH_4 emissions estimate is 54 percent lower than in the previous *Inventory*. The largest increase between the updates and the previous *Inventory* for CH_4 emissions is 134 percent in 1998 with an average increase of 92 percent over the 1990 through 2010 time period. CH_4 emissions decreased or were similar for 2011 forward and the largest decrease between the updates and the previous *Inventory* is 54 percent in 2021. CH_4 emissions increased on average across the time series, but particularly in earlier years due to gas well HF completions that were non-REC with venting, particularly in the Appalachian basin (Eastern Overthrust) [basin 160a]. The Appalachian basin (Eastern Overthrust) had a large number of gas well HF completion events that were non-REC with venting and the highest EF of any basin. The update resulted in CO_2 emissions estimates that are on average 54 percent higher across the time series than in the previous *Inventory*. The 2021 CO_2 emissions estimate is 3 percent lower than in the previous *Inventory*. The largest increase between the updates and the previous *Inventory* for CO_2 emissions is 141 percent in 1996, and the largest decrease between the updates and the previous *Inventory* is 44 percent in 2013. CO_2 emissions increased predominantly due to non-REC with flaring events in the Appalachian basin (basin 160A) and the East Texas basin (basin 260); these two basins had the highest EFs of any basin.

Non-HF Completions (Methodological Update)

EPA updated the activity data sources and calculation methodology for non-HF completions to use basin-level non-HF completion counts from Enverus and basin-specific activity factors and emission factors, calculated from Subpart W data for each control category (i.e., vented, flared). Previously, national non-HF completion counts and national annual average activity and emission factors calculated using historical data analyses, and Subpart W data were applied to estimate non-HF gas well completion emissions. In this update, EPA developed national emission estimates by summing calculated basin-level total emission estimates. The *Completions and Workovers* memo presents additional information and considerations for this update.

EPA calculated basin-specific activity factors and CH_4 and CO_2 emission factors for all basins that reported Subpart W data. The factors were year-specific for reporting year (RY) 2011 through RY2022. For basin-level non-HF gas well completion event counts, EPA used Enverus data across the time series. For the fraction of completions in each control category, EPA implemented at the basin level the previous *Inventory's* approach and the percent of non-HF gas well completions that are vented in 2011 is applied to all prior years. For 2011 to 2022, EPA determined the percent contribution of each control category directly from Subpart W data for each basin. EPA developed year- and basin-specific Subpart W EFs for 2011 forward. Year 2011 emission factors were applied to all prior years for each basin. For basins without Subpart W data available, EPA applied national average activity and emission factors (unweighted average of all Subpart W reported data).

As a result of this methodological update, CH_4 emissions estimates for non-HF completions are on average 419 percent higher across the time series than in the previous *Inventory*. The 2021 CH_4 estimate is 43 percent higher than in the previous *Inventory*. The largest increase between the updates and the previous *Inventory* for CH_4 emissions is 1,533 percent in 1991, and the largest decrease between the updates and the previous *Inventory* is 63 percent in 2018. Methane emissions increased primarily due to gas well non-HF completions that were vented. The Appalachian basin (Eastern Overthrust) [basin 160a] and the Appalachian basin (basin 160) had many non-HF completion events that were vented and average EFs more than 2 times higher than the national average across the 1990-2022 time series. The update resulted in CO_2 emissions estimates that are on average 1,312 percent higher across the time series than in the previous *Inventory*. The 2021 CO_2 emissions estimate is 7,331 percent higher than in the previous *Inventory*. The largest increase between the updates and the previous *Inventory* for CO_2 emissions is 7,331 percent in 2021, and the largest decrease between the updates and the previous *Inventory* is 47 percent in 2018. The increase in CO_2 emissions is due to non-HF completions that were flared, primarily in the Gulf Coast basin (basin 220). The Gulf Coast basin had the highest fraction of non-HF completions that were flared of any basin.

Production

HF Workovers (Methodological Update)

EPA updated the activity data source and calculation methodology for HF workovers to use basin-specific activity factors and emission factors, calculated from Subpart W data for each control category (i.e., non-reduced emission completion (REC) with venting, non-REC with flaring, REC with venting, REC with flaring). Previously, national HF workover counts calculated using analyses for NSPS OOOO (i.e., 1 percent of HF gas wells were worked over annually) and national annual average emission factors calculated using Subpart W data were applied to estimate HF gas well workover emissions. In this update, EPA developed national emission estimates by summing calculated basin-level total emission estimates. The *Completions and Workovers* memo presents additional information and considerations for this update.

EPA calculated basin-specific activity factors and CH_4 and CO_2 emission factors for all basins that reported Subpart W data. For basin-level workover counts, instead of applying a 1 percent workover rate to HF gas wells, EPA developed year- and basin-specific Subpart W AFs for 2015 forward that represent the number of HF workovers per gas well. Year 2015 Subpart W AFs were applied to all prior years for each basin. For the fraction of workovers in each control subcategory, EPA retained the previous *Inventory's* assumption that all HF gas well workovers were non-REC for 1990 to 2000. The previous Inventory also assumed that 10 percent of HF workovers were non-REC with flaring from 1990 to 2010; EPA updated this value using basin-specific data from Subpart W. For 2011 forward, EPA determined the percent contribution of each control category directly from Subpart W data at the basin-level. EPA used linear interpolation for interpolation between 2000 and 2011 to determine the percent of gas wells with RECs. EPA developed year-and basin-specific Subpart W EFs for 2011 forward. Year 2011 emission factors were applied to all prior years for each basin. For basins without Subpart W data available, EPA applied national average activity and emission factors (unweighted average of all Subpart W reported data).

As a result of this methodological update, CH_4 emissions estimates for HF workovers are on average 43 percent lower across the time series than in the previous *Inventory*. The 2021 CH_4 emissions estimate is 94 percent lower than in the previous *Inventory*. The largest increase between the updates and the previous *Inventory* for CH_4 emissions is 5 percent in 1990, and the largest decrease between the updates and the previous *Inventory* is 99 percent in 2019. The update resulted in CO_2 emissions estimates that are on average 60 percent lower than in the previous *Inventory*. The 2021 CO_2 emissions estimate is 67 percent lower than in the previous *Inventory*. The largest increase between the updates and the previous *Inventory* for CO_2 emissions is 53 percent in 2013, and the

largest decrease between the updates and the previous *Inventory* is 99 percent in 2019. The decrease in emissions for both CH_4 and CO_2 was primarily due to the change in calculation method for workover counts. HF gas well workover counts decreased by an average of 73 percent across the 1990 through 2021 time series compared to the previous *Inventory*.

Non-HF Workovers (Methodological Update)

EPA updated the activity data source and calculation methodology for non-HF workovers to use basin-specific activity factors and emission factors, calculated from Subpart W data for each control category (i.e., vented, flared). Previously, national annual average activity and emission factors calculated using historical data analyses and Subpart W data were applied along with national gas well counts to estimate non-HF gas well workover emissions. In this update, EPA developed national emission estimates by summing calculated basin-level total emission estimates. The *Completions and Workovers* memo presents additional information and considerations for this update.

EPA calculated basin-specific activity factors and CH_4 and CO_2 emission factors for all basins that reported Subpart W data. For basin-level workover counts, EPA developed year-specific Subpart W AFs for 2015 forward. Year 2015 Subpart W data was applied to prior years for each basin. For the fraction of workovers in each control subcategory, EPA applied year- and basin-specific AFs for 2011 forward, retained the previous *Inventory's* assumption that all non-HF workovers were vented in 1990 to 1992, and used linear interpolation between the 1992 and 2011 activity factors at the basin-level. EPA developed year- and basin-specific Subpart W EFs for 2011 forward. Year 2011 emission factors were applied to all prior years for each basin. For basins without Subpart W data available, EPA applied national average activity and emission factors (unweighted average of all Subpart W reported data).

As a result of this methodological update, CH_4 emissions estimates for non-HF workovers are on average 277 percent higher than in the previous *Inventory*. The 2021 estimate is 180 percent higher than in the previous *Inventory*. The largest increase between the estimates and the previous *Inventory* for CH_4 emissions is 698 percent

in 2017, and the smallest increase is 78 percent in 2018. The increase in CH_4 emissions is due to non-HF workovers that were vented. In the Chautauqua Platform basin (basin 355), all non-HF workovers were vented, and it had the highest CH_4 EF in 2017. The update resulted in CO_2 emissions estimates for non-HF workovers that are higher across the entire time series than the previous *Inventory* (on average 3,067 percent higher). The 2021 CO_2 emissions estimate is 116 percent higher than in the previous *Inventory*. The largest increase between estimates and the previous *Inventory* for CO_2 emissions is 7,432 percent in 1994, and the smallest increase is 78 percent in 2018. The increase in CO_2 emissions is due to non-HF workovers that were flared, particularly in the Bend Arch basin (basin 425). The Bend Arch basin has a high non-HF completion per total gas well AF and a high fraction of non-HF workovers that were flared compared to other basins over the time series.

Equipment Leaks (Methodological Update)

In the previous *Inventory*, EPA updated the CH_4 emissions calculation methodology for onshore production equipment leaks to use basin-specific equipment-level activity factors (e.g., separators per well) from GHGRP data. However, the CO_2 emissions calculation methodology was not updated and instead the previous *Inventory* still relied on a national-level methodology to estimate CO_2 emissions. For this year's *Inventory*, EPA calculated equipment leak CO_2 emissions in the same manner as CH_4 emissions. EPA calculated CO_2 estimates using the basin-specific equipment-level activity factors for RY2015 through RY2022 from GHGRP, consistent with the methodology used to calculate the CH_4 activity factors, and the CO_2 emissions factors for onshore production segment equipment leaks. Note, this methodological update applies only for activity factors. The previous *Inventory's* CO_2 emission factors for onshore production segment equipment leaks (by equipment type) were retained and used to develop CO_2 estimates.

The update for CO_2 emission estimates for equipment leaks resulted in an average increase of 12 percent across the time series compared to the previous *Inventory*. Years 1990 through 2002 were minimally impacted by the updates, with an increase of 2 percent for CO_2 emissions. Years 2020 and 2021 showed larger increases of 69 and 48 percent for 2020 and 2021, respectively, which is mostly due to much higher emissions from meters and piping in the Powder River Basin.

Methane emissions for equipment leaks were impacted due to recalculations with updated data. CH_4 emission estimates were an average of 5 percent lower across the time series compared to the previous *Inventory*. The 2021 CH_4 estimate is 2 percent lower in 2021 compared to the previous *Inventory*. These CH_4 emissions changes were due to GHGRP submission revisions.

Chemical Injection Pumps (Methodological Update)

In the previous *Inventory*, EPA updated the CH_4 emissions calculation methodology for chemical injection pumps to use basin-specific equipment-level activity factors (e.g., pumps per well) from GHGRP data. However, the CO_2 emissions calculation methodology was not updated and instead the previous *Inventory* still relied on a national-level methodology to estimate CO_2 emissions. For the current *Inventory*, EPA calculated chemical injection pump CO_2 emissions in the same manner as CH_4 emissions. EPA calculated CO_2 estimates using the basin-specific equipment-level activity factors for RY2015 through RY2022 from GHGRP, consistent with the methodology used to calculate the CH_4 activity factors, and the CO_2 emission factor. Note, this methodological update applies only for activity factors. The previous *Inventory's* chemical injection pumps CO_2 emission factor was retained and used to develop CO_2 estimates.

The update for CO_2 emission estimates resulted in an average decrease of 9 percent across the time series compared to the previous *Inventory*. There were larger decreases of 31 and 39 percent for 2020 and 2021, respectively. The recent years of the time series used basin-specific activity factors and certain basins had lower activity factors compared to the national average factors (e.g., Permian Basin, Denver Basin, San Juan, Paradox, AK Cook Inlet).

Table 3-92: Chemical Injection Pumps National CO_2 Emissions (Metric Tons CO_2)

Pneumatic Controllers (Methodological Update)

In the previous *Inventory*, EPA updated the CH_4 emissions calculation methodology for pneumatic controllers to use basin-specific activity factors and emission factors by bleed type (i.e., low, high, intermittent bleed) from GHGRP data. However, the CO_2 emissions calculation methodology was not updated and instead the previous

Inventory still relied on a national-level methodology to estimate CO_2 emissions. For the current *Inventory*, EPA calculated pneumatic controller CO_2 emissions using basin-specific emissions data such that the CO_2 emissions reflect the unique CO_2 composition of the gas in a basin.

The update for pneumatic controller CO_2 emission estimates resulted in an average decrease of 44 percent across the time series compared to the previous *Inventory*. This average decrease is generally consistent for all years.

Methane emissions for pneumatic controllers were impacted due to recalculations with updated data. Methane emissions estimates are on average 0.3 percent lower across the time-series than in the previous *Inventory*. The estimate for 2021 is 2 percent lower than in the previous *Inventory*. These changes were due to GHGRP submission revisions.

Table 3-93: Pneumatic Controllers National CO_2 Emissions (Metric Tons CO_2)

Source	1990	2005	2018	2019	2020	2021	2022

Storage Tanks (Recalculation with Updated Data)

Methane emissions for production condensate storage tanks are on average lower than the previous *Inventory* by less than 0.1 percent across the 1990 to 2021 time series. The 2021 estimate is 6 percent lower than in the previous *Inventory*. The production storage tanks CO_2 emissions estimates are on average 3 percent higher across the 1990 to 2021 time series than in the previous Inventory. The 2021 estimate is 25 percent higher than in the previous *Inventory*. These changes were due to GHGRP submission revisions.

Transmission and Storage

Transmission Compressor Station Leaks and Venting (Methodological Update)

EPA updated the methodology to estimate national level activity data for transmission compressor stations (i.e., station and compressor counts). EPA used annual data for 1996 to 2022 from FERC and PHMSA to estimate national transmission station counts and total transmission compressor counts. FERC requires major interstate transmission compression facilities to report annual data on station counts, total compressor counts, and total transmission pipeline miles. EPA compiled annual FERC data and scaled it up to the national level using PHMSA national transmission pipeline miles for 1996 to 2022. EPA retained existing *Inventory* activity data for 1990 to 1992 and used linear interpolation to estimate national station and total compressor counts for 1993 to 1995.

Total compressor counts were apportioned to reciprocating and centrifugal compressor types using data from GHGRP's Subpart W. EPA retained existing *Inventory* activity data for 1990 to 1992 and used linear interpolation

for intermediate time series years. For more details on this update, refer to the *Transmission Station Activity* memo.

This update impacts CH_4 and CO_2 emissions from leaks (including compressor leaks), dehydrator vents, pneumatic devices, flaring, and venting at transmission compression stations. As a result of this update, CH_4 emissions estimates increased by an average of 2.6 percent across the time series and decreased by 18 percent in 2021, compared to the previous *Inventory*. Emissions estimates of CO_2 increased by an average of 2.5 percent across the time series and decreased by 16 percent in 2021, compared to the previous *Inventory*.

Underground Natural Gas Storage Well Events (Methodological Update)

EPA updated the *Inventory* with CO_2 and CH_4 estimates resulting from underground natural gas storage well events that occurred in several years across the inventory time series. Previously, EPA included emissions only from the Aliso Canyon event (occurring 2015 to 2016). This update incorporates emissions from 9 events identified as occurring at storage wells. For the update, emissions from individual events were added to the year in which they occurred.

EPA calculated CH_4 emissions using the reported leak size and applying inventory assumptions for CH_4 content. The CH_4 emissions estimates were then adjusted using a 60 percent combustion efficiency if there was evidence of combustion or ignition during the event. EPA calculated CO_2 emissions only for the events where combustion or ignition occurred, using the 60 percent combustion efficiency. The *Storage Well Events* memo presents additional information and considerations for this update.

One commenter provided feedback and it focused on the 60 percent combustion efficiency. The commenter suggested using 30 percent as the combustion efficiency instead of 60 percent based on research from Gvakharia et al., 2017, which lists 30 percent as the lowest flare efficiency.[83] The commenter noted the study used to justify the 60 percent combustion efficiency evaluated engineered flares which may not be representative of combustion during emergency events.

The newly incorporated events occurred in years 1992, 1998, 2001, 2002, 2003, 2004, 2006, 2010, and 2011. They emitted on average 7,085 metric tons of CH_4 and 27,056 metric tons CO_2.

Methane emissions estimates for underground natural gas storage wells increased 15 percent across the time series compared to previous estimates. The largest increase between the updates and the previous estimates occurs in 2004, which incorporates CH_4 emissions from the Moss Bluff event.

Updates to CO_2 emissions resulted in an increase of 1,693 percent across the time series compared to previous estimates. This increase is mostly due to additions for 2001 and 2004 estimates, resulting from Yaggy and Moss Bluff events, respectively. Combustion occurred at both of these events, resulting in the application of the 60 percent combustion efficiency.

Pipeline Venting (Recalculation with Updated Data)

Transmission pipeline venting CH_4 emission estimates are on average 0.1 percent lower across the 1990 to 2021 time series than in the previous *Inventory*. The CH_4 emissions estimate for 2021 is 4 percent lower than in the previous *Inventory*. These changes were due to GHGRP submission revisions.

Table 3-108: Pipeline Venting National CH_4 Emissions (Metric Tons CH_4)

Distribution

There were no methodological updates to the distribution segment and recalculations resulted in an average decrease in CH_4 emissions across the 1990 to 2021 time series of less than 0.1 percent and an average decrease in calculated CO_2 emissions across the 1990 to 2021 time series of less than 0.1 percent, compared to the previous *Inventory*.

[83] Gvakharia et al, 2017. Methane, Black Carbon, and Ethane Emissions from Natural Gas Flares in the Bakken Shale, North Dakota. *Environmental Science & Technology.* 51: 5317-5325. https://doi.org/10.1021/acs.est.6b05183.

Post-Meter

There were no methodological updates to estimate post-meter emissions and recalculations resulted in an average decrease in CH_4 emissions across the 1990 to 2021 time series of less than 0.1 percent and an average decrease in calculated CO_2 emissions across the 1990 to 2021 time series of less than 0.1 percent, compared to the previous *Inventory*.

Planned Improvements

Planned Improvements for 2025 *Inventory*

EPA updated the Enverus data and there were notable increases in the number of wells and completions identified as being hydraulically fractured compared with previous versions of the database. EPA will assess the underlying Enverus data to determine the cause of these changes.

Upcoming Data, and Additional Data that Could Inform the *Inventory*

EPA will assess new data received by EPA's Greenhouse Gas Reporting Program and Methane Challenge Program on an ongoing basis, which may be used to validate or improve existing estimates and assumptions.

EPA continues to track studies that contain data that may be used to update the *Inventory*. EPA will also continue to assess studies that include and compare both top-down and bottom-up emission estimates, which could lead to improved understanding of unassigned high emitters (e.g., identification of emission sources and information on frequency of high emitters) as recommended in previous stakeholder comments.

3.8 Abandoned Oil and Gas Wells (CRT Source Categories 1B2a and 1B2b)

The term "abandoned wells", as used in the *Inventory*, encompasses various types of oil and gas wells, including orphaned wells and other non-producing wells:

- Wells with no recent production, and not plugged. Common terms (such as those used in state databases) might include: inactive, temporarily abandoned, shut-in, dormant, and idle.
- Wells with no recent production and no responsible operator. Common terms might include: orphaned, deserted, long-term idle, and abandoned.
- Wells that have been plugged to prevent migration of gas or fluids.

The U.S. population of abandoned oil and gas wells (including orphaned wells and other non-producing wells) is around 3.9 million (with around 3.0 million abandoned oil wells and 0.9 million abandoned gas wells). The methods to calculate emissions from abandoned wells involve calculating the total populations of plugged and unplugged abandoned oil and gas wells in the United States and the application of emission factors. An estimate of the number of orphaned wells within this population is not developed as part of the methodology. Wells that are plugged have much lower average emissions than wells that are unplugged (less than 1 kg CH_4 per well per year, versus over 100 kg CH_4 per well per year). Around 43 percent of the abandoned well population in the United States is plugged. This fraction has increased over the *Inventory* time series (from around 22 percent in 1990) as more wells fall under regulations and programs requiring or promoting plugging of abandoned wells.

Abandoned oil wells. Abandoned oil wells emitted 235 kt CH_4 and 5 kt CO_2 in 2022. Emissions of both gases increased by 3 percent from 1990, while the total population of abandoned oil wells increased 40 percent.

Abandoned gas wells. Abandoned gas wells emitted 68 kt CH_4 and 3 kt CO_2 in 2022. Emissions of both gases increased by 33 percent from 1990, while the total population of abandoned gas wells increased 83 percent.

Methodology and Time-Series Consistency

EPA uses a Tier 2 method from IPCC (2019) to quantify emissions from abandoned oil and gas wells. EPA's approach is based on the number of plugged and unplugged abandoned wells in the Appalachian region and in the rest of the U.S., and emission factors for plugged and unplugged abandoned wells in Appalachia and the rest of the U.S. Methods for abandoned wells are unavailable in IPCC (2006). The details of this approach and of the data sources used are described in the memorandum *Inventory of U.S. Greenhouse Gas Emissions and Sinks 1990-2016: Abandoned Wells in Natural Gas and Petroleum Systems (2018 Abandoned Wells Memo).*

EPA developed abandoned well CH_4 emission factors using data from Kang et al. (2016) and Townsend-Small et al. (2016). Plugged and unplugged abandoned well CH_4 emission factors were developed at the national-level (using emission data from Townsend-Small et al.) and for the Appalachia region (using emission data from measurements in Pennsylvania and Ohio conducted by Kang et al. and Townsend-Small et al., respectively). The Appalachia region emissions factors were applied to abandoned wells in states in the Appalachian basin region, and the national-level emission factors were applied to abandoned wells in all other states. EPA developed abandoned well CO_2 emission factors using the CH_4 emission factors and an assumed ratio of CO_2-to-CH_4 gas content, similar to the approach used to calculate CO_2 emissions for many sources in Petroleum Systems and Natural Gas Systems. For abandoned

oil wells, EPA used the Petroleum Systems default production segment associated gas ratio of 0.020 MT CO_2/MT CH_4, which was derived through API TankCalc modeling runs. For abandoned gas wells, EPA used the Natural Gas Systems default production segment CH_4 and CO_2 gas content values (GRI/EPA 1996, GTI 2001) to develop a ratio of 0.044 MT CO_2/MT CH_4. The same respective emission factors are applied for each year of the time series.

EPA developed state-level annual counts of abandoned wells for 1990 through 2022 by summing together an annual estimate of abandoned wells in the Enverus data set (Enverus 2023), and an estimate of total abandoned wells not included the Enverus dataset (see 2018 Abandoned Wells Memo for additional information on how the value was calculated) for each state. References reviewed to develop the number of abandoned wells not included in the Enverus dataset include historical records collected by state agencies and by USGS.

The state-level abandoned well population was then split into plugged and unplugged wells by applying an assumption that all abandoned wells were unplugged in 1950 and using Enverus data to calculate the fraction of plugged abandoned wells in 2022. Linear interpolation was applied between the 1950 value and 2022 value to calculate the plugged fraction for intermediate years. See the memorandum *Inventory of U.S. Greenhouse Gas Emissions and Sinks 1990-2016: Abandoned Wells in Natural Gas and Petroleum Systems (2018 Abandoned Wells Memo)* for details.[84]

Abandoned Oil Wells

Uncertainty

To characterize uncertainty surrounding estimates of abandoned well emissions, EPA conducted a quantitative uncertainty analysis using the IPCC Approach 2 methodology (Monte Carlo simulation technique). See the 2018 Abandoned Wells Memo for details of the uncertainty analysis methods. EPA used Microsoft Excel's @RISK add-in tool to estimate the 95 percent confidence bound around total methane emissions from abandoned oil and gas wells in year 2022, then applied the calculated bounds to both CH_4 and CO_2 emissions estimates for each population. The @RISK add-in provides for the specification of probability density functions (PDFs) for key variables within a computational structure that mirrors the calculation of the inventory estimate. EPA used measurement data from the Kang et al. (2016) and Townsend-Small et al. (2016) studies to characterize the CH_4 emission factor PDFs. For activity data inputs (e.g., total count of abandoned wells, split between plugged and unplugged), EPA assigned default uncertainty bounds of ± 10 percent based on expert judgment.

The IPCC guidance notes that in using this method, "some uncertainties that are not addressed by statistical means may exist, including those arising from omissions or double counting, or other conceptual errors, or from incomplete understanding of the processes that may lead to inaccuracies in estimates developed from models." As a result, the understanding of the uncertainty of emission estimates for this category evolves and improves as the underlying methodologies and datasets improve. The uncertainty bounds reported below only reflect those uncertainties that EPA has been able to quantify and do not incorporate considerations such as modeling uncertainty, data representativeness, measurement errors, misreporting or misclassification.

The results presented below in Table 3-115 provide the 95 percent confidence bound within which actual emissions from abandoned oil and gas wells are likely to fall for the year 2022, using the recommended IPCC methodology. Abandoned oil well CH_4 emissions in 2022 were estimated to be between 1.1 and 19.7 MMT CO_2 Eq., while abandoned gas well CH_4 emissions were estimated to be between 0.3 and 5.4 MMT CO_2 Eq. at a 95 percent confidence level. Uncertainty bounds for other years of the time series have not been calculated, but uncertainty is expected to vary over the time series.

Table 3-115: Approach 2 Quantitative Uncertainty Estimates for CH_4 and CO_2 Emissions from Petroleum and Natural Gas Systems (MMT CO_2 Eq. and Percent)

Source	Gas	2022 Emission Estimate (MMT CO_2 Eq.)[b]	Uncertainty Range Relative to Emission Estimate[a] (MMT CO_2 Eq.)		(%)	
			Lower Bound	Upper Bound	Lower Bound	Upper Bound
Abandoned Oil Wells	CH_4	6.6	1.1	19.7	-83%	+204%
Abandoned Gas Wells	CH_4	1.9	0.3	5.4	-83%	+204%
Abandoned Oil Wells	CO_2	0.005	0.001	0.014	-83%	+204%
Abandoned Gas Wells	CO_2	0.003	0.0005	0.008	-83%	+204%

[a] Range of emission estimates estimated by applying the 95 percent confidence intervals obtained from the Monte Carlo simulation analysis conducted for total abandoned oil and gas well CH_4 emissions in year 2022.

[b] All reported values are rounded after calculation. As a result, lower and upper bounds may not be duplicable from other rounded values as shown in the table.

QA/QC and Verification Discussion

The emission estimates in the *Inventory* are continually reviewed and assessed to determine whether emission factors and activity factors accurately reflect current industry practices. In order to ensure the quality of emission estimates for abandoned wells, general (IPCC Tier 1) quality assurance/quality control (QA/QC) procedures were implemented consistent with the U.S. Inventory QA/QC plan outlined in Annex 8. Additionally, EPA reviewed the current Enverus dataset and compared it with results from the previous dataset to identify outliers and instances of significant changes to abandoned oil and gas well counts.

EPA performs a thorough review of information associated with new studies to assess whether the assumptions in the *Inventory* are consistent with industry practices and whether new data is available that could be considered for updates to the estimates. As in previous years, EPA conducted early engagement and communication with stakeholders on updates prior to public review. EPA held a stakeholder webinar on greenhouse gas data for oil and gas in October of 2023.

Recalculations Discussion

EPA updated the *Inventory* with revised abandoned oil and gas well counts developed from Enverus data (Enverus 2023). Compared to the previous *Inventory*, annual abandoned oil well counts increased by an average of 2 percent across the time series and increased by 4 percent in 2021. Annual abandoned gas well counts increased by 2 percent across the time series and 7 percent in 2021. Similarly, both plugged wells and unplugged wells increased by 2 percent across the time series. As a result of this update, calculated abandoned oil well CH_4 and CO_2 emissions increased by an average of 2 percent each year across the time series and increased by 3 percent in 2021, compared to the previous *Inventory*. Abandoned gas well CH_4 and CO_2 emissions increased by an average of 1 percent across the time series and increased by 8 percent in 2021, compared to the previous *Inventory*.

Planned Improvements

EPA will continue to assess new data and stakeholder feedback on considerations (such as potential use of emission factor data from regions not included in the measurement studies on which current emission factors are based) to improve the abandoned well count estimates and emission factors. In future Inventories, EPA will assess data that become available from Department of Interior and Department of Energy orphan well plugging programs.

3.9 International Bunker Fuels (CRT Source Category 1: Memo Items)

Emissions resulting from the combustion of fuels used for international transport activities, termed international bunker fuels under the Paris Agreement and the UNFCCC, are not included in national emission totals, but are reported separately based upon location of fuel sales. The decision to report emissions from international bunker fuels separately, instead of allocating them to a particular country, was made by the Intergovernmental

Negotiating Committee in establishing the Framework Convention on Climate Change.[85] These decisions are reflected in the IPCC methodological guidance, including IPCC (2006), in which countries are requested to report emissions from ships or aircraft that depart from their ports with fuel purchased within national boundaries and are engaged in international transport separately from national totals (IPCC 2006).[86]

Two transport modes are addressed under the IPCC definition of international bunker fuels: aviation and marine.[87] Greenhouse gases emitted from the combustion of international bunker fuels, like other fossil fuels, include CO_2, CH_4 and N_2O for marine transport modes, and CO_2 and N_2O for aviation transport modes. Emissions from ground transport activities—by road vehicles and trains—even when crossing international borders are allocated to the country where the fuel was loaded into the vehicle and, therefore, are not counted as bunker fuel emissions.

The *2006 IPCC Guidelines* distinguish between three different modes of air traffic: civil aviation, military aviation, and general aviation. Civil aviation comprises aircraft used for the commercial transport of passengers and freight, military aviation comprises aircraft under the control of national armed forces, and general aviation applies to recreational and small corporate aircraft. The *2006 IPCC Guidelines* further define international bunker fuel use from civil aviation as the fuel combusted for civil (e.g., commercial) aviation purposes by aircraft arriving or departing on international flight segments. However, as mentioned above, and in keeping with the *2006 IPCC Guidelines*, only the fuel purchased in the United States and used by aircraft taking-off (i.e., departing) from the United States are reported here. The standard fuel used for civil and military aviation is kerosene-type jet fuel, while the typical fuel used for general aviation is aviation gasoline.[88]

Emissions of CO_2 from aircraft are essentially a function of fuel consumption. Nitrous oxide emissions also depend upon engine characteristics, flight conditions, and flight phase (i.e., take-off, climb, cruise, decent, and landing). Recent data suggest that little or no CH_4 is emitted by modern engines (Anderson et al. 2011), and as a result, CH_4 emissions from this category are reported as zero. In jet engines, N_2O is primarily produced by the oxidation of atmospheric nitrogen, and the majority of emissions occur during the cruise phase.

International marine bunkers comprise emissions from fuels burned by ocean-going ships of all flags that are engaged in international transport. Ocean-going ships are generally classified as cargo and passenger carrying, military (i.e., U.S. Navy), fishing, and miscellaneous support ships (e.g., tugboats). For the purpose of estimating greenhouse gas emissions, international bunker fuels are solely related to cargo and passenger carrying vessels, which is the largest of the four categories, and military vessels. Two main types of fuels are used on sea-going vessels: distillate diesel fuel and residual fuel oil. Carbon dioxide is the primary greenhouse gas emitted from marine shipping.

Overall, aggregate greenhouse gas emissions in 2022 from the combustion of international bunker fuels from both aviation and marine activities were 99.1 MMT CO_2 Eq., or 5.2 percent below emissions in 1990 (see Table 3-116 and Table 3-117). Emissions from international flights and international shipping voyages departing from the United States have increased by 74.4 percent and decreased by 51.7 percent, respectively, since 1990. The majority of these emissions were in the form of CO_2; however, small amounts of CH_4 (from marine transport modes) and N_2O were also emitted.

[85] See report of the Intergovernmental Negotiating Committee for a Framework Convention on Climate Change on the work of its ninth session, held at Geneva from 7 to 18 February 1994 (A/AC.237/55, annex I, para. 1c).

[86] Note that the definition of international bunker fuels used by the UNFCCC differs from that used by the International Civil Aviation Organization.

[87] Most emission related international aviation and marine regulations are under the rubric of the International Civil Aviation Organization (ICAO) or the International Maritime Organization (IMO), which develop international codes, recommendations, and conventions, such as the International Convention of the Prevention of Pollution from Ships (MARPOL).

[88] Naphtha-type jet fuel was used in the past by the military in turbojet and turboprop aircraft engines.

Methodology and Time-Series Consistency

Emissions of CO_2 were for the most part estimated by applying carbon content and fraction oxidized factors to fuel consumption activity data. This approach is analogous to that described under Section 3.1. Carbon content and fraction oxidized factors for jet fuel (except for commercial aviation as per below), distillate fuel oil, and residual fuel oil are the same as used for CO_2 from Fossil Fuel Combustion and are presented in Annex 2.1, Annex 2.2, and Annex 3.8 of this *Inventory*. Density conversions were taken from ASTM (1989) and USAF (1998). Heat content for distillate fuel oil and residual fuel oil were taken from EIA (2024) and USAF (1998), and heat content for jet fuel was taken from EIA (2024). See below for details on how emission estimates for commercial aviation were determined.

A complete description of the methodology and a listing of the various factors employed can be found in Annex 2.1. See Annex 3.8 for a specific discussion on the methodology used for estimating emissions from international bunker fuel use by the U.S. military.

Emission estimates for CH_4 and N_2O were calculated by multiplying emission factors by measures of fuel consumption by fuel type and mode. Emission factors used in the calculations of CH_4 and N_2O emissions were obtained from the *Revised 1996 IPCC Guidelines* (IPCC/UNEP/OECD/IEA 1997), which is also referenced in the *2006 IPCC Guidelines* (IPCC 2006). For aircraft emissions, the following value, in units of grams of pollutant per kilogram of fuel consumed (g/kg), was employed: 0.1 for N_2O (IPCC 2006). For marine vessels consuming either distillate diesel or residual fuel oil the following values (g/MJ), were employed: 0.315 for CH_4 and 0.08 for N_2O. Activity data for aviation included solely jet fuel consumption statistics, while the marine mode included both distillate diesel and residual fuel oil.

Activity data on domestic and international aircraft fuel consumption were developed by the U.S. Federal Aviation Administration (FAA) using radar-informed data from the FAA Enhanced Traffic Management System (ETMS) for 1990 and 2000 through 2022 as modeled with the Aviation Environmental Design Tool (AEDT). This bottom-up approach is built from modeling dynamic aircraft performance for each flight occurring within an individual calendar year. The analysis incorporates data on the aircraft type, date, flight identifier, departure time, arrival time, departure airport, arrival airport, ground delay at each airport, and real-world flight trajectories. To generate results for a given flight within AEDT, the radar-informed aircraft data is correlated with engine and aircraft performance data to calculate fuel burn and exhaust emissions. Information on exhaust emissions for in-production aircraft engines comes from the International Civil Aviation Organization (ICAO) Aircraft Engine Emissions Databank (EDB). This bottom-up approach is in accordance with the Tier 3B method from the *2006 IPCC Guidelines* (IPCC 2006).

International aviation CO_2 estimates for 1990 and 2000 through 2022 were obtained directly from FAA's AEDT model (FAA 2024). The radar-informed method that was used to estimate CO_2 emissions for commercial aircraft for 1990 and 2000 through 2022 was not possible for 1991 through 1999 because the radar dataset was not available for years prior to 2000. FAA developed Official Airline Guide (OAG) schedule-informed inventories modeled with AEDT and great circle trajectories for 1990, 2000, and 2010. Because fuel consumption and CO_2 emission estimates for years 1991 through 1999 are unavailable, consumption estimates for these years were calculated using fuel consumption estimates from the Bureau of Transportation Statistics (DOT 1991 through 2013), adjusted based on 2000 through 2005 data. See Annex 3.3 for more information on the methodology for estimating emissions from commercial aircraft jet fuel consumption.

Data on U.S. Department of Defense (DoD) aviation bunker fuels and total jet fuel consumed by the U.S. military was supplied by the Office of the Under Secretary of Defense (Installations and Environment), DoD. Estimates of the percentage of each Service's total operations that were international operations were developed by DoD. Military aviation bunkers included international operations, operations conducted from naval vessels at sea, and operations conducted from U.S. installations principally over international water in direct support of military operations at sea. Military aviation bunker fuel emissions were estimated using military fuel and operations data synthesized from unpublished data from DoD's Defense Logistics Agency Energy (DLA Energy 2023). Together, the data allow the quantity of fuel used in military international operations to be estimated. Densities for each jet fuel type were obtained from a report from the U.S. Air Force (USAF 1998). Final jet fuel consumption estimates are presented in Table 3-118. See Annex 3.8 for additional discussion of military data.

Table 3-118: Aviation Jet Fuel Consumption for International Transport (TBtu)

Nationality	1990	2005	2018	2019	2020	2021	2022
U.S. and Foreign Carriers	426	791	1,104	1,068	521	677	902
U.S. Military	116	64	44	44	43	44	44
Total	**542**	**854**	**1,148**	**1,112**	**564**	**721**	**946**

Note: Totals may not sum due to independent rounding.

In order to quantify the civilian international component of marine bunker fuels, activity data on distillate diesel and residual fuel oil consumption by cargo or passenger carrying marine vessels departing from U.S. ports were collected for individual shipping agents on a monthly basis by the U.S. Customs and Border Protection. This information was then reported in unpublished data collected by the Foreign Trade Division of the U.S. Department of Commerce's Bureau of the Census (DOC 1991 through 2022) for 1990 through 2001, 2007 through 2022, and the Department of Homeland Security's Bunker Report for 2003 through 2006 (DHS 2008). Fuel consumption data for 2002 was interpolated due to inconsistencies in reported fuel consumption data. Activity data on distillate diesel consumption by military vessels departing from U.S. ports were provided by DLA Energy (2023). The total amount of fuel provided to naval vessels was reduced by 21 percent to account for fuel used while the vessels were not underway (i.e., in port). Data on the percentage of steaming hours underway versus not underway were provided by the U.S. Navy. These fuel consumption estimates are presented in Table 3-119.

Table 3-119: Marine Fuel Consumption for International Transport (Million Gallons)

Fuel Type	1990	2005	2018	2019	2020	2021	2022
Residual Fuel Oil	4,781	3,881	2,790	2,246	1,964	1,953	2,172
Distillate Diesel Fuel & Other	617	444	684	702	461	437	435
U.S. Military Naval Fuels	522	471	285	281	296	285	263
Total	**5,920**	**4,796**	**3,759**	**3,229**	**2,721**	**2,674**	**2,870**

Note: Totals may not sum due to independent rounding.

Methodological recalculations were applied to the entire time series to ensure time-series consistency from 1990 through 2022.

Uncertainty

Emission estimates related to the consumption of international bunker fuels are subject to the same uncertainties as those from domestic aviation and marine mobile combustion emissions; however, additional uncertainties result from the difficulty in collecting accurate fuel consumption activity data for international transport activities separate from domestic transport activities.[89] For example, smaller aircraft on shorter routes often carry sufficient fuel to complete several flight segments without refueling in order to minimize time spent at the airport gate or take advantage of lower fuel prices at particular airports. This practice, called tankering, when done on international flights, complicates the use of fuel sales data for estimating bunker fuel emissions. Tankering is less common with the type of large, long-range aircraft that make many international flights from the United States, however. Similar practices occur in the marine shipping industry where fuel costs represent a significant portion of overall operating costs and fuel prices vary from port to port, leading to some tankering from ports with low fuel costs.

Uncertainties exist with regard to the total fuel used by military aircraft and ships. Total aircraft and ship fuel use estimates were developed from DoD records, which document fuel sold to the DoD Components (e.g., Army, Department of Navy and Air Force) from the Defense Logistics Agency Energy. These data may not include fuel used in aircraft and ships as a result of a Service procuring fuel from, selling fuel to, trading fuel with, or giving fuel to other ships, aircraft, governments, or other entities.

Additionally, there are uncertainties in historical aircraft operations and training activity data. Estimates for the quantity of fuel actually used in Navy and Air Force flying activities reported as bunker fuel emissions had to be estimated based on a combination of available data and expert judgment. Estimates of marine bunker fuel emissions were based on Navy vessel steaming hour data, which reports fuel used while underway and fuel used while not underway. This approach does not capture some voyages that would be classified as domestic for a commercial vessel. Conversely, emissions from fuel used while not underway preceding an international voyage are reported as domestic rather than international as would be done for a commercial vessel. There is uncertainty associated with ground fuel estimates for 1997 through 2022, including estimates for the quantity of jet fuel allocated to ground transportation. Small fuel quantities may have been used in vehicles or equipment other than that which was assumed for each fuel type.

There are also uncertainties in fuel end-uses by fuel type, emissions factors, fuel densities, diesel fuel sulfur content, aircraft and vessel engine characteristics and fuel efficiencies, and the methodology used to back-calculate the data set to 1990 using the original set from 1995. The data were adjusted for trends in fuel use based on a closely correlating, but not matching, data set. All assumptions used to develop the estimate were based on process knowledge, DoD data, and expert judgments. The magnitude of the potential errors related to the various uncertainties has not been calculated but is believed to be small. The uncertainties associated with future military bunker fuel emission estimates could be reduced through revalidation of assumptions based on data regarding current equipment and operational tempo, however, it is doubtful data with more fidelity exist at this time.

[89] See uncertainty discussions under section 3.1 CO_2 from Fossil Fuel Combustion.

Although aggregate fuel consumption data have been used to estimate emissions from aviation, the recommended method for estimating emissions of gases other than CO_2 in the *2006 IPCC Guidelines* (IPCC 2006) is to use data by specific aircraft type, number of individual flights and, ideally, movement data to better differentiate between domestic and international aviation and to facilitate estimating the effects of changes in technologies. The IPCC also recommends that cruise altitude emissions be estimated separately using fuel consumption data, while landing and take-off (LTO) cycle data be used to estimate near-ground level emissions of gases other than CO_2.[90]

There is also concern regarding the reliability of the existing DOC (1991 through 2022) data on marine vessel fuel consumption reported at U.S. customs stations due to the significant degree of inter-annual variation.

QA/QC and Verification

In order to ensure the quality of the emission estimates from international bunker fuels, General (IPCC Tier 1) and category-specific (Tier 2) Quality Assurance/Quality Control (QA/QC) procedures were implemented consistent with the U.S. Inventory QA/QC plan outlined in Annex 8 The Tier 2 procedures that were implemented involved checks specifically focusing on the activity data and emission factor sources and methodology used for estimating CO_2, CH_4, and N_2O emissions from international bunker fuels in the United States. Emission totals for the different sectors and fuels were compared and trends were investigated. No corrective actions were necessary.

Recalculations Discussion

No recalculations were performed for the current *Inventory*.

Planned Improvements

EPA will evaluate data availability to update the sources for densities, energy contents, and emission factors applied to estimate emissions from aviation and marine fuels. Many are from sources from the late 1990s, such as IPCC/UNEP/OECD/IEA (1997). Potential sources with more recent data include the International Maritime Organization (IMO) greenhouse gas emission inventory, International Air Transport Association (IATA)/ICAO greenhouse gas reporting system (CORSIA), and the EPA Greenhouse Gas Reporting Program (GHGRP) Technical Support Document for Petroleum Products. Specifically, EPA will evaluate data availability to support updating the heat contents and carbon contents of jet fuel with input from EIA.

A longer-term effort is underway to consider the feasibility of including data from a broader range of domestic and international sources for bunker fuels. Potential sources include the IMO greenhouse gas emission inventory, data from the U.S. Coast Guard on vehicle operation currently used in criteria pollutant modeling, data from the International Energy Agency (IEA), relevant updated FAA models to improve aviation bunker fuel estimates, and researching newly available marine bunker data.

[90] U.S. aviation emission estimates for CO, NO_x, and NMVOCs are reported by EPA's National Emission Inventory (NEI) Air Pollutant Emission Trends website, and reported under the Mobile Combustion section. It should be noted that these estimates are based solely upon LTO cycles and consequently only capture near ground-level emissions, which are more relevant for air quality evaluations. These estimates also include both domestic and international flights. Therefore, estimates reported under the Mobile Combustion section overestimate IPCC-defined domestic CO, NO_x, and NMVOC emissions by including landing and take-off (LTO) cycles by aircraft on international flights, but underestimate because they do not include emissions from aircraft on domestic flight segments at cruising altitudes.

3.10 Biomass and Biofuels Consumption (CRT Source Category 1A)

The combustion of biomass—such as wood, charcoal, the biogenic portions of MSW, and wood waste and biofuels such as ethanol, biogas, and biodiesel—generates CO_2 in addition to CH_4 and N_2O already covered in this chapter. In line with the reporting requirements for inventories submitted under the Paris Agreement and the UNFCCC, CO_2 emissions from biomass and biofuel combustion have been estimated separately from fossil fuel CO_2 emissions and are not directly included in the energy sector contributions to U.S. totals. In accordance with IPCC methodological guidelines, any such emissions are calculated by accounting for net carbon fluxes from changes in biogenic carbon reservoirs in wooded or crop lands. For a more complete description of this methodological approach, see the Land Use, Land-Use Change, and Forestry chapter (Chapter 6), which accounts for the contribution of any resulting CO_2 emissions to U.S. totals within the Land Use, Land-Use Change, and Forestry sector's approach.

Therefore, CO_2 emissions from biomass and biofuel consumption are not included specifically in summing energy sector totals. However, they are presented here for informational purposes and to provide detail on biomass and biofuels consumption.

In 2022, total CO_2 emissions from the burning of woody biomass in the industrial, residential, commercial, and electric power sectors were approximately 195.3 MMT CO_2 Eq. (195,338 kt) (see Table 3-120 and Table 3-121). As the largest consumer of woody biomass, the industrial sector was responsible for 62.9 percent of the CO_2 emissions from this source. The residential sector was the second largest emitter, constituting 22.3 percent of the total, while the electric power and commercial sectors accounted for the remainder.

Table 3-120: CO_2 Emissions from Wood Consumption by End-Use Sector (MMT CO_2 Eq.)

End-Use Sector	1990	2005	2018	2019	2020	2021	2022

Carbon dioxide emissions from combustion of the biogenic components of MSW by the electric power sector were an estimated 14.9 MMT CO_2 (14,864 kt) in 2022. Emissions across the time series are shown in Table 3-122 and Table 3-123. As discussed in Section 3.3, MSW is combusted to produce electricity and the CO_2 emissions from the fossil portion of the MSW (e.g., plastics, textiles, etc.) are included in the energy sector FFC estimates. The MSW also includes biogenic components (e.g., food waste, yard trimmings, natural fibers) and the CO_2 emissions associated with that biogenic portion is included here.

The transportation sector is responsible for most of the fuel ethanol consumption in the United States. Ethanol used for fuel is currently produced primarily from corn grown in the Midwest, but it can be produced from a variety of biomass feedstocks. Most ethanol for transportation use is blended with gasoline to create a 90 percent gasoline, 10 percent by volume ethanol blend known as E-10 or gasohol.

In 2022, the United States transportation sector consumed an estimated 1,094.9 trillion Btu of ethanol (94 percent of total), and as a result, produced approximately 75.0 MMT CO_2 Eq. (74,953 kt) (see Table 3-124 and Table 3-125) of CO_2 emissions. Smaller quantities of ethanol were also used in the industrial and commercial sectors. Ethanol fuel production and consumption has grown significantly since 1990 due to the favorable economics of blending ethanol into gasoline and federal policies that have encouraged use of renewable fuels.

Table 3-124: CO_2 Emissions from Ethanol Consumption (MMT CO_2 Eq.)

[a] See Annex 3.2, Table A-74 for additional information on transportation consumption of these fuels.
Note: Totals may not sum due to independent rounding.

The transportation sector is assumed to be responsible for all of the biodiesel consumption in the United States (EIA 2024a). Biodiesel is currently produced primarily from soybean oil, but it can be produced from a variety of biomass feedstocks including waste oils, fats, and greases. Biodiesel for transportation use appears in low-level blends (less than 5 percent) with diesel fuel, high-level blends (between 6 and 20 percent) with diesel fuel, and 100 percent biodiesel (EIA 2024b).

In 2022, the United States consumed an estimated 211.6 trillion Btu of biodiesel, and as a result, produced approximately 15.6 MMT CO_2 Eq. (15,622 kt) (see Table 3-126 and Table 3-127) of CO_2 emissions. Biodiesel production and consumption has grown significantly since 2001 due to the favorable economics of blending biodiesel into diesel and federal policies that have encouraged use of renewable fuels (EIA 2024b). There was no measured biodiesel consumption prior to 2001 EIA (2024a).

Table 3-126: CO_2 Emissions from Biodiesel Consumption (MMT CO_2 Eq.)

Methodology and Time-Series Consistency

Woody biomass emissions were estimated by applying two gross heat contents from EIA (Lindstrom 2006) to U.S. consumption data (EIA 2024a) (see Table 3-129), provided in energy units for the industrial, residential, commercial, and electric power sectors. One heat content (16.95 MMBtu/MT wood and wood waste) was applied to the industrial sector's consumption, while the other heat content (15.43 MMBtu/MT wood and wood waste) was applied to the consumption data for the other sectors. An EIA emission factor of 0.434 MT C/MT wood (Lindstrom 2006) was then applied to the resulting quantities of woody biomass to obtain CO_2 emission estimates. The woody biomass is assumed to contain black liquor and other wood wastes, have a moisture content of 12 percent, and undergo complete combustion to be converted into CO_2.

Data for total waste incinerated, excluding tires, from 1990 to 2022 was derived following the methodology described in Section 3.3. Biogenic CO_2 emissions associated with MSW combustion were obtained from EPA's GHGRP FLIGHT data for MSW combustion sources (EPA 2023). Dividing biogenic CO_2 emissions from GHGRP FLIGHT data for MSW combustors by estimated MSW tonnage combusted yielded an annual biogenic CO_2 emission factor. This approach follows the same approach used to develop the fossil CO_2 emissions from MSW combustion as discussed in Section 3.3. As this data was only available following 2011, all years prior use an average of the emission factors from 2011 through 2015.

Biogenic CO_2 emissions from MSW combustion were calculated by multiplying the annual tonnage estimates, excluding tires, by the calculated emissions factor. Calculated biogenic CO_2 emission factors are shown in Table 3-128.

Table 3-128: Calculated Biogenic CO_2 Content per Ton Waste (kg CO_2/Short Ton Combusted)

End-Use Sector	1990	2005	2018	2019	2020	2021	2022
CO_2 Emission Factors	556	556	553	558	566	550	564

The amount of ethanol allocated across the transportation, industrial, and commercial sectors was based on the sector allocations of ethanol-blended motor gasoline. The sector allocations of ethanol-blended motor gasoline were determined using a bottom-up analysis conducted by EPA, as described in the Methodology section of Fossil Fuel Combustion. Total U.S. ethanol consumption from EIA (2024a) was allocated to individual sectors using the same sector allocations as ethanol-blended motor gasoline. The emissions from ethanol consumption were calculated by applying an emission factor of 18.67 MMT C/Qbtu (EPA 2010) to adjusted ethanol consumption estimates (see Table 3-130). The emissions from biodiesel consumption were calculated by applying an emission

factor of 20.1 MMT C/Qbtu (EPA 2010) to U.S. biodiesel consumption estimates that were provided in energy units (EIA 2024a) (see Table 3-131).[91]

NO (Not Occurring)

Methodological recalculations were applied to the entire time series to ensure time-series consistency from 1990 through 2022.

Uncertainty

It is assumed that the combustion efficiency for biomass is 100 percent, which is believed to be an overestimate of the efficiency of biomass combustion processes in the United States. Decreasing the combustion efficiency would decrease emission estimates for CO_2. Additionally, the heat content applied to the consumption of woody biomass in the residential, commercial, and electric power sectors is unlikely to be a completely accurate representation of the heat content for all the different types of woody biomass consumed within these sectors. Emission estimates from ethanol and biodiesel production are more certain than estimates from woody biomass consumption due to better activity data collection methods and uniform combustion techniques.

Recalculations Discussion

EIA (2024a) updated 2020 and 2021 wood energy consumed by the residential sector due to new underlying data collected by the Residential Energy Consumption Survey (RECS), which collects data about once every 5 years and uses Annual Energy Outlook growth rates to estimate data for other years. This caused CO_2 emissions from residential wood consumption to decrease by 9.9 MMT CO_2 Eq. (4.9 percent) in 2020 and 12.3 MMT CO_2 Eq. (6.0 percent) in 2021 compared to estimates in the previous *Inventory* for these years.

[91] CO_2 emissions from biodiesel do not include emissions associated with the carbon in the fuel that is from the methanol used in the process. Emissions from methanol use and combustion are assumed to be accounted for under Non-Energy Use of Fuels. See Annex 2.3 – Methodology for Estimating Carbon Emitted from Non-Energy Uses of Fossil Fuels.

Planned Improvements

Future research will investigate the availability of data on woody biomass heat contents and carbon emission factors to see if there are newer, improved data sources available for these factors.

Currently, emission estimates from biomass and biomass-based fuels included in this *Inventory* are limited to woody biomass, biogenic components of MSW, ethanol, and biodiesel. Additional forms of biomass-based fuel consumption include biogas, and other renewable diesel fuels. EPA will investigate additional forms of biomass-based fuel consumption, research the availability of relevant emissions factors, and integrate these into the *Inventory* as feasible. EPA will examine EIA data on biogas and other renewable diesel fuels to see if these fuel types can be included in future Inventories. EIA (2024a) natural gas data already deducts biogas used in the natural gas supply, so no adjustments are needed to the natural gas fuel consumption data to account for biogas. Distillate fuel statistics are adjusted in this *Inventory* to remove other renewable diesel fuels as well as biodiesel. Additionally, options for including "Other Renewable Fuels," as defined by EIA, will be evaluated.

The availability of facility-level combustion emissions through EPA's GHGRP will be examined to help better characterize the industrial sector's energy consumption in the United States and further classify woody biomass consumption by business establishments according to industrial economic activity type. Most methodologies used in EPA's GHGRP are consistent with IPCC, although for EPA's GHGRP, facilities collect detailed information specific to their operations according to detailed measurement standards, which may differ with the more aggregated data collected for the *Inventory* to estimate total, national U.S. emissions. In addition, and unlike the reporting requirements for this chapter under Paris Agreement and UNFCCC reporting guidelines, some facility-level fuel combustion emissions reported under EPA's GHGRP may also include industrial process emissions.[92]

In line with the Paris Agreement and UNFCCC reporting guidelines, fuel combustion emissions are included in this chapter, while process emissions are included in the Industrial Processes and Product Use chapter of this report. In examining data from EPA's GHGRP that would be useful to improve the emission estimates for the CO_2 from biomass combustion category, particular attention will also be made to ensure time-series consistency, as the facility-level reporting data from EPA's GHGRP are not available for all inventory years as reported in this *Inventory*. Additionally, analyses will focus on aligning reported facility-level fuel types and IPCC fuel types per the national energy statistics, ensuring CO_2 emissions from biomass are separated in the facility-level reported data, and maintaining consistency with national energy statistics provided by EIA. In implementing improvements and integration of data from EPA's GHGRP, the latest guidance from the IPCC on the use of facility-level data in national inventories will be relied upon.[93]

3.11 Energy Sources of Precursor Greenhouse Gases

In addition to the main greenhouse gases addressed above, energy-related activities are also sources of greenhouse gas precursors. The reporting requirements of the Paris Agreement and the UNFCCC[94] request that information should be provided on precursor emissions, which include carbon monoxide (CO), nitrogen oxides (NO_x), non-methane volatile organic compounds (NMVOCs), and sulfur dioxide (SO_2). These gases are not direct greenhouse gases, but indirectly impact Earth's radiative balance by altering the concentrations of greenhouse

gases (e.g., tropospheric ozone) and atmospheric aerosol (e.g., particulate sulfate). Total emissions of NO_x, CO, NMVOCs, and SO_2 from energy-related activities from 1990 to 2022 are reported in Table 3-132.

Table 3-132: NO_x, CO, NMVOC, and SO_2 Emissions from Energy-Related Activities (kt)

NA (Not Applicable)

[a] The scope of the NEI for aircraft related precursor emissions included under the transportation is different from the Paris Agreement and UNFCCC reporting scope. The NEI precursor estimate methodology does not exclude emissions that could be considered international bunkers given local impacts from these emissions. The precursor estimates are based on modeled using FAA- and state-supplied landing and take-off data for all aircraft types (including ground support equipment and auxiliary engines) used for public, private, and military purposes.

Note: Totals may not sum due to independent rounding.

Source: (EPA 2023a). Emission categories from EPA (2023a) are aggregated into sectors and categories reported under the Paris Agreement and the UNFCCC as shown in Table ES-3.

Methodology and Time-Series Consistency

Emission estimates for 1990 through 2022 were obtained from data published on the National Emissions Inventory (NEI) Air Pollutant Emissions Trends Data website (EPA 2023a). For Table 3-132, NEI reported emissions of CO, NO_x, NMVOCs, and SO_2 were recategorized from NEI Emissions Inventory System (EIS) sectors to source categories more

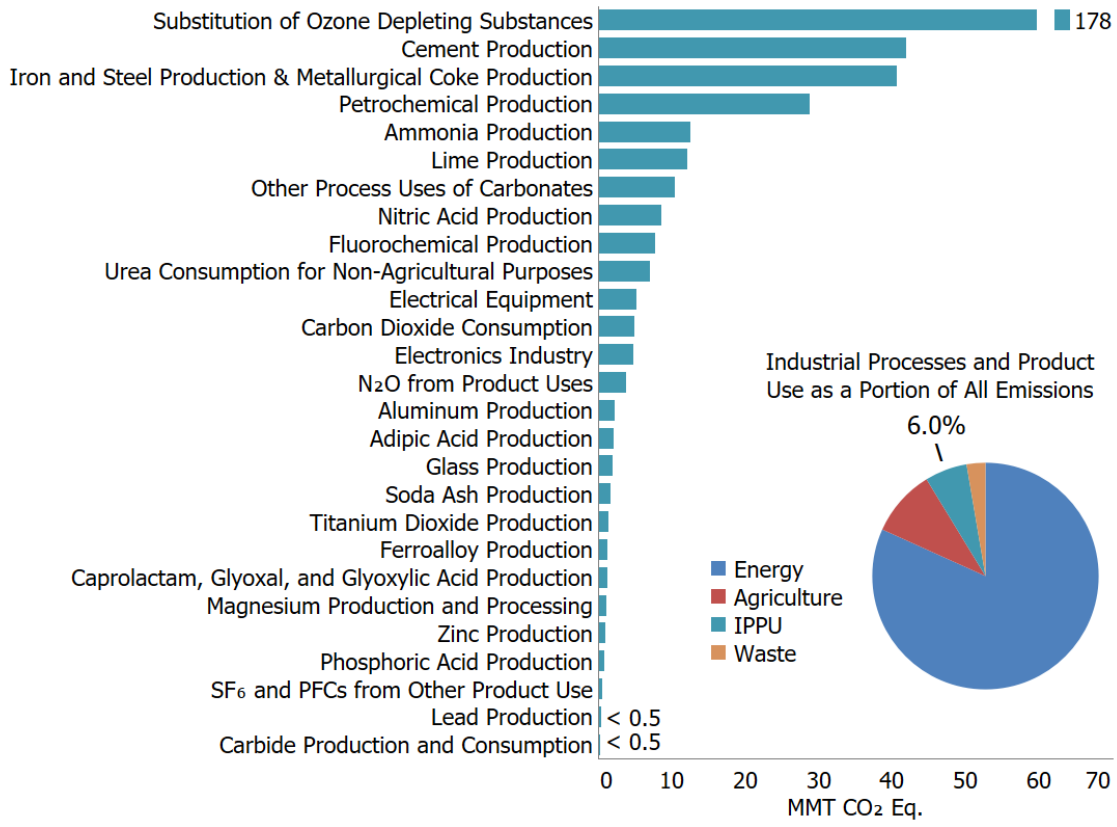
closely aligned with reporting sectors and categories under the Paris Agreement and the UNFCCC, based on discussions between the EPA *Inventory* and NEI staff (see crosswalk documented in Annex 6.3).[95] EIS sectors mapped to the energy sector categories in this report include: fuel combustion for electric utilities, industrial, and other; petroleum and related industries; highway vehicles; off-highway; and other mobile sources (e.g., commercial marine vessels and rail). As described in the NEI Technical Support Documentation (TSD) (EPA 2023b), NEI emissions are estimated through a combination of emissions data submitted directly to the EPA by state, local, and tribal air agencies, as well as additional information added by the Agency from EPA emissions programs, such as the emission trading program, Toxics Release Inventory (TRI), and data collected during rule development or compliance testing.

Methodological approaches were applied to the entire time series to ensure time-series consistency from 1990 through 2022, which are described in detail in the NEI's TSD and on EPA's Air Pollutant Emission Trends website (EPA 2023a; EPA 2023b). No quantitative estimates of uncertainty were calculated for this source category.

[95] The NEI estimates and reports emissions from six criteria air pollutants (CAPs) and 187 hazardous air pollutants (HAPs) in support of National Ambient Air Quality Standards. EPA reported CAP emission trends are grouped into 60 sectors and 15 Tier 1 source categories, which broadly cover similar source categories to those presented in this chapter. For reporting precursor emissions in the common reporting tables (CRTs), EPA has mapped and regrouped emissions of greenhouse gas precursors (CO, NO_x, SO_2, and NMVOCs) from NEI's EIS sectors to better align with NIR source categories, and to ensure consistency and completeness to the extent possible. See Annex 6.3 for more information on this mapping.

4. Industrial Processes and Product Use

Industrial Processes and Product Use (IPPU) chapter includes greenhouse gas emissions occurring from industrial processes and from the use of greenhouse gases in products. The industrial processes and product use categories included in this chapter are presented in Figure 4-1 and Figure 4-2. Greenhouse gas emissions from industrial processes can occur in two different ways. First, they may be generated and emitted as the byproducts of various non-energy-related industrial activities. Second, they may be emitted due to their use in manufacturing processes or by end-consumers. Combustion-related energy use emissions from industry are reported in Chapter 3, Energy.



In the case of byproduct emissions, the emissions are generated by an industrial process itself and are not directly a result of energy consumed during the process. For example, raw materials can be chemically or physically transformed from one state to another. This transformation can result in the release of greenhouse gases such as carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), and fluorinated greenhouse gases (e.g., HFC-23). The greenhouse gas byproduct generating processes included in this chapter include iron and steel production and metallurgical coke production, cement production, petrochemical production, ammonia production, lime production, other process uses of carbonates (e.g., flux stone, flue gas desulfurization, ceramics production, non-metallurgical magnesia production, and soda ash consumption not associated with glass manufacturing), nitric acid production, adipic acid production, urea consumption for non-agricultural purposes, aluminum production, HCFC-22 production, other fluorochemical production, glass production, soda ash production, ferroalloy production, titanium dioxide production, caprolactam production, zinc production, phosphoric acid production, lead production, and silicon carbide production and consumption.

Greenhouse gases that are used in manufacturing processes or by end-consumers include man-made compounds such as hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), sulfur hexafluoride (SF_6), and nitrogen trifluoride (NF_3). The present contribution of HFCs, PFCs, SF_6, and NF_3 gases to the radiative forcing effect of all anthropogenic greenhouse gases is small; however, because of their extremely long lifetimes, many of them will continue to persist in the atmosphere long after they were first released. In addition, many of these gases have high global warming potentials; SF_6 is the most potent greenhouse gas the Intergovernmental Panel on Climate Change (IPCC) has evaluated. Use of HFCs continues since they are the primary substitutes for ozone depleting substances (ODS), which are being phased-out under the Montreal Protocol on Substances that Deplete the Ozone Layer; however, production and consumption of HFCs are being phased down under the Kigali Amendment to the Montreal Protocol and in the United States under the American Innovation and Manufacturing Act. Hydrofluorocarbons, PFCs, SF_6, and NF_3 are employed and emitted by a number of other industrial sources in the United States, such as the electronics industry, electric power transmission and distribution, PFCs and SF_6 for other product use, and magnesium metal production and processing. Carbon dioxide is also consumed and emitted through various end-use applications. In addition, nitrous oxide is used in and emitted by the electronics industry and anesthetic and aerosol applications.

In 2022, IPPU generated emissions of 383.2 million metric tons of CO_2 equivalent (MMT CO_2 Eq.), or 6.0 percent of total U.S. greenhouse gas emissions.[1] Carbon dioxide emissions from all industrial processes were 168.9 MMT CO_2 Eq. (168,937 kt CO_2) in 2022, or 3.3 percent of total U.S. CO_2 emissions. Methane emissions from industrial processes resulted in emissions of approximately 0.04 MMT CO_2 Eq. (1 kt CH_4) in 2022, which was 0.01 percent of U.S. CH_4 emissions. Nitrous oxide emissions from IPPU were 16.1 MMT CO_2 Eq. (61 kt N_2O) in 2022, or 4.1 percent of total U.S. N_2O emissions. In 2022 combined emissions of HFCs, PFCs, SF_6, and NF_3 totaled 198.1 MMT CO_2 Eq. Total emissions from IPPU in 2022 were 3.9 percent more than 1990 emissions. Total emissions from IPPU remained relatively constant between 2021 and 2022, increasing by 0.4 percent due to offsetting trends within the sector. More information on emissions of greenhouse gas precursors emissions that also result from IPPU are presented in Section 4.27 of this chapter.

The largest source of IPPU-related emissions is the substitution of ozone depleting substances, which accounted for 46.5 percent of sector emissions in 2022. These emissions have increased by 79.1 percent since 2005, and 3.2 percent between 2021 and 2022. Cement production was the second largest source of IPPU emissions in 2022, accounting for 10.9 percent of IPPU emissions in 2022. Iron and steel production and metallurgical coke production was the third largest source of IPPU emissions, accounting for 10.6 percent of the sector total in 2022.

Figure 4-1: Industrial Processes and Product Use Sector Greenhouse Gas Sources

The increase in overall IPPU emissions since 1990 reflects a range of emission trends among the emission sources, as shown in Figure 4-2. Emissions resulting from most types of metal production have declined significantly since 1990, largely due to production shifting to other countries, but also due to transitions to less-emissive methods of

[1] Emissions reported in the IPPU chapter include those from all 50 states, including Hawaii and Alaska, as well as from U.S. Territories.

production (in the case of iron and steel) and to improved practices (in the case of PFC emissions from aluminum production). Carbon dioxide and CH_4 emissions from some chemical production sources (e.g., petrochemical production, urea consumption for non-agricultural purposes) have increased since 1990, while emissions from other chemical production sources (e.g., ammonia production, phosphoric acid production) have decreased. Emissions from mineral sources have either increased (e.g., cement production) or not changed significantly (e.g., lime production) since 1990 and largely follow economic cycles. Hydrofluorocarbon emissions from the substitution of ODS have increased drastically since 1990 and are the largest source of IPPU emissions (46.5 percent in 2022), while the emissions of HFCs, PFCs, SF_6, and NF_3 from other sources have generally declined. Nitrous oxide emissions from the production of nitric acid have decreased. Some emission sources (e.g., adipic acid) exhibit varied interannual trends. Trends are explained further within each emission source category throughout the chapter.

Figure 4-2: Trends in Industrial Processes and Product Use Sector Greenhouse Gas Sources

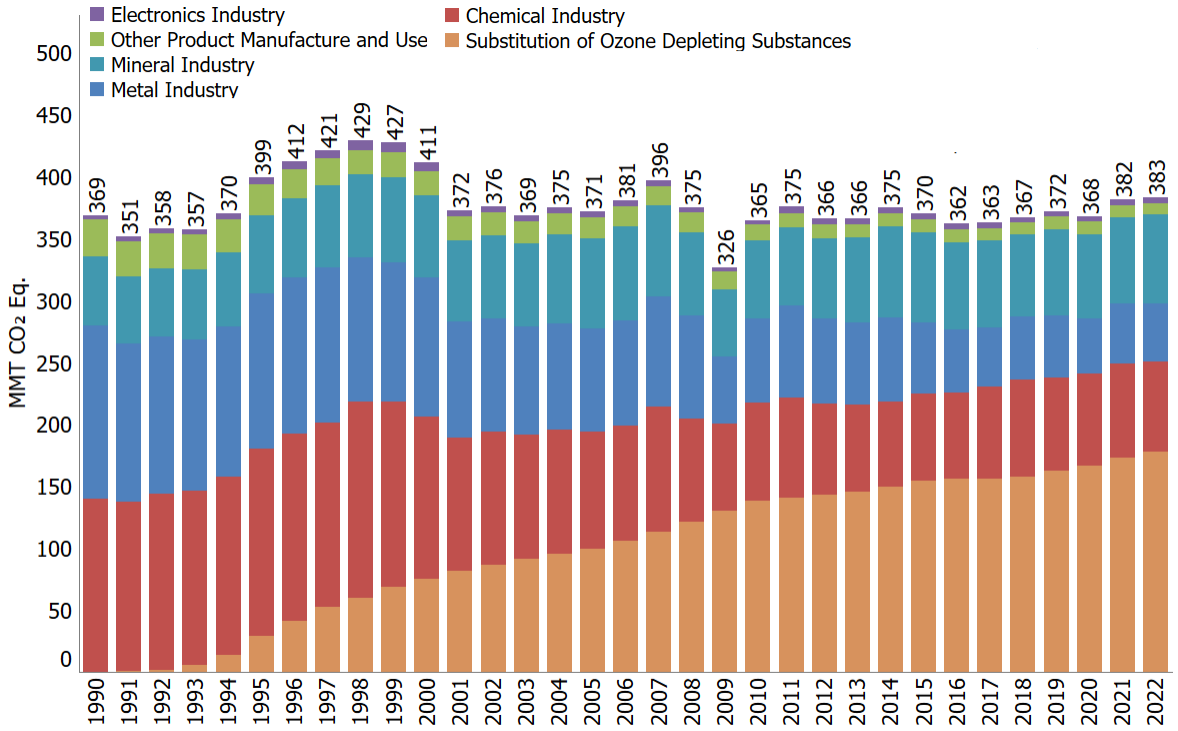


Table 4-1 summarizes emissions for the IPPU chapter in MMT CO_2 Eq. using IPCC *Fifth Assessment Report* (AR5) GWP values, following the requirements of the current United Nations Framework Convention on Climate Change (UNFCCC) reporting guidelines for national inventories (IPCC 2007).[2] Unweighted gas emissions in kt are also provided in Table 4-2. The source descriptions that follow in the chapter are presented in the order as reported to the UNFCCC in the Common Reporting Tables (CRTs), corresponding generally to: mineral industry, chemical industry, metal industry, and emissions from the uses of HFCs, PFCs, SF_6, and NF_3.

Each year, some emission and sink estimates in the IPPU sector of the *Inventory* are recalculated and revised with improved methods and/or data. In general, recalculations are made to the U.S. greenhouse gas emission estimates either to incorporate new methodologies or, most commonly, to update recent historical data. These improvements are implemented consistently across the previous *Inventory's* time series (i.e., 1990 to 2021) to

[2] See http://unfccc.int/resource/docs/2013/cop19/eng/10a03.pdf.

ensure that the trend is accurate. Key updates to this year's *Inventory* include the addition of new categories previously not estimated: CO_2 emissions from ceramics production and non-metallurgical magnesia within other process use of carbonates category; fluorinated gases from production of fluorochemicals other than HCFC-22 within the fluorochemical production category; and SF_6 and PFCs from additional product uses within the other product manufacture and use category. In addition, there were changes to the petrochemical production methodology to calculate emissions from methanol production; updates to emission estimates from urea consumption for non-agricultural purposes driven by revisions to quantities of urea applied, urea imports, and urea exports; and revisions to the method for estimating SF_6 emissions from electrical equipment for estimating using CARB data from electrical equipment in California. Together, these methodological and data updates increased IPPU sector greenhouse gas emissions by an average 20.4 MMT CO_2 Eq. (7.2 percent) across the time series. For more information on specific methodological updates, please see the Recalculations Discussion section for each category in this chapter.

This chapter presents emission estimates calculated in accordance with the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (*2006 IPCC Guidelines*) and its refinements. For additional detail on IPPU sources that are not included in this *Inventory* report, please review Annex 5, Assessment of the Sources and Sinks of Greenhouse Gas Emissions Not Included. These sources are not included due to various national circumstances, such as emissions from a source may not currently occur in the United States, data are not currently available for those emission sources (e.g., glyoxal and glyoxylic acid production, CH_4 from direct reduced iron production), emissions are included elsewhere within the *Inventory* report, or data suggest that emissions are not significant (e.g., other various fluorinated gas emissions from other product uses). In terms of geographic scope, emissions reported in the IPPU chapter include those from all 50 states, including Hawaii and Alaska, as well as from District of Columbia and U.S. Territories to the extent to which industries are occurring. While most IPPU sources do not occur in U.S. Territories (e.g., electronics manufacturing does not occur in U.S. Territories), they are estimated and accounted for where they are known to occur (e.g., cement production, lime production, electrical equipment). EPA will review this on an ongoing basis to ensure emission sources are included across all geographic areas if they occur. Information on planned improvements for specific IPPU source categories can be found in the Planned Improvements section of the individual source category.

In addition, as mentioned in the Energy chapter of this report (Box 3-5), fossil fuels consumed for non-energy uses for primary purposes other than combustion for energy (including lubricants, paraffin waxes, bitumen asphalt, and solvents) are reported in the Energy chapter. According to the *2006 IPCC Guidelines*, these non-energy uses of fossil fuels are to be reported under the IPPU, rather than the Energy sector; however, due to national circumstances regarding the allocation of energy statistics and carbon balance data, the United States reports these non-energy uses in the Energy chapter of this *Inventory*. Although emissions from these non-energy uses are reported in the Energy chapter, the methodologies used to determine emissions are compatible with the *2006 IPCC Guidelines* and are well documented and scientifically based. The methodologies used are described in Section 3.2, Carbon Emitted from Non-Energy Uses of Fossil Fuels and Annex 2.3, Methodology for Estimating Carbon Emitted from Non-Energy Uses of Fossil Fuels. The emissions are reported under the Energy chapter to improve transparency, report a more complete carbon balance, and avoid double counting. For example, only the emissions from the first use of lubricants and waxes are to be reported under the IPPU sector, and emissions from use of lubricants in 2-stroke engines and emissions from secondary use of lubricants and waxes in waste incineration with energy recovery are to be reported under the Energy sector. Reporting non-energy use emissions from only first use of lubricants and waxes under IPPU would involve making artificial adjustments to the non-energy use carbon balance and could potentially result in double counting of emissions. These artificial adjustments would also be required for asphalt and road oil and solvents (which are captured as part of petrochemical feedstock emissions) and could also potentially result in double counting of emissions. For more information, see the Methodology discussion in Section 3.1, CO_2 from Fossil Fuel Combustion, Section 3.2, Carbon Emitted from Non-Energy Uses of Fossil Fuels and Annex 2.3, Methodology for Estimating Carbon Emitted from Non-Energy Uses of Fossil Fuels.

Finally, as stated in the Energy chapter, portions of the fuel consumption data for seven fuel categories—coking coal, distillate fuel, industrial other coal, petroleum coke, natural gas, residual fuel oil, and other oil—are

reallocated to the IPPU chapter, as they are consumed during non-energy related industrial process activity. Emissions from uses of fossil fuels as feedstocks or reducing agents (e.g., petrochemical production, aluminum production, titanium dioxide, zinc production) are reported in the IPPU chapter, unless otherwise noted due to specific national circumstances. This approach is compatible with the *2006 IPCC Guidelines* and is well documented and scientifically based. The emissions from these feedstocks and reducing agents are reported under the IPPU chapter to improve transparency and to avoid double counting of emissions under both the Energy and IPPU sectors. More information on the methodology to adjust for these emissions within the Energy chapter is described in the Methodology section of CO_2 from Fossil Fuel Combustion (3.1 Fossil Fuel Combustion [CRT Source Category 1A]) and Annex 2.1 Methodology for Estimating Emissions of CO_2 from Fossil Fuel Combustion. Additional information is listed within each IPPU emission source in which this approach applies.

Box 4-1: Methodological Approach for Estimating and Reporting U.S. Emissions and Removals

Consistent with Article 13.7(a) of the Paris Agreement and Article 4.1(a) of the UNFCCC as well as relevant decisions under those agreements, the emissions and removals presented in this report and this chapter are organized by source and sink categories and calculated using internationally accepted methods provided by the Intergovernmental Panel on Climate Change (IPCC) in the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (*2006 IPCC Guidelines*) and its supplements and refinements. Additionally, the calculated emissions and removals in a given year for the United States are presented in a common format in line with the reporting guidelines for the reporting of inventories under the Paris Agreement and the UNFCCC. The Parties' use of consistent methods to calculate emissions and removals for their inventories helps to ensure that these reports are comparable. The presentation of emissions and removals provided in the IPPU chapter do not preclude alternative examinations. Rather, this chapter presents emissions and removals in a common format consistent with how Parties are to report inventories under the Paris Agreement and the UNFCCC. The report itself, and this chapter, follows this common format, and provides an explanation of the application of methods used to calculate emissions and removals from industrial processes and from the use of greenhouse gases in products.

QA/QC and Verification Procedures

The quality of IPPU source categories is assured through application of the U.S. Inventory QA/QC plan outlined in Annex 8. Two types of checks were performed using this plan: (1) general (Tier 1) procedures consistent with Volume 1, Chapter 6 of the *2006 IPCC Guidelines* that focus on annual procedures and checks to be used when gathering, maintaining, handling, documenting, checking, and archiving the data, supporting documents, and files; and (2) source category-specific (Tier 2) procedures that focus on checks and comparisons of the emission factors, activity data, and methodologies used for estimating emissions from the relevant industrial process and product use sources. Examples of these procedures include: checks to ensure that activity data and emission estimates are consistent with historical trends; that consistent, complete and data sources are used and documented; that interpolation or extrapolation techniques are consistent across sources; and that common units, and conversion factors are used where applicable. Consistent with the *2006 IPCC Guidelines*, additional category-specific QC procedures were performed for more significant emission categories or sources where significant methodological and data updates have taken place. Any significant findings and errors identified are documented and corrected. Application of these procedures, specifically category-specific QC procedures and updates/improvements as a result of QA processes (expert, public, and UNFCCC technical expert reviews), are described further within respective source categories, in the Recalculations Discussion and Planned Improvement sections.

For sources that use data from EPA's Greenhouse Gas Reporting Program (GHGRP), EPA verifies annual facility-level reports through a multi-step process (e.g., including a combination of pre-and post-submittal electronic

checks and manual reviews by staff) to identify potential errors and ensure that data submitted to EPA are accurate, complete, and consistent.[3] Based on the results of the verification process, EPA follows up with facilities to resolve mistakes that may have occurred. The post-submittals checks are consistent with the general and category-specific QC procedures including: range checks, statistical checks, algorithm checks, and year-to-year checks of reported data and emissions. See Box 4-2 below for more information on use of GHGRP data in this chapter.

For most IPPU categories, activity data are obtained via aggregation of facility-level data from EPA's GHGRP (see Box 4-2 below and Annex 9), national commodity surveys conducted by U.S. Geological Survey (USGS) National Minerals Information Center, U.S. Department of Energy (DOE), U.S. Census Bureau, and industry associations such as Air-Conditioning, Heating, and Refrigeration Institute (AHRI), American Chemistry Council (ACC), and American Iron and Steel Institute (AISI) (specified within each source category). The emission factors used include those derived from the EPA's GHGRP and application of IPCC default factors.

Box 4-2: Industrial Process and Product Use Data from EPA's Greenhouse Gas Reporting Program

EPA collects greenhouse gas emissions data from individual facilities and suppliers of certain fossil fuels and industrial gases through its Greenhouse Gas Reporting Program (GHGRP). The GHGRP applies to direct greenhouse gas emitters, fossil fuel suppliers, industrial gas suppliers, and facilities that inject CO_2 underground for sequestration or other reasons and requires reporting by sources or suppliers in 41 industrial categories. Annual reporting is at the facility level, except for certain suppliers of fossil fuels and industrial greenhouse gases.

In general, the threshold for reporting is 25,000 metric tons or more of CO_2 Eq. per year, but reporting is required for all facilities in some industries. Calendar year 2010 was the first year for which data were collected for facilities subject to 40 CFR Part 98, though some source categories first collected data for calendar year 2011. For more information, see Annex 9, Use of EPA Greenhouse Gas Reporting Program in Inventory.

EPA uses annual GHGRP data in a number of categories to improve the national estimates presented in this *Inventory*, consistent with IPCC guidelines (e.g., minerals, chemicals, product uses). Methodologies used in EPA's GHGRP are consistent with IPCC guidelines, including higher tier methods; however, it should be noted that the coverage and definitions for source categories (e.g., allocation of energy and IPPU emissions) in EPA's GHGRP may differ from those used in this *Inventory* in meeting the Paris Agreement and UNFCCC reporting guidelines (IPCC 2011) and is an important consideration when incorporating GHGRP data in the *Inventory*. In line with the Paris Agreement and UNFCCC reporting guidelines, the *Inventory* is a comprehensive accounting of all emissions from source categories identified in the *2006 IPCC Guidelines*. EPA has paid particular attention to ensuring both completeness and time-series consistency for major recalculations that have occurred from the incorporation of GHGRP data into these categories, consistent with *2006 IPCC Guidelines* and the *2019 Refinement*, Volume 1, Chapter 2, Section 2.3, *Use of Facility Data in Inventories.*[4]

For certain source categories in this *Inventory* (e.g., nitric acid production, lime production, cement production, petrochemical production, carbon dioxide consumption, ammonia production, and urea consumption for non-agricultural purposes), EPA has integrated data values that have been calculated by aggregating GHGRP data that are considered confidential business information (CBI) at the facility level. EPA, with industry engagement, has put forth criteria to confirm that a given data aggregation shields underlying CBI from public disclosure. EPA is

[3] See https://www.epa.gov/sites/production/files/2015-07/documents/ghgrp_verification_factsheet.pdf.

[4] See https://www.ipcc-nggip.iges.or.jp/public/2019rf/pdf/1_Volume1/19R_V1_Ch02_DataCollection.pdf.

only publishing data values that meet these aggregation criteria.[5] Specific uses of aggregated facility-level data are described in the respective methodological sections (e.g., including other sources using GHGRP data that is not aggregated CBI, such as aluminum, electronics industry, electrical equipment, HCFC-22 production, and magnesium production and processing). For other source categories in this chapter, as indicated in the respective planned improvements sections,[6] EPA is continuing to analyze how facility-level GHGRP data may be used to improve the national estimates presented in this *Inventory*, giving particular consideration to ensuring time-series consistency and completeness.

Additionally, EPA's GHGRP has and will continue to enhance QA/QC procedures and assessment of uncertainties within the IPPU categories (see those categories for specific QA/QC details regarding the use of GHGRP data).

4.1 Cement Production (CRT Source Category 2A1)

Cement production is an energy- and raw material-intensive process that results in the generation of carbon dioxide (CO_2) both from the energy consumed in making the clinker precursor to cement and from the chemical process to make the clinker. This reporting category (2A1) includes emissions from production of clinker and use of cement kiln dust. Per the IPCC methodological guidance, emissions from fuels consumed for energy purposes during the production of cement are accounted for as part of fossil fuel combustion in the industrial end-use sector reported under the Energy chapter.

During the clinker production process, the key reaction occurs when calcium carbonate ($CaCO_3$), in the form of limestone or similar rocks or in the form of cement kiln dust (CKD), is heated in a cement kiln at a temperature range of about 700 to 1,000 degrees Celsius (1,300 to 1,800 degrees Fahrenheit) to form lime (i.e., calcium oxide, or CaO) and CO_2 in a process known as calcination or calcining. The quantity of CO_2 emitted during clinker production is directly proportional to the lime content of the clinker. During calcination, each mole of $CaCO_3$ heated in the clinker kiln forms one mole of CaO and one mole of CO_2. The CO_2 is vented to the atmosphere as part of the kiln exhaust:

$$CaCO_3 + heat \rightarrow CaO + CO_2$$

Next, over a temperature range of 1000 to 1450 degrees Celsius, the CaO combines with alumina, iron oxide and silica that are also present in the clinker raw material mix to form hydraulically reactive compounds within white-hot semifused (sintered) nodules of clinker. These "sintering" reactions are highly exothermic and produce few CO_2 process emissions. The clinker is then rapidly cooled to maintain quality and then very finely ground with a small amount of gypsum and potentially other materials (e.g., ground granulated blast furnace slag, etc.) to make portland and similar cements.

Masonry cement consists of plasticizers (e.g., ground limestone, lime, etc.) and portland cement, and the amount of portland cement used accounts for approximately 3 percent of total clinker production (USGS 2023b; 2023c). No

[5] U.S. EPA Greenhouse Gas Reporting Program. Developments on Publication of Aggregated Greenhouse Gas Data, November 25, 2014. See http://www.epa.gov/ghgreporting/confidential-business-information-ghg-reporting.

[6] Ammonia production, glass production, lead production, and other fluorinated gas production.

additional emissions are associated with the production of masonry cement. Carbon dioxide emissions that result from the production of lime used to produce portland and masonry cement are included in Section 4.2.

Carbon dioxide emitted from the chemical process of cement production is the second largest source of industrial CO_2 emissions in the United States. Cement is produced in 34 states and Puerto Rico. Texas, Missouri, California, and Florida were the leading cement-producing states in 2022 and accounted for approximately 43 percent of total U.S. production (USGS 2023b). In 2022, shipments of cement were estimated to have increased by about 3 percent from 2021, and net imports increased by about 17 percent compared to 2021 (USGS 2023b).

In 2022, U.S. clinker production totaled 80,500 kilotons, which was an increase of 1 percent compared to 2021 and an increase of 25 percent compared to 1990 (EPA 2023). The resulting CO_2 emissions were estimated to be 41.9 MMT CO_2 Eq. (41,884 kt) (see Table 4-3 and Table 4-4). The total construction value and cement shipments increased by 11 percent and 4 percent, respectively, during the first nine months of 2022 compared to the same time period in 2021. This increase was attributed to continued economic recovery from the COVID-19 pandemic and the November 2021 passage of the Bipartisan Infrastructure Law. Despite the increases, growth was constrained by increased costs, labor and production shortages, and ongoing supply chain disruptions (USGS 2023b).

Table 4-3: CO_2 Emissions from Cement Production (MMT CO_2 Eq.)

Year	1990	2005	2018	2019	2020	2021	2022
Cement Production	33.5	46.2	39.0	40.9	40.7	41.3	41.9

Table 4-4: CO_2 Emissions from Cement Production (kt CO_2)

Year	1990	2005	2018	2019	2020	2021	2022
Cement Production	33,484	46,194	38,971	40,896	40,688	41,312	41,884

Greenhouse gas emissions from cement production, which are primarily driven by production levels, increased every year from 1991 through 2006 but decreased in the following years until 2009. Emissions from cement production were at their highest levels in 2006 and at their lowest levels in 2009. Emissions in 2009 were approximately 28 percent lower than 2008 emissions and 12 percent lower than 1990 due to the economic recession and the associated decrease in demand for construction materials. Since 2009, emissions have increased by 41 percent due to increasing demand for cement. Cement continues to be a critical component of the construction industry; therefore, the availability of public and private construction funding, as well as overall economic conditions, have considerable impact on the level of cement production.

Methodology and Time-Series Consistency

Carbon dioxide emissions from cement production are estimated using the Tier 2 method from the *2006 IPCC Guidelines* as this is a key category, in accordance with the IPCC methodological decision tree and available data. The Tier 2 methodology was used because detailed and complete data (including weights and composition) for carbonate(s) consumed in clinker production are not available,[7] and thus a rigorous Tier 3 approach is impractical. Tier 2 specifies the use of aggregated plant or national clinker production data and an emission factor, which is the product of the average lime mass fraction for clinker of 65 percent and a constant reflecting the mass of CO_2 released per unit of lime. The U.S. Geological Survey (USGS) mineral commodity expert for cement has confirmed that this is a reasonable assumption for the United States (Van Oss 2013a). This calculation yields an emission factor of 0.510 tons of CO_2 per ton of clinker produced, which was determined as follows:

[7] As discussed further under "Planned Improvements," most cement-producing facilities that report their emissions to the GHGRP use CEMS to monitor combined process and fuel combustion emissions for kilns, making it difficult to quantify the process emissions on a facility-specific basis. By the end of 2022, the percentage of facilities not using CEMS was 1 percent.

Equation 4-1: *2006 IPCC Guidelines* Tier 1 Emission Factor for Clinker (precursor to Equation 2.4)

$$EF_{clinker} = 0.650\ CaO \times \left[\left(44.01 \frac{g}{mole} CO_2\right) \div \left(56.08 \frac{g}{mole} CaO\right)\right] = 0.510 \frac{\text{tons } CO_2}{\text{ton clinker}}$$

During clinker production, some of the raw materials, partially reacted raw materials, and clinker enters the kiln line's exhaust system as non-calcinated, partially calcinated, or fully calcinated cement kiln dust (CKD). To the degree that the CKD contains carbonate raw materials which are then calcined, there are associated CO_2 emissions. At some plants, essentially all CKD is directly returned to the kiln, becoming part of the raw material feed, or is likewise returned to the kiln after first being removed from the exhaust. In either case, the returned CKD becomes a raw material, thus forming clinker, and the associated CO_2 emissions are a component of those calculated for the clinker overall. At some plants, however, the CKD cannot be returned to the kiln because it is chemically unsuitable as a raw material or chemical issues limit the amount of CKD that can be so reused. Any clinker that cannot be returned to the kiln is either used for other (non-clinker) purposes or is landfilled. The CO_2 emissions attributable to the non-returned calcinated portion of the CKD are not accounted for by the clinker emission factor and thus a CKD correction factor should be applied to account for those emissions. The USGS reports the amount of CKD used to produce clinker, but no information is currently available on the total amount of CKD produced annually.[8] Because data are not currently available to derive a country-specific CKD correction factor, a default correction factor of 1.02 (2 percent) was used to account for CKD CO_2 emissions, as recommended by the IPCC (IPCC 2006).[9] Total cement production emissions were calculated by adding the emissions from clinker production and the emissions assigned to CKD.

Small amounts of impurities (i.e., not calcium carbonate) may exist in the raw limestone used to produce clinker. The proportion of these impurities is generally minimal, although a small amount (1 to 2 percent) of magnesium oxide (MgO) may be desirable as a flux. Per the IPCC Tier 2 methodology, a correction for MgO is not used, since the amount of MgO from carbonate is likely very small and the assumption of a 100 percent carbonate source of CaO already yields an overestimation of emissions (IPCC 2006).

The 1990 through 2012 activity data for clinker production were obtained from USGS (Van Oss 2013a; Van Oss 2013b). Clinker production data for 2013 were also obtained from USGS (USGS 2014). USGS compiled the data (to the nearest ton) through questionnaires sent to domestic clinker and cement manufacturing plants, including facilities in Puerto Rico. Clinker production values in the current *Inventory* report utilize GHGRP data for the years 2014 through 2022 (EPA 2023). Clinker production data are summarized in Table 4-5. Details on how this GHGRP data compares to USGS reported data can be found in the section on QA/QC and Verification.

Table 4-5: Clinker Production (kt)

Year	1990	2005	2018	2019	2020	2021	2022
Clinker Production	64,355	88,783	74,900	78,600	78,200	79,400	80,500

Note: Clinker production from 1990 through 2022 includes Puerto Rico (relevant U.S. Territories).

Methodological approaches were applied to the entire time series to ensure time-series consistency from 1990 through 2022. The methodology for cement production spliced activity data from two different sources: USGS for

[8] The USGS *Minerals Yearbook: Cement* notes that CKD values used for clinker production are likely underreported.

[9] As stated on p. 2.12 of the *2006 IPCC Guidelines*, Vol. 3, Chapter 2: "…As data on the amount of CKD produced may be scarce (except possibly for plant-level reporting), estimating emissions from lost CKD based on a default value can be considered good practice. The amount of CO_2 from lost CKD can vary but range typically from about 1.5 percent (additional CO_2 relative to that calculated for clinker) for a modern plant to about 20 percent for a plant losing a lot of highly calcinated CKD (van Oss 2005). In the absence of data, the default CKD correction factor (CF_{ckd}) is 1.02 (i.e., add 2 percent to the CO_2 calculated for clinker). If no calcined CKD is believed to be lost to the system, the CKD correction factor will be 1.00 (van Oss 2005)…"

1990 through 2013 and GHGRP starting in 2014. Consistent with the *2006 IPCC Guidelines*, the overlap technique was applied to compare the two data sets for years where there was overlap, with findings that the data sets were consistent and adjustments were not needed.

Uncertainty

The uncertainties contained in these estimates are primarily due to uncertainties in the lime content of clinker and in the percentage of CKD recycled inside the cement kiln. Uncertainty is also associated with the assumption that all calcium-containing raw materials are $CaCO_3$, when a small percentage likely consists of other carbonate and non-carbonate raw materials. The lime content of clinker varies from 60 to 67 percent; 65 percent is used as a representative value (Van Oss 2013a). This contributes to the uncertainty surrounding the emission factor for clinker which has an uncertainty range of ±3 percent with uniform densities (Van Oss 2013b). The amount of CO_2 from CKD loss can range from 1.5 to 8 percent depending upon plant specifications, and uncertainty was estimated at ±5 percent with uniform densities (Van Oss 2013b). Additionally, some amount of CO_2 is reabsorbed when the cement is used for construction. As cement reacts with water, alkaline substances such as calcium hydroxide are formed. During this curing process, these compounds may react with CO_2 in the atmosphere to create calcium carbonate. This reaction only occurs in roughly the outer 0.2 inches of the total thickness. Because the amount of CO_2 reabsorbed is thought to be minimal, it was not estimated. EPA assigned uncertainty bounds of ±3 percent and a normal probability density function for clinker production and uncertainty bounds of ±5 percent and a uniform probability density function for the emission factor, based on expert judgment (Van Oss 2013b).

The results of the Approach 2 quantitative uncertainty analysis are summarized in Table 4-6. Based on the uncertainties associated with total U.S. clinker production, the CO_2 emission factor for clinker production, and the emission factor for additional CO_2 emissions from CKD, 2022 CO_2 emissions from cement production were estimated to be between 40.1 and 43.8 MMT CO_2 Eq. at the 95 percent confidence level. This confidence level indicates a range of approximately 4 percent below and 5 percent above the emission estimate of 41.9 MMT CO_2 Eq.

Table 4-6: Approach 2 Quantitative Uncertainty Estimates for CO_2 Emissions from Cement Production (MMT CO_2 Eq. and Percent)

Source	Gas	2022 Emission Estimate (MMT CO_2 Eq.)	Uncertainty Range Relative to Emission Estimate [a] (MMT CO_2 Eq.)		(%)	
			Lower Bound	Upper Bound	Lower Bound	Upper Bound
Cement Production	CO_2	41.9	40.1	43.8	-4%	+5%

[a] Range of emission estimates predicted by Monte Carlo stochastic simulation for a 95 percent confidence interval.

QA/QC and Verification

General quality assurance/quality control (QA/QC) procedures were applied consistent with the U.S. Inventory QA/QC plan, which is in accordance with Volume 1, Chapter 6 of *2006 IPCC Guidelines* as described in the introduction of the IPPU chapter (see Annex 8 for more details).

EPA relied upon the latest guidance from the IPCC on the use of facility-level data in national inventories and applied a category-specific QC process to compare activity data from EPA's GHGRP with existing data from USGS surveys. This was to ensure time-series consistency of the emission estimates presented in the *Inventory*. Total U.S. clinker production is assumed to have low uncertainty because facilities routinely measure this for economic reasons and because both USGS and GHGRP take multiple steps to ensure that reported totals are accurate. EPA verifies annual facility-level GHGRP reports through a multi-step process that is tailored to the reporting industry (e.g., combination of electronic checks including range checks, statistical checks, algorithm checks, year-to-year

comparison checks, along with manual reviews involving outside data checks) to identify potential errors and ensure that data submitted to EPA are accurate, complete, and consistent (EPA 2015). Based on the results of the verification process, EPA follows up with facilities to resolve mistakes that may have occurred.[10] Facilities are also required to monitor and maintain records of monthly clinker production per section 98.84 of the GHGRP regulation (40 CFR 98.84).

EPA's GHGRP requires all facilities producing portland cement to report greenhouse gas emissions, including CO_2 process emissions from each kiln, CO_2 combustion emissions from each kiln, CH_4 and N_2O combustion emissions from each kiln, and CO_2, CH_4, and N_2O emissions from each stationary combustion unit other than kilns (40 CFR Part 98 Subpart H). Source-specific quality control measures for the cement production category are included in section 98.84, Monitoring and QA/QC Requirements.

As mentioned above, EPA compares GHGRP clinker production data (EPA 2023) to the USGS clinker production data (USGS 2023a; USGS 2023c). For the year 2014, 2020, and 2022, USGS and GHGRP clinker production data showed a difference of approximately 1 percent. In 2018, the difference between USGS and GHGRP clinker production data was approximately 3 percent, which resulted in a difference in emissions of about 1.2 MMT CO_2 Eq. In 2015, 2016, 2017, 2019, and 2021, that difference was less than 0.5 percent (less than 0.2 MMT CO_2 Eq.) between the two sets of activity data. The information collected by the USGS National Minerals Information Center surveys continue to be an important data source.

Recalculations Discussion

No recalculations were performed for the 1990 through 2021 portion of the time series.

Planned Improvements

EPA is continuing to evaluate and analyze data reported under EPA's GHGRP that would be useful to improve the emission estimates for the Cement Production source category. Most cement production facilities reporting under EPA's GHGRP use Continuous Emission Monitoring Systems (CEMS) to monitor and report CO_2 emissions, thus reporting combined process and combustion emissions from kilns. In implementing further improvements and integration of data from EPA's GHGRP, the latest guidance from the IPCC on the use of facility-level data in national inventories will be relied upon, in addition to category-specific QC methods recommended by the *2006 IPCC Guidelines*.[11] EPA's long-term improvement plan includes continued assessment of the feasibility of using additional GHGRP information beyond aggregation of reported facility-level clinker data, in particular disaggregating the combined process and combustion emissions reported using CEMS, to separately present national process and combustion emissions streams consistent with IPCC and UNFCCC guidelines. This long-term planned analysis is still in development and has not been applied for this current *Inventory*.

EPA continues to review methods and data used to estimate CO_2 emissions from cement production in order to account for organic material in the raw material and to discuss the carbonation that occurs across the duration of the cement product. Work includes identifying data and studies on the average carbon content for organic materials in kiln feed in the United States and on CO_2 reabsorption rates via carbonation for various cement products. This information is not reported by facilities subject to GHGRP reporting. This is a long-term improvement.

4.2 Lime Production (CRT Source Category 2A2)

Lime is a manufactured product with many industrial, chemical, and environmental applications. This reporting category (2A2) includes process emissions from the production of lime. Per the IPCC methodological guidance, emissions from fuels consumed for energy purposes during the production of lime are accounted for as part of fossil fuel combustion in the industrial end-use sector reported under the Energy chapter.

Lime production involves three main processes: stone preparation, calcination, and hydration. Carbon dioxide (CO_2) is generated during the calcination stage, when limestone—consisting of calcium carbonate ($CaCO_3$) and/or magnesium carbonate ($MgCO_3$)—is roasted at high temperatures in a kiln to produce calcium oxide (CaO) and CO_2. The CO_2 is given off as a gas and is normally emitted to the atmosphere.

$$CaCO_3 \rightarrow CaO + CO_2$$

Some facilities, however, recover CO_2 generated during the production process for use in sugar refining and precipitated calcium carbonate (PCC) production.[12] PCC is used as a filler or coating in the paper, food, and plastic industries and is derived from reacting hydrated high-calcium quicklime with CO_2, a production process that does not result in net emissions of CO_2 to the atmosphere.

For U.S. operations, the term "lime" refers to a variety of chemical compounds. These include CaO, or high-calcium quicklime; calcium hydroxide ($Ca(OH)_2$), or hydrated lime; dolomitic quicklime ([CaO•MgO]); and dolomitic hydrate ([$Ca(OH)_2$•MgO] or [$Ca(OH)_2$•$Mg(OH)_2$]).

The current lime market is approximately distributed across six end-use categories, as follows: metallurgical uses, 35 percent; environmental uses, 29 percent; chemical and industrial uses, 21 percent; construction uses, 10 percent; miscellaneous uses, 3 percent; and refractory dolomite, 1 percent (USGS 2021). The major uses are in steel making, chemical and industrial applications (such as the manufacture of fertilizer, glass, paper and pulp, and precipitated calcium carbonate, and in sugar refining), flue gas desulfurization (FGD) systems at coal-fired electric power plants, construction, and water treatment, as well as uses in mining, pulp and paper and precipitated calcium carbonate manufacturing (USGS 2023a). Lime is also used as a CO_2 scrubber, and there has been experimentation on the use of lime to capture CO_2 from electric power plants. Both lime (CaO) and limestone ($CaCO_3$) can be used as a sorbent for FGD systems. Emissions from limestone consumption for FGD systems are reported under Section 4.4 Other Process Uses of Carbonate Production (CRT Source Category 2A4).

Emissions from lime production have fluctuated over the time series depending on lime end-use markets – primarily the steel making industry and FGD systems for utility and industrial plants – and also energy costs. One significant change to lime end-use since 1990 has been the increase in demand for lime for FGD at coal-fired electric power plants, which can be attributed to compliance with sulfur dioxide (SO_2) emission regulations of the Clean Air Act Amendments of 1990. Phase I went into effect on January 1, 1995, followed by Phase II on January 1, 2000. To supply lime for the FGD market, the lime industry installed more than 1.8 million tons per year of new capacity by the end of 1995 (USGS 2023a). The need for air pollution controls continued to drive the FGD lime market, which had doubled between 1990 and 2019 (2021, 2023a, 2023b).

The U.S. lime industry temporarily shut down some individual gas-fired kilns and, in some case, entire lime plants during 2000 and 2001, due to significant increases in the price of natural gas. Lime production continued to

[12] The amount of CO_2 captured from lime production for sugar refining and PCC production is reported under CRT Source Category 2H3 "Other", but within this report, they are included in this chapter.

decrease in 2001 and 2002, a result of lower demand from the steel making industry, lime's largest end-use market, when domestic steel producers were affected by low priced imports and slowing demand (USGS 2023a).

Emissions from lime production peaked in 2006 at approximately 30.3 percent above 1990 levels, due to strong demand from the steel and construction markets (road and highway construction projects), before dropping to its second lowest level in 2009 at approximately 2.5 percent below 1990 emissions, driven by the economic recession and downturn in major markets including construction, mining, and steel (USGS 2023a). In 2010, the lime industry began to recover as the steel, FGD, and construction markets also recovered (USGS 2023a). Fluctuation in lime production since 2015 has been driven largely by demand from the steel making industry (USGS 2021). In 2020, a significant decline in lime production occurred due to plants temporarily closing as a result of the global COVID-19 pandemic (USGS 2023a). This resulted in the lowest level of emissions in 2020 at approximately 3.4 percent below 1990 emissions. Emissions increased annually since then, with 2022 levels similar to emissions in 2019.

Lime production in the United States—including Puerto Rico—was reported to be 16,994 kilotons in 2022, an increase of about 1.3 percent compared to 2021 levels (USGS 2023a). Compared to 1990, lime production increased by about 7.3 percent. At year-end 2022, 73 primary lime plants were operating in the United States, including Puerto Rico (USGS 2023a).[13] Principal lime producing states were, in alphabetical order, Kentucky, Missouri, Ohio, and Texas (USGS 2023a).

U.S. lime production resulted in estimated net CO_2 emissions of 12.2 MMT CO_2 Eq. (12,208 kt) (see Table 4-7 and Table 4-8). Carbon dioxide emissions from lime production increased by about 2.8 percent compared to 2021 levels. Compared to 1990, CO_2 emissions have increased by about 4.3 percent. The trends in CO_2 emissions from lime production are directly proportional to trends in production, which are described above.

Table 4-7: CO_2 Emissions from Lime Production (MMT CO_2 Eq.)

Year	1990	2005	2018	2019	2020	2021	2022
Lime Production	11.7	14.6	13.1	12.1	11.3	11.9	12.2

Table 4-8: Gross, Recovered, and Net CO_2 Emissions from Lime Production (kt CO_2)

Year	1990	2005	2018	2019	2020	2021	2022
Gross	11,959	15,074	13,609	12,676	11,875	12,586	12,750

Methodology and Time-Series Consistency

To calculate emissions, the amounts of high-calcium and dolomitic lime produced were multiplied by their respective emission factors, consistent with Tier 2 methodology from the *2006 IPCC Guidelines* and in accordance with the IPCC methodological decision tree and available data. The emission factor is the product of the stoichiometric ratio between CO_2 and CaO, and the average CaO and MgO content for lime. The CaO and MgO content for lime is assumed to be 95 percent for both high-calcium and dolomitic lime (IPCC 2006). The emission factors were calculated as follows:

[13] In 2022, 68 operating primary lime facilities in the United States reported to the EPA Greenhouse Gas Reporting Program.

Equation 4-2: *2006 IPCC Guidelines* Tier 2 Emission Factor for Lime Production, High-Calcium Lime (Equation 2.9)

$$EF_{\text{High-Calcium Lime}} = \left[\left(44.01\frac{\text{g}}{\text{mole}}CO_2\right) \div \left(56.08\frac{\text{g}}{\text{mole}}CaO\right)\right] \times \left(0.9500\frac{CaO}{\text{lime}}\right) = 0.7455\ \frac{\text{g } CO_2}{\text{g lime}}$$

Equation 4-3: *2006 IPCC Guidelines* Tier 2 Emission Factor for Lime Production, Dolomitic Lime (Equation 2.9)

$$EF_{\text{Dolomitic Lime}} = \left[\left(88.02\frac{\text{g}}{\text{mole}}CO_2\right) \div \left(96.39\frac{\text{g}}{\text{mole}}CaO \bullet MgO\right)\right] \times \left(0.9500\ \frac{CaO \bullet MgO}{\text{lime}}\right) = 0.8675\ \frac{\text{g } CO_2}{\text{g lime}}$$

Production was adjusted to remove the mass of chemically combined water found in hydrated lime, determined according to the molecular weight ratios of H_2O to ($Ca(OH)_2$ and $[Ca(OH)_2 \bullet Mg(OH)_2]$) (IPCC 2006). These factors set the chemically combined water content to 27 percent for high-calcium hydrated lime, and 30 percent for dolomitic hydrated lime.

The *2006 IPCC Guidelines* (Tier 2 method) also recommends accounting for emissions from lime kiln dust (LKD) through application of a correction factor. LKD is a byproduct of the lime manufacturing process typically not recycled back to kilns. LKD is a very fine-grained material and is especially useful for applications requiring very small particle size. Most common LKD applications include soil reclamation and agriculture. Emissions from the application of lime for agricultural purposes are reported in the Agriculture chapter under 5.5 Liming (CRT Source Category 3G). Currently, data on annual LKD production is not readily available to develop a country-specific correction factor. Lime emission estimates were multiplied by a factor of 1.02 to account for emissions from LKD (IPCC 2006). See the Planned Improvements section associated with efforts to improve uncertainty analysis and emission estimates associated with LKD.

Lime emission estimates were further adjusted to account for the amount of CO_2 captured for use in on-site processes. All the domestic lime facilities are required to report these data to EPA under its GHGRP. The total national-level annual amount of CO_2 captured for on-site process use was obtained from EPA's GHGRP (EPA 2023) based on reported facility-level data for years 2010 through 2022. The amount of CO_2 captured/recovered for non-marketed on-site process use is deducted from the total gross emissions (i.e., from lime production and LKD). The net lime emissions are presented in Table 4-7 and Table 4-8. GHGRP data on CO_2 removals (i.e., CO_2 captured/recovered) was available only for 2010 through 2022. Since GHGRP data are not available for 1990 through 2009, IPCC "splicing" techniques were used as per the *2006 IPCC Guidelines* on time-series consistency (IPCC 2006, Volume 1, Chapter 5).

Lime production data (i.e., lime sold and non-marketed lime used by the producer) by type (i.e., high-calcium and dolomitic quicklime, high-calcium and dolomitic hydrated lime, and dead-burned dolomite) for 1990 through 2022 (see Table 4-9) were obtained from U.S. Geological Survey (USGS) *Minerals Yearbook* (USGS 2023a) and are compiled by USGS to the nearest ton. Dead-burned dolomite data are additionally rounded by USGS to no more than one significant digit to avoid disclosing company proprietary data. Production data for the individual quicklime (i.e., high-calcium and dolomitic) and hydrated lime (i.e., high-calcium and dolomitic) types were not provided prior to 1997. These were calculated based on total quicklime and hydrated lime production data from 1990 through 1996 and the three-year average ratio of the individual lime types from 1997 to 1999. Natural hydraulic lime, which is produced from CaO and hydraulic calcium silicates, is not manufactured in the United States (USGS 2023a). Total lime production was adjusted to account for the water content of hydrated lime by converting hydrate to oxide equivalent based on recommendations from the IPCC and using the water content values for high-calcium hydrated lime and dolomitic hydrated lime mentioned above, and is presented in Table 4-10 (IPCC 2006). The CaO and CaO•MgO contents of lime, both 95 percent, were obtained from the IPCC (IPCC 2006).

Table 4-9: High-Calcium- and Dolomitic-Quicklime, High-Calcium- and Dolomitic-Hydrated, and Dead-Burned-Dolomite Lime Production (kt)

Year	1990	2005	2018	2019	2020	2021	2022
High-Calcium Quicklime	11,166	14,100	12,400	11,300	10,700	11,200	11,500
Dolomitic Quicklime	2,234	2,990	2,810	2,700	2,390	2,700	2,640
High-Calcium Hydrated	1,781	2,220	2,430	2,430	2,320	2,430	2,410
Dolomitic Hydrated	319	474	265	267	252	244	244
Dead-Burned Dolomite	342	200	200	200	200	200	200

Table 4-10: Adjusted Lime Production (kt)

Year	1990	2005	2018	2019	2020	2021	2022
High-Calcium	12,466	15,721	14,174	13,074	12,394	12,974	13,259
Dolomitic	2,800	3,522	3,196	3,087	2,766	3,071	3,011

Note: Minus water content of hydrated lime.

Methodological approaches were applied to the entire time series to ensure consistency in emissions from 1990 through 2022.

Uncertainty

The uncertainties contained in these estimates can be attributed to slight differences in the chemical composition of lime products and CO_2 recovery rates for on-site process use over the time series. Although the methodology accounts for various formulations of lime, it does not account for the trace impurities found in lime, such as iron oxide, alumina, and silica. Due to differences in the limestone used as a raw material, a rigid specification of lime material is impossible. As a result, few plants produce lime with exactly the same properties.

In addition, a portion of the CO_2 emitted during lime production will actually be reabsorbed when the lime is consumed, especially at captive lime production facilities. As noted above, lime has many different chemical, industrial, environmental, and construction applications. In many processes, CO_2 reacts with the lime to create calcium carbonate (e.g., water softening). Carbon dioxide reabsorption rates vary, however, depending on the application. For example, 100 percent of the lime used to produce precipitated calcium carbonate reacts with CO_2, whereas most of the lime used in steel making reacts with impurities such as silica, sulfur, and aluminum compounds. Quantifying the amount of CO_2 that is reabsorbed would require a detailed accounting of lime use in the United States and additional information about the associated processes where both the lime and byproduct CO_2 are "reused." Research conducted thus far has not yielded the necessary information to quantify CO_2 reabsorption rates.[14] Some additional information on the amount of CO_2 consumed on site at lime facilities, however, has been obtained from EPA's GHGRP.

In some cases, lime is generated from calcium carbonate byproducts at pulp mills and water treatment plants.[15] The lime generated by these processes is included in the USGS data for commercial lime consumption. In the pulping industry, mostly using the Kraft (sulfate) pulping process, lime is consumed in order to causticize a process liquor (green liquor) composed of sodium carbonate and sodium sulfide. The green liquor results from the dilution of the smelt created by combustion of the black liquor where biogenic carbon (C) is present from the wood. Kraft

[14] Representatives of the National Lime Association estimate that CO_2 reabsorption that occurs from the use of lime may offset as much as a quarter of the CO_2 emissions from calcination (Males 2003).

[15] Some carbide producers may also regenerate lime from their calcium hydroxide byproducts, which does not result in emissions of CO_2. In making calcium carbide, quicklime is mixed with coke and heated in electric furnaces. The regeneration of lime in this process is done using a waste calcium hydroxide (hydrated lime) [$CaC_2 + 2H_2O \rightarrow C_2H_2 + Ca(OH)_2$], not calcium carbonate [$CaCO_3$]. Thus, the calcium hydroxide is heated in the kiln to simply expel the water [$Ca(OH)_2 + \text{heat} \rightarrow CaO + H_2O$], and no CO_2 is released.

mills recover the calcium carbonate "mud" after the causticizing operation and calcine it back into lime—thereby generating CO_2—for reuse in the pulping process. Although this re-generation of lime could be considered a lime manufacturing process, the CO_2 emitted during this process is mostly biogenic in origin and therefore is not included in the industrial processes totals (Miner and Upton 2002). In accordance with IPCC methodological guidelines, any such emissions are calculated by accounting for net carbon fluxes from changes in biogenic carbon reservoirs in wooded or crop lands (see the Land Use, Land-Use Change, and Forestry chapter).

In the case of water treatment plants, lime is used in the softening process. Some large water treatment plants may recover their waste calcium carbonate and calcine it into quicklime for reuse in the softening process. Further research is necessary to determine the degree to which lime recycling is practiced by water treatment plants in the United States.

Another uncertainty is the assumption that calcination emissions for LKD are around 2 percent. EPA assigned uncertainty ranges of ±2 percent and a triangular probability density function for the LKD correction factor based on expert judgment (RTI 2023). The National Lime Association (NLA) has commented that the estimates of emissions from LKD in the United States could be closer to 6 percent. They also note that additional emissions (approximately 2 percent) may also be generated through production of other byproducts/wastes (off-spec lime that is not recycled, scrubber sludge) at lime plants (Seeger 2013). Publicly available data on LKD generation rates, total quantities not used in cement production, and types of other byproducts/wastes produced at lime facilities are limited. NLA compiled and shared historical emissions information and quantities for some waste products reported by member facilities associated with generation of total calcined byproducts and LKD, as well as methodology and calculation worksheets that member facilities complete when reporting. There is uncertainty regarding the availability of data across the time series needed to generate a representative country-specific LKD factor. Uncertainty of the activity data is also a function of the reliability and completeness of voluntarily reported plant-level production data. EPA assigned uncertainty ranges of ±1 percent for lime production and a normal probability density function, based on expert judgment (USGS 2012). Further research, including discussion with NLA, and data is needed to improve understanding of additional calcination emissions to consider revising the current assumptions that are based on the *2006 IPCC Guidelines*. More information can be found in the Planned Improvements section below.

The results of the Approach 2 quantitative uncertainty analysis are summarized in Table 4-11. Lime CO_2 emissions for 2022 were estimated to be between 12.1 and 12.3 MMT CO_2 Eq. at the 95 percent confidence level. This confidence level indicates a range of approximately 1 percent below and 1 percent above the emission estimate of 12.2 MMT CO_2 Eq.

Table 4-11: Approach 2 Quantitative Uncertainty Estimates for CO_2 Emissions from Lime Production (MMT CO_2 Eq. and Percent)

Source	Gas	2022 Emission Estimate (MMT CO_2 Eq.)	Uncertainty Range Relative to Emission Estimate[a] (MMT CO_2 Eq.)		(%)	
			Lower Bound	Upper Bound	Lower Bound	Upper Bound
Lime Production	CO_2	12.2	12.1	12.3	-1%	+1%

[a] Range of emission estimates predicted by Monte Carlo stochastic simulation for a 95 percent confidence interval.

QA/QC and Verification

General quality assurance/quality control (QA/QC) procedures were applied consistent with the U.S. Inventory QA/QC plan, which is in accordance with Volume 1, Chapter 6 of *2006 IPCC Guidelines* as noted in the introduction of the IPPU chapter (see Annex 8 for more details).

More details on the greenhouse gas calculation, monitoring and QA/QC methods associated with reporting on CO_2 captured for onsite use applicable to lime manufacturing facilities can be found under Subpart S (lime

manufacturing) of the GHGRP regulation (40 CFR Part 98).[16]EPA verifies annual facility-level GHGRP reports through a multi-step process (e.g., combination of electronic checks and manual reviews) to identify potential errors and ensure that data submitted to EPA are accurate, complete, and consistent (EPA 2023).[17] Based on the results of the verification process, EPA follows up with facilities to resolve mistakes that may have occurred. The post-submittals checks are consistent with a number of general and category-specific QC procedures, including: range checks, statistical checks, algorithm checks, and year-to-year checks of reported data and emissions.

Recalculations Discussion

No recalculations were performed for the 1990 through 2021 portion of the time series.

Planned Improvements

EPA plans to review GHGRP emissions and activity data reported to EPA under Subpart S of the GHGRP regulation (40 CFR Part 98), and aggregated activity data on lime production by type in particular. In addition, initial review of data has identified that several facilities use CEMS to report emissions. Under Subpart S, if a facility is using a CEMS, they are required to report combined combustion emissions and process emissions. EPA continues to review how best to incorporate GHGRP and notes that particular attention will be made to also ensuring time-series consistency of the emissions estimates presented in future *Inventory* reports, consistent with IPCC and UNFCCC guidelines. This is required because the facility-level reporting data from EPA's GHGRP, with the program's initial requirements for reporting of emissions in calendar year 2010, are not available for all inventory years (i.e., 1990 through 2009) as required for this *Inventory*. In implementing improvements and integration of data from EPA's GHGRP, the latest guidance from the IPCC on the use of facility-level data in national inventories will be relied upon.[18]

Future improvements involve improving and/or confirming the representativeness of current assumptions associated with emissions from production of LKD and other byproducts/wastes as discussed in the Uncertainty section, per comments from the NLA provided during a prior Public Review comment period for a previous (1990 through 2018) *Inventory.* EPA met with NLA in summer of 2020 for clarification on data needs and available data and to discuss planned research into GHGRP data. Previously, EPA met with NLA in spring of 2015 to outline specific information required to apply IPCC methods to develop a country-specific correction factor to more accurately estimate emissions from production of LKD. In 2016, NLA compiled and shared historical emissions information reported by member facilities on an annual basis under voluntary reporting initiatives from 2002 through 2011 associated with generation of total calcined byproducts and LKD. Reporting of LKD was only differentiated for the years 2010 and 2011. This emissions information was reported on a voluntary basis consistent with NLA's facility-level reporting protocol, which was also provided to EPA. To reflect information provided by NLA, EPA updated the qualitative description of uncertainty. At the time of this *Inventory*, this planned improvement is in process and has not been incorporated into this current *Inventory* report.

4.3 Glass Production (CRT Source Category 2A3)

Glass production is an energy and raw-material intensive process that results in the generation of carbon dioxide (CO_2) from both the energy consumed in making glass and the glass production process itself. This reporting category (2A3) includes emissions from the production of glass. Emissions from fuels consumed for energy purposes during the production of glass are accounted for as part of fossil fuel combustion in the industrial end-use sector reported under the Energy chapter.

Glass production employs a variety of raw materials in a glass-batch. These include formers, fluxes, stabilizers, and sometimes colorants. The major raw materials (i.e., fluxes and stabilizers) that emit process-related CO_2 emissions during the glass melting process are limestone, dolomite, and soda ash. The main former in all types of glass is silica (SiO_2). Other major formers in glass include feldspar and boric acid (i.e., borax). Fluxes are added to lower the temperature at which the batch melts. Most commonly used flux materials are soda ash (sodium carbonate, Na_2CO_3) and potash (potassium carbonate, K_2O). Stabilizers make glass more chemically stable and keep the finished glass from dissolving and/or falling apart. Commonly used stabilizing agents in glass production are limestone ($CaCO_3$), dolomite ($CaCO_3MgCO_3$), alumina (Al_2O_3), magnesia (MgO), barium carbonate ($BaCO_3$), strontium carbonate ($SrCO_3$), lithium carbonate (Li_2CO_3), and zirconia (ZrO_2) (DOE 2002). Glass makers also use a certain amount of recycled scrap glass (cullet), which comes from in-house return of glassware broken in the production process or other glass spillage or retention, such as recycling or from cullet broker services.

The raw materials (primarily soda ash, limestone, and dolomite) release CO_2 emissions in a complex high-temperature chemical reaction during the glass melting process. This process is not directly comparable to the calcination process used in lime manufacturing, cement manufacturing, and process uses of carbonates (i.e., limestone/dolomite use) but has the same net effect in terms of generating process CO_2 emissions (IPCC 2006).

The U.S. glass industry can be divided into four main categories: containers, flat (window) glass, fiber glass, and specialty glass. The majority of commercial glass produced is container and flat glass (EPA 2009). The United States is one of the major global exporters of glass. Domestically, demand comes mainly from the construction, auto, bottling, and container industries. There are more than 1,700 facilities that manufacture glass in the United States, with the largest companies being Corning, Guardian Industries, Owens-Illinois, and PPG Industries.[19]

The glass container sector is one of the leading soda ash consuming sectors in the United States. In 2022, glass production accounted for 49 percent of total domestic soda ash consumption (USGS 2023). Emissions from soda ash production are reported in Section 4.12.

In 2022, 2,250 kilotons of soda ash, 1,370 kilotons of limestone, 925 kilotons of dolomite, and 1.9 kilotons of other carbonates were consumed for glass production (USGS 2023; EPA 2023). Use of soda ash, limestone, dolomite, and other carbonates in glass production resulted in aggregate CO_2 emissions of 2.0 MMT CO_2 Eq. (1,956 kt), which are summarized in Table 4-12 and Table 4-13. Overall, emissions have decreased by 14 percent compared to 1990. Emissions decreased by 1 percent compared to 2021 levels.

Emissions from glass production have remained relatively consistent over the time series with some fluctuations since 1990. In general, these fluctuations were related to the behavior of the export market and the U.S. economy. Specifically, the extended downturn in residential and commercial construction and automotive industries between 2008 and 2010 resulted in reduced consumption of glass products, causing a drop in global demand for limestone, dolomite, and soda ash and resulting in lower emissions. Some commercial food and beverage package

[19] Excerpt from Glass & Glass Product Manufacturing Industry Profile, First Research. Available online at: http://www.firstresearch.com/Industry-Research/Glass-and-Glass-Product-Manufacturing.html.

manufacturers are shifting from glass containers towards lighter and more cost-effective polyethylene terephthalate (PET) based containers, putting downward pressure on domestic consumption of soda ash (USGS 1995 through 2015b). Glass production in 2022 was steady, changing by no more than 2 percent over the course of the year (Federal Reserve 2023).

Table 4-12: CO_2 Emissions from Glass Production (MMT CO_2 Eq.)

Year	1990	2005	2018	2019	2020	2021	2022
Glass Production	2.3	2.4	2.0	1.9	1.9	2.0	2.0

Table 4-13: CO_2 Emissions from Glass Production (kt CO_2)

Year	1990	2005	2018	2019	2020	2021	2022
Glass Production	2,263	2,402	1,989	1,940	1,858	1,969	1,956

Methodology and Time-Series Consistency

Carbon dioxide emissions were calculated based on Tier 3 method from the *2006 IPCC Guidelines*, in accordance with the IPCC methodological decision tree and available data, by multiplying the quantity of input carbonates (i.e., limestone, dolomite, soda ash, and other carbonates) by the carbonate-based emission factor (in metric tons CO_2/metric ton carbonate) and the average carbonate-based mineral mass fraction.

2010 through 2022

The methodology for estimating CO_2 emissions from glass production for years 2010 through 2022 used the quantities of limestone, dolomite, and a group of other carbonates (i.e., barium carbonate, potassium carbonate, lithium carbonate, and strontium carbonate) used for glass production, obtained from GHGRP (EPA 2023). USGS data on the quantity of soda ash used for glass production was used because it was obtained directly from the soda ash producers and includes use by smaller artisanal glass operations, which are excluded in the GHGRP data.

GHGRP collects data from glass production facilities with greenhouse gas emissions greater than 25,000 metric tons CO_2 Eq. The reporting threshold is used to exclude artisanal glass operations that are expected to have much lower greenhouse gas emissions than the threshold. These smaller facilities have not been accounted for yet for this portion of the time series for limestone, dolomite, or other carbonates due to limited data. Facilities report the total quantity of each type of carbonate used in glass production each year to GHGRP, with data collection starting in 2010 (EPA 2023).

Using the total quantities of each carbonate, EPA calculated the metric tons of emissions resulting from glass production by multiplying the quantity of input carbonates (i.e., limestone, dolomite, soda ash, and other carbonates) by carbonate-based emission factors in metric tons CO_2/metric ton carbonate (limestone, 0.43971; dolomite, 0.47732; soda ash, 0.41492; and other carbonates, 0.262), and by the average carbonate-based mineral mass fraction for each year. IPCC default emission factors were used for limestone, dolomite, and soda ash, and the emission factor for other carbonates is based on expert judgment (RTI 2022).

1990 through 2009

Data from GHGRP on the quantity of limestone, dolomite, and other carbonates used in glass production are not available for 1990 through 2009. Additionally, USGS does not collect data on the quantity of other carbonates used for glass production.

To address time-series consistency, total emissions from 1990 to 2009 were calculated using the Federal Reserve Industrial Production Index for glass production in the United States as a surrogate for the total quantity of carbonates used in glass production. The production index measures real output expressed as a percentage of real output in a base year, which is currently 2017 (Federal Reserve 2023). Since January 1971, the Federal Reserve has released the monthly glass production index for NAICS code 3272 (Glass and Glass Product Manufacturing) as part

of release G.17, "Industrial Production and Capacity Utilization" (Federal Reserve 2023). The monthly index values for each year were averaged to calculate an average annual glass production index value. Total annual process emissions were calculated by taking a ratio of the average annual glass production index for each year to the average annual glass production index for base year 2017, and multiplying by the calculated 2017 emissions (process-related) based on GHGRP data.

Emissions from limestone, dolomite, and other carbonate consumption were disaggregated from total annual emissions, using the average percent contribution of each to annual emissions from these three carbonates for 2010 through 2014 based on GHGRP data: 64.5 percent limestone, 35.5 percent dolomite, and 0.1 percent other carbonates.

The methodology for estimating CO_2 emissions from the use of soda ash for glass production and data sources for the amount of soda ash used in glass production are consistent with the methodology used for 2010 through 2022. The average mineral mass fractions for soda ash are only available starting in 2010. The average carbonate-based mineral mass fractions from the GHGRP, averaged across 2010 through 2014, indicate that soda ash contained 98.7 percent sodium carbonate (Na_2CO_3). This averaged value is used to estimate emissions for 1990 through 2009. The years 2010 to 2014 were used to determine the average carbonate-based mineral mass fractions because those years were deemed to better represent historic glass production from 1990 to 2009.

Data on soda ash used for glass production for 1990 through 2022 were obtained from the U.S. Bureau of Mines (1991 and 1993a), the USGS *Minerals Yearbook: Soda Ash* (USGS 1995 through 2015b), and USGS *Mineral Industry Surveys for Soda Ash* (USGS 2017 through 2023). Data on limestone, dolomite, and other carbonates used for glass production and on average carbonate-based mineral mass fraction for 2010 through 2022 were obtained from GHGRP (EPA 2023). The quantities of limestone, dolomite, and other carbonates were calculated for 1990 through 2009 using the Federal Reserve Industrial Production Index (Federal Reserve 2023).

The amount of limestone, dolomite, soda ash, and other carbonates used in glass production each year and the annual average Federal Reserve production indices for glass production are shown in Table 4-14.

Table 4-14: Limestone, Dolomite, Soda Ash, and Other Carbonates Used in Glass Production (kt) and Average Annual Production Index for Glass and Glass Product Manufacturing

Activity	1990	2005	2018	2019	2020	2021	2022
Limestone	1,409	1,690	1,442	1,370	1,334	1,397	1,370
Dolomite	714	857	871	883	824	893	925
Soda Ash	3,177	3,050	2,280	2,220	2,130	2,280	2,250
Other Carbonates	2	3	2	2	2	2	1.9
Total	**5,302**	**5,599**	**4,596**	**4,475**	**4,289**	**4,572**	**4,547**
Production Index[a]	94.3	113.1	102.5	99.8	92.4	88.3	86.8

[a] Average Annual Production Index uses 2017 as the base year.

Note: Totals may not sum due to independent rounding.

As discussed above, methodological approaches were applied to the entire time series to ensure consistency in emissions from 1990 through 2022. Consistent with the *2006 IPCC Guidelines*, the overlap technique was applied to compare USGS and GHGRP data sets for 2010 through 2022. To address the inconsistencies, adjustments were made as described above.

Uncertainty

The methodology in this *Inventory* report uses GHGRP data for the average mass fraction of each mineral used in glass production. These minerals are limestone, dolomite, soda ash, and other carbonates (barium carbonate ($BaCO_3$), potassium carbonate (K_2CO_3), lithium carbonate (Li_2CO_3), and strontium carbonate ($SrCO_3$)). The mass fractions are reported directly by the glass manufacturers, for each year from 2010 to 2022.

The methodology uses the quantities of limestone, dolomite, and other carbonates used in glass manufacturing which is reported directly by the glass manufacturers for years 2010 through 2022 and the amount of soda ash used in glass manufacturing which is reported by soda ash producers for the full time series. EPA assigned an uncertainty range of ±5 percent and a normal probability density function for all carbonate quantities and the Federal Reserve Industrial Production Index for glass production, and using this suggested uncertainty provided in Section 2.4.2.2 of the *2006 IPCC Guidelines* is appropriate based on expert judgment (RTI 2023). EPA assigned an uncertainty range of ±2 percent for the carbonate emission factors, ±2 percent for the mineral mass fractions, and ±1 percent for the calcination fraction, and using this suggested uncertainty provided in Section 2.4.2.1 of the *2006 IPCC Guidelines* is appropriate based on expert judgment (RTI 2023). Per this expert judgment, a triangular probability density function was assigned for emission factors, mineral mass fractions, and calcination fraction.

The results of the Approach 2 quantitative uncertainty analysis are summarized in Table 4-15. In 2022, glass production CO_2 emissions were estimated to be between 1.9 and 2.0 MMT CO_2 Eq. at the 95 percent confidence level. This indicates a range of approximately 2 percent below and 2 percent above the emission estimate of 2.0 MMT CO_2 Eq.

Table 4-15: Approach 2 Quantitative Uncertainty Estimates for CO_2 Emissions from Glass Production (MMT CO_2 Eq. and Percent)

Source	Gas	2022 Emission Estimate (MMT CO_2 Eq.)	Uncertainty Range Relative to Emission Estimate[a] (MMT CO_2 Eq.)		(%)	
			Lower Bound	Upper Bound	Lower Bound	Upper Bound
Glass Production	CO_2	2.0	1.9	2.0	-2%	+2%

[a] Range of emission estimates predicted by Monte Carlo stochastic simulation for a 95 percent confidence interval.

QA/QC and Verification

General quality assurance/quality control (QA/QC) procedures were applied consistent with the U.S. Inventory QA/QC plan, which is in accordance with Volume 1, Chapter 6 of *2006 IPCC Guidelines* as described in the introduction of the IPPU chapter (see Annex 8 for more details). For the GHGRP data, EPA verifies annual facility-level reports through a multi-step process (e.g., including a combination of pre-and post-submittal electronic checks and manual reviews by staff) to identify potential errors and ensure that data submitted to EPA are accurate, complete, and consistent (EPA 2015).[20] Based on the results of the verification process, EPA follows up with facilities to resolve mistakes that may have occurred. The post-submittals checks are consistent with a number of general and category-specific QC procedures, including: range checks, statistical checks, algorithm checks, and year-to-year checks of reported data and emissions.

Recalculations Discussion

During annual QC, a transcription error for the 1990 value of CO_2 emissions from glass production was identified and corrected in Table 4-12 and Table 4-13. No recalculations were needed or performed due to this transcription error, and no other recalculations were performed for the 1990 through 2021 portion of the time series.

Planned Improvements

EPA plans to evaluate updates to uncertainty levels for the activity data and mineral mass fraction values from EPA's GHGRP. This is a near-term planned improvement that is anticipated for inclusion in 2025 report.

Some glass producing facilities in the United States do not report to EPA's GHGRP because they fall below the reporting threshold for this industry. EPA will continue ongoing research on the availability of data to better assess the completeness of emission estimates from glass production and how to refine the methodology to ensure complete national coverage of this category. When reporting began in 2010, EPA received data from more facilities that were above the reporting threshold than expected, and total emissions for these reporting facilities were higher than expected for all glass production facilities in the United States (EPA 2009). Research will include reassessing previous assessments of GHGRP industry coverage using the reporting threshold of 25,000 metric tons CO_2 Eq. This is a medium-term planned improvement.

4.4 Other Process Uses of Carbonates (CRT Source Category 2A4)

Limestone ($CaCO_3$), dolomite ($CaCO_3MgCO_3$),[21] and other carbonates such as soda ash, magnesite, and siderite are basic materials used by a wide variety of industries, including construction, agriculture, chemical, metallurgy (i.e., iron and steel production, ferroalloy production, and magnesium production), glass production, environmental pollution control, ceramics production, and non-metallurgical magnesia production. This reporting category (2A4) includes emissions from other uses of limestone, dolomite, and other carbonates not included in other categories; the production of ceramics; other uses of soda ash not included elsewhere; and the production of non-metallurgical magnesia. This section addresses mineral industry use of these carbonates: limestone, dolomite, soda ash, and magnesite. Emissions from the use of these carbonates are organized into four subcategories: other process uses of carbonates (i.e., limestone and dolomite consumption), ceramics production, other uses of soda ash, and non-metallurgical magnesia production.

For industrial applications, carbonates are heated sufficiently enough to calcine the material and generate CO_2 as a byproduct.

$$CaCO_3 \rightarrow CaO + CO_2$$

$$MgCO_3 \rightarrow MgO + CO_2$$

Examples of such applications include limestone used as a flux or purifier in metallurgical furnaces, as a sorbent in flue gas desulfurization (FGD) systems for utility and industrial plants, and as a raw material for the production of glass, lime, and cement.

Emissions from limestone and dolomite used in the production of cement, lime, glass, and iron and steel are excluded from the other process uses of carbonates category and reported under their respective source categories (e.g., Section 4.3, Glass Production). Emissions from soda ash production are reported under Section 4.12, Soda Ash Production (CRT Source Category 2B7). Emissions from soda ash consumption associated with glass manufacturing are reported under Section 4.3, Glass Production (CRT Source Category 2A3). Emissions from the use of limestone and dolomite in liming of agricultural soils are included in the Agriculture chapter under Section 5.5, Liming (CRT Source Category 3G). Emissions from limestone and dolomite used in the production of iron and steel and magnesium production are reported under Section 4.18, Iron and Steel Production (CRT Source Category 2C1).

[21] Limestone and dolomite are collectively referred to as limestone by the industry, and intermediate varieties are seldom distinguished.

Emissions from dolomite used in the production of magnesium are reported under Section 4.21, Magnesium Production and Processing (CRT Source Category 2C4). As noted in Section 4.19, Ferroalloy Production (CRT Source Category 2C2), emissions from the production of ferromanganese are not included in this *Inventory* because of the small number of manufacturers of these materials in the United States. Government information disclosure rules prevent the publication of production data for these production facilities. Emissions from fuels consumed for energy purposes during these processes are accounted for as part of fossil fuel combustion in the industrial end-use sector reported under the Energy chapter in Section 3.1, Fossil Fuel Combustion (CRT Source Category 1A). Both lime (CaO) and limestone ($CaCO_3$) can be used as a sorbent for FGD systems. Emissions from lime consumption for FGD systems and from sugar refining are reported under Section 4.3, Lime Production (CRT Source Category 2A2). Emissions from the use of dolomite in primary magnesium metal production are reported under Section 4.21, Magnesium Production and Processing (CRT Source Category 2C4).

Limestone and dolomite are widely distributed throughout the world in deposits of varying sizes and degrees of purity. Large deposits of limestone occur in nearly every state in the United States, and significant quantities are extracted for industrial applications. In 2018, the leading limestone producing states were Texas, Florida, Ohio, Missouri, and Pennsylvania, which contributed 46 percent of the total U.S. output (USGS 2022a). Dolomite deposits are found in the United States, Canada, Mexico, Europe, Africa, and Brazil. In the United States, the leading dolomite producing states are Pennsylvania, New York, and Utah which currently contribute more than a third of the total U.S. output (USGS 2022a).

Ceramics include the production of bricks and roof tiles, vitrified clay pipes, refractory products, expanded clay products, wall and floor tiles, table and ornamental ware (i.e., household ceramics), sanitary ware, technical ceramics (e.g., aerospace, automotive, electronic, or biomedical applications), and inorganic bonded abrasives. Most ceramic products are made from one or more different types of clay (e.g., shales, fire clay, and ball clay) with varying carbonate contents. The process of manufacturing ceramic products, regardless of the product type or scale, is essentially the same. This process consists of raw material processing (grinding, calcining, and drying), forming (wet or dry process), firing (single or multiple stage firing process), and final processing. Process CO_2 emissions are produced during the calcination process in the kiln or dryer, where carbonates are heated to high temperatures which results in metal oxides and CO_2. In 2018, the leading clay producing states were Georgia, Wyoming, Texas, Alabama, and North Carolina, which contributed 60 percent of the total U.S. output (USGS 2022f).

Other uses of soda ash include the consumption of soda ash for non-glass purposes. Excluding glass production, soda ash consumption by end use in 2022 included chemicals, 54 percent, soap and detergent manufacturing, 9 percent; distributers, 10 percent; flue gas desulfurization, 7 percent; other uses, 17 percent; pulp and paper production, 1 percent; and water treatment, 2 percent (USGS 2023a). Chemicals produced using soda ash include sodium-based inorganic chemicals such as sodium bicarbonate, sodium chromates, sodium phosphates, and sodium silicates. (USGS 2022g). Internationally, two types of soda ash are produced: natural and synthetic. In 2019, 93 percent of the global soda ash production came from China, the United States, Russia, Germany, India, Turkey, Poland, and France. The United States only produces natural soda ash and only in two states: Wyoming and California (USGS 2021a).
