Foreword

The National Association of Local Boards of Health (NALBOH) is pleased to provide *Understanding Concentrated Animal Feeding Operations and Their Impact on Communities* to assist local boards of health who have concerns about concentrated animal feeding operations (CAFOs) or large industrial animal farms in their communities. The Environmental Health Services Branch of the Centers for Disease Control and Prevention (CDC), National Center for Environmental Health (NCEH) encouraged the development of this product and provided technical oversight and financial support. This publication was supported by Cooperative Agreement Number 5U38HM000512. Its contents are solely the responsibility of the authors and do not necessarily represent the official views of the CDC.

The mission of NALBOH is to strengthen boards of health, enabling them to promote and protect the health of their communities, through education, technical assistance, and advocacy. Boards of health are responsible for fulfilling three public health core functions: assessment, policy development, and assurance. For a health agency, this includes overseeing and ensuring that there are sufficient resources, effective policies and procedures, partnerships with other organizations and agencies, and regular evaluation of an agency's services.

NALBOH is confident that *Understanding Concentrated Animal Feeding Operations and Their Impact on Communities* will help local board of health members understand their role in developing ways to mitigate potential problems associated with CAFOs. We trust that the information provided in this guide will enable board of health members to develop and sustain monitoring programs, investigate developing policy related to CAFOs, and create partnerships with other local and state agencies and officials to improve the health and well-being of communities everywhere.

A special thanks to Jeffrey Neistadt (NALBOH's Director – Education and Training), NALBOH's Environmental Health subcommittee, and any local board of health members and health department staff who were contacted during the development of this document for their contributions and support.

Introduction

Livestock farming has undergone a significant transformation in the past few decades. Production has shifted from smaller, family-owned farms to large farms that often have corporate contracts. Most meat and dairy products now are produced on large farms with single species buildings or open-air pens (MacDonald & McBride, 2009). Modern farms have also become much more efficient. Since 1960, milk production has doubled, meat production has tripled, and egg production has quadrupled (Pew Commission on Industrial Animal Farm Production, 2009). Improvements to animal breeding, mechanical innovations, and the introduction of specially formulated feeds and animal pharmaceuticals have all increased the efficiency and productivity of animal agriculture. It also takes much less time to raise a fully grown animal. For example, in 1920, a chicken took approximately 16 weeks to reach 2.2 lbs., whereas now they can reach 5 lbs. in 7 weeks (Pew, 2009).

New technologies have allowed farmers to reduce costs, which mean bigger profits on less land and capital. The current agricultural system rewards larger farms with lower costs, which results in greater profit and more incentive to increase farm size.

AFO vs. CAFO

A CAFO is a specific type of large-scale industrial agricultural facility that raises animals, usually at high-density, for the consumption of meat, eggs, or milk. To be considered a CAFO, a farm must first be categorized as an animal feeding operation (AFO). An AFO is a lot or facility where animals are kept confined and fed or maintained for 45 or more days per year, and crops, vegetation, or forage growth are not sustained over a normal growing period (Environmental Protection Agency [EPA], 2009). CAFOs are classified by the type and number of animals they contain, and the way they discharge waste into the water supply. CAFOs are AFOs that contain at least a certain number of animals, or have a number of animals that fall within a range and have waste materials that come into contact with the water supply. This contact can either be through a pipe that carries manure or wastewater to surface water, or by animal contact with surface water that runs through their confined area. (See Appendix A)

History

AFOs were first identified as potential pollutants in the 1972 Clean Water Act. Section 502 identified "feedlots" as "point sources" for pollution along with other industries, such as fertilizer manufacturing. Consequently, a permit program entitled the National Pollutant Discharge Elimination System (NPDES) was created which set effluent limitation guidelines and standards (ELGs) for CAFOs. CAFOs have since been regulated by NPDES or a state equivalent since the mid-1970s. The definitions of what was considered an AFO or CAFO were created by the EPA for the NPDES process in 1976. These regulations remained in effect for more than 25 years, but increases and changes to farm size and production methods required an update to the permit system.

The regulations guiding CAFO permits and operations were revised in 2003. New inclusions in the 2003 regulations were that all CAFOs had to apply for a NPDES permit even if they only discharged in the event of a large storm. Large poultry operations were included in the regulations, regardless of their waste disposal system, and all CAFOs that held a NPDES permit were required to develop and implement a nutrient management plan. These plans had CAFOs identify ways to treat or process waste in a way that maintained nutrient levels at the appropriate amount.

The 2003 CAFO rule was subsequently challenged in court. A Second Circuit Court of Appeals decision required alteration to the CAFO permitting system. In *Water Keeper et al. vs. the EPA*, the court directed the EPA to remove the requirement for all CAFOs to apply for NPDES. Instead, the court required that nutrient management plans be submitted with the permit application, reviewed by officials and the public, and the terms of the plan be incorporated into the permit.

As a result of this court decision, the CAFO rule was again updated. The current final CAFO rule, which was revised in 2008, requires that only CAFOs which discharge or propose to discharge waste apply for permits. The EPA has also provided clarification in the discussion surrounding the rule on how CAFOs should assess whether they discharge or propose to discharge. There is also the opportunity to receive a no discharge certification for CAFOs that do not discharge or propose to discharge. This certification demonstrates that the CAFO is not required to acquire a permit. And while CAFOs were required to create nutrient management plans under the 2003 rule, these plans were now included with permit applications, and had a built-in time period for public review and comment.

Benefits of CAFOs

When properly managed, located, and monitored, CAFOs can provide a low-cost source of meat, milk, and eggs, due to efficient feeding and housing of animals, increased facility size, and animal specialization. When CAFOs are proposed in a local area, it is usually argued that they will enhance the local economy and increase employment. The effects of using local materials, feed, and livestock are argued to ripple throughout the economy, and increased tax expenditures will lead to increase funds for schools and infrastructure.

Environmental Health Effects

The most pressing public health issue associated with CAFOs stems from the amount of manure they produce. CAFO manure contains a variety of potential contaminants. It can contain plant nutrients such as nitrogen and phosphorus, pathogens such as *E. coli*, growth hormones, antibiotics, chemicals used as additives to the manure or to clean equipment, animal blood, silage leachate from corn feed, or copper sulfate used in footbaths for cows.

Depending on the type and number of animals in the farm, manure production can range between 2,800 tons and 1.6 million tons a year (Government Accountability Office [GAO], 2008). Large farms can produce more waste than some U.S. cities—a feeding operation with 800,000 pigs could produce over 1.6 million tons of waste a year. That amount is one and a half times more than the annual sanitary waste produced by the city of Philadelphia, Pennsylvania (GAO, 2008). Annually, it is estimated that livestock animals in the U.S. produce each year somewhere between 3 and 20 times more manure than people in the U.S. produce, or as much as 1.2–1.37 billion tons of waste (EPA, 2005). Though sewage treatment plants are required for human waste, no such treatment facility exists for livestock waste.

While manure is valuable to the farming industry, in quantities this large it becomes problematic. Many farms no longer grow their own feed, so they cannot use all the manure they produce as fertilizer. CAFOs must find a way to manage the amount of manure produced by their animals. Ground application of untreated manure is one of the most common disposal methods due to its low cost. It has limitations, however, such as the inability to apply manure while the ground is frozen. There are also limits as to how many nutrients from manure a land area can handle. Over application of livestock wastes can overload

soil with macronutrients like nitrogen and phosphorous and micronutrients that have been added to animal feed like heavy metals (Burkholder et al., 2007). Other manure management strategies include pumping liquefied manure onto spray fields, trucking it off-site, or storing it until it can be used or treated. Manure can be stored in deep pits under the buildings that hold animals, in clay or concrete pits, treatment lagoons, or holding ponds.

Animal feeding operations are developing in close proximity in some states, and fields where manure is applied have become clustered. When manure is applied too frequently or in too large a quantity to an area, nutrients overwhelm the absorptive capacity of the soil, and either run off or are leached into the groundwater. Storage units can break or become faulty, or rainwater can cause holding lagoons to overflow. While CAFOs are required to have permits that limit the levels of manure discharge, handling the large amounts of manure inevitably causes accidental releases which have the ability to potentially impact humans.

The increased clustering and growth of CAFOs has led to growing environmental problems in many communities. The excess production of manure and problems with storage or manure management can affect ground and surface water quality. Emissions from degrading manure and livestock digestive processes produce air pollutants that often affect ambient air quality in communities surrounding CAFOs. CAFOs can also be the source of greenhouse gases, which contribute to global climate change.

All of the environmental problems with CAFOs have direct impact on human health and welfare for communities that contain large industrial farms. As the following sections demonstrate, human health can suffer because of contaminated air and degraded water quality, or from diseases spread from farms. Quality of life can suffer because of odors or insect vectors surrounding farms, and property values can drop, affecting the financial stability of a community. One study found that 82.8% of those living near and 89.5% of those living far from CAFOs believed that their property values decreased, and 92.2% of those living near and 78.9% of those living far from CAFOs believed the odor from manure was a problem. The study found that real estate values had not dropped and odor infestations were not validated by local governmental staff in the areas. However, the concerns show that CAFOs remain contentious in communities (Schmalzried and Fallon, 2007). CAFOs are an excellent example of how environmental problems can directly impact human and community well-being.

Groundwater

Groundwater can be contaminated by CAFOs through runoff from land application of manure, leaching from manure that has been improperly spread on land, or through leaks or breaks in storage or containment units. The EPA's 2000 National Water Quality Inventory found that 29 states specifically identified animal feeding operations, not just concentrated animal feeding operations, as contributing to water quality impairment (Congressional Research Service, 2008). A study of private water wells in Idaho detected levels of veterinary antibiotics, as well as elevated levels of nitrates (Batt, Snow, & Alga, 2006). Groundwater is a major source of drinking water in the United States. The EPA estimates that 53% of the population relies on groundwater for drinking water, often at much higher rates in rural areas (EPA, 2004). Unlike surface water, groundwater contamination sources are more difficult to monitor. The extent and source of contamination are often harder to pinpoint in groundwater than surface water contamination. Regular testing of household water wells for total and fecal coliform bacteria is a crucial element in monitoring groundwater quality, and can be the first step in discovering contamination issues related to CAFO discharge. Groundwater contamination can also affect surface water (Spellman &

Whiting, 2007). Contaminated groundwater can move laterally and eventually enter surface water, such as rivers or streams.

When groundwater is contaminated by pathogenic organisms, a serious threat to drinking water can occur. Pathogens survive longer in groundwater than surface water due to lower temperatures and protection from the sun. Even if the contamination appears to be a single episode, viruses could become attached to sediment near groundwater and continue to leach slowly into groundwater. One pollution event by a CAFO could become a lingering source of viral contamination for groundwater (EPA, 2005).

Groundwater can still be at risk for contamination after a CAFO has closed and its lagoons are empty. When given increased air exposure, ammonia in soil transforms into nitrates. Nitrates are highly mobile in soil, and will reach groundwater quicker than ammonia. It can be dangerous to ignore contaminated soil. The amount of pollution found in groundwater after contamination depends on the proximity of the aquifer to the CAFO, the size of the CAFO, whether storage units or pits are lined, the type of subsoil, and the depth of the groundwater.

If a CAFO has contaminated a water system, community members should be concerned about nitrates and nitrate poisoning. Elevated nitrates in drinking water can be especially harmful to infants, leading to blue baby syndrome and possible death. Nitrates oxidize iron in hemoglobin in red blood cells to methemoglobin. Most people convert methemoglobin back to hemoglobin fairly quickly, but infants do not convert back as fast. This hinders the ability of the infant's blood to carry oxygen, leading to a blue or purple appearance in affected infants. However, infants are not the only ones who can be affected by excess nitrates in water. Low blood oxygen in adults can lead to birth defects, miscarriages, and poor general health. Nitrates have also been speculated to be linked to higher rates of stomach and esophageal cancer (Bowman, Mueller, & Smith, 2000). In general, private water wells are at higher risk of nitrate contamination than public water supplies.

Surface Water

The agriculture sector, including CAFOs, is the leading contributor of pollutants to lakes, rivers, and reservoirs. It has been found that states with high concentrations of CAFOs experience on average 20 to 30 serious water quality problems per year as a result of manure management problems (EPA, 2001). This pollution can be caused by surface discharges or other types of discharges. Surface discharges can be caused by heavy storms or floods that cause storage lagoons to overfill, running off into nearby bodies of water. Pollutants can also travel over land or through surface drainage systems to nearby bodies of water, be discharged through manmade ditches or flushing systems found in CAFOs, or come into contact with surface water that passes directly through the farming area. Soil erosion can contribute to water pollution, as some pollutants can bond to eroded soil and travel to watersheds (EPA, 2001). Other types of discharges occur when pollutants travel to surface water through other mediums, such as groundwater or air.

Contamination in surface water can cause nitrates and other nutrients to build up. Ammonia is often found in surface waters surrounding CAFOs. Ammonia causes oxygen depletion from water, which itself can kill aquatic life. Ammonia also converts into nitrates, which can cause nutrient overloads in surface waters (EPA, 1998). Excessive nutrient concentrations, such as nitrogen or phosphorus, can lead to eutrophication and make water inhabitable to fish or indigenous aquatic life (Sierra Club Michigan Chapter, n.d.). Nutrient over-enrichment causes algal blooms, or a rapid increase of algae growth in an aquatic environment (Science Daily, n.d.). Algal blooms can cause a spiral of environmental problems to an aquatic system. Large groups of algae can block sunlight from underwater plant life, which are

habitats for much aquatic life. When algae growth increases in surface water, it can also dominate other resources and cause plants to die. The dead plants provide fuel for bacteria to grow and increased bacteria use more of the water's oxygen supply. Oxygen depletion once again causes indigenous aquatic life to die. Some algal blooms can contain toxic algae and other microorganisms, including *Pfiesteria*, which has caused large fish kills in North Carolina, Maryland, and the Chesapeake Bay area (Spellman & Whiting, 2007). Eutrophication can cause serious problems in surface waters and disrupt the ecological balance.

Water tests have also uncovered hormones in surface waters around CAFOs (Burkholder et al., 2007). Studies show that these hormones alter the reproductive habits of aquatic species living in these waters, including a significant decrease in the fertility of female fish. CAFO runoff can also lead to the presence of fecal bacteria or pathogens in surface water. One study showed that protozoa such as *Cryptosporidium parvum* and *Giardia* were found in over 80% of surface water sites tested (Spellman & Whiting, 2007). Fecal bacteria pollution in water from manure land application is also responsible for many beach closures and shellfish restrictions.

Air Quality

In addition to polluting ground and surface water, CAFOs also contribute to the reduction of air quality in areas surrounding industrial farms. Animal feeding operations produce several types of air emissions, including gaseous and particulate substances, and CAFOs produce even more emissions due to their size. The primary cause of gaseous emissions is the decomposition of animal manure, while particulate substances are caused by the movement of animals. The type, amount, and rate of emissions created depends on what state the manure is in (solid, slurry, or liquid), and how it is treated or contained after it is excreted. Sometimes manure is "stabilized" in anaerobic lagoons, which reduces volatile solids and controls odor before land application.

The most typical pollutants found in air surrounding CAFOs are ammonia, hydrogen sulfide, methane, and particulate matter, all of which have varying human health risks. Table 1 on page 6 provides information on these pollutants.

Most manure produced by CAFOs is applied to land eventually and this land application can result in air emissions (Merkel, 2002). The primary cause of emission through land application is the volatilization of ammonia when the manure is applied to land. However, nitrous oxide is also created when nitrogen that has been applied to land undergoes nitrification and denitrification. Emissions caused by land application occur in two phases: one immediately following land application and one that occurs later and over a longer period as substances in the soil break down. Land application is not the only way CAFOs can emit harmful air emissions—ventilation systems in CAFO buildings can also release dangerous contaminants. A study by Iowa State University, which was a result of a lawsuit settlement between the Sierra Club and Tyson Chicken, found that two chicken houses in western Kentucky emitted over 10 tons of ammonia in the year they were monitored (Burns et al., 2007).

Most studies that examine the health effects of CAFO air emissions focus on farm workers, however some have studied the effect on area schools and children. While all community members are at risk from lowered air quality, children take in 20-50% more air than adults, making them more susceptible to lung disease and health effects (Kleinman, 2000). Researchers in North Carolina found that the closer children live to a CAFO, the greater the risk of asthma symptoms (Barrett, 2006). Of the 226 schools that were included in the study, 26% stated that there were noticeable odors from CAFOs outdoors, while 8% stated

Table 1 Typical pollutants found in air surrounding CAFOs.

CAFO Emissions	Source	Traits	Health Risks
Ammonia	Formed when microbes decompose undigested organic nitrogen compounds in manure	Colorless, sharp pungent odor	Respiratory irritant, chemical burns to the respiratory tract, skin, and eyes, severe cough, chronic lung disease
Hydrogen Sulfide	Anaerobic bacterial decomposition of protein and other sulfur containing organic matter	Odor of rotten eggs	Inflammation of the moist membranes of eye and respiratory tract, olfactory neuron loss, death
Methane	Microbial degradation of organic matter under anaerobic conditions	Colorless, odorless, highly flammable	No health risks. Is a greenhouse gas and contributes to climate change.
Particulate Matter	Feed, bedding materials, dry manure, unpaved soil surfaces, animal dander, poultry feathers	Comprised of fecal matter, feed materials, pollen, bacteria, fungi, skin cells, silicates	Chronic bronchitis, chronic respiratory symptoms, declines in lung function, organic dust toxic syndrome

they experience odors from CAFOs inside the schools. Schools that were closer to CAFOs were often attended by students of lower socioeconomic status (Mirabelli, Wing, Marshall, & Wilcosky, 2006).

There is consistent evidence suggesting that factory farms increase asthma in neighboring communities, as indicated by children having higher rates of asthma (Sigurdarson & Kline, 2006; Mirabelli et al., 2006). CAFOs emit particulate matter and suspended dust, which is linked to asthma and bronchitis. Smaller particles can actually be absorbed by the body and can have systemic effects, including cardiac arrest. If people are exposed to particulate matter over a long time, it can lead to decreased lung function (Michigan Department of Environmental Quality [MDEQ] Toxics Steering Group [TSG], 2006). CAFOs also emit ammonia, which is rapidly absorbed by the upper airways in the body. This can cause severe coughing and mucous build-up, and if severe enough, scarring of the airways. Particulate matter may lead to more severe health consequences for those exposed by their occupation. Farm workers can develop acute and chronic bronchitis, chronic obstructive airways disease, and interstitial lung disease. Repeated exposure to CAFO emissions can increase the likelihood of respiratory diseases. Occupational asthma, acute and chronic bronchitis, and organic dust toxic syndrome can be as high as 30% in factory farm workers

(Horrigan, Lawrence, & Walker, 2002). Other health effects of CAFO air emissions can be headaches, respiratory problems, eye irritation, nausea, weakness, and chest tightness.

There is evidence that CAFOs affect the ambient air quality of a community. There are three laws that potentially govern CAFO air emissions—the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, also known as the Superfund Act), the Emergency Planning & Community Right to Know Act (EPCRA), and the Clean Air Act (CAA). However, the EPA passed a rule that exempts all CAFOs from reporting emissions under CERCLA. Only CAFOs that are classified as large are required to report any emission event of 100 pounds of ammonia or hydrogen sulfide or more during a 24-hour period locally or to the state under EPCRA (Michigan State University Extension, n.d.). The EPA has also instituted a voluntary Air Quality Compliance Agreement in which they will monitor some CAFO air emissions, and will not sue offenders but instead charge a small civil penalty. These changes have attracted criticism from environmental and community leaders who state that the EPA has yielded to influence from the livestock industry. The changes also leave ambiguity as to whether emission standards and air quality near CAFOs are being monitored.

Greenhouse Gas and Climate Change

Aside from the possibility of lowering air quality in the areas around them, CAFOs also emit greenhouse gases, and therefore contribute to climate change. Globally, livestock operations are responsible for approximately 18% of greenhouse gas production and over 7% of U.S. greenhouse gas emissions (Massey & Ulmer, 2008). While carbon dioxide is often considered the primary greenhouse gas of concern, manure emits methane and nitrous oxide which are 23 and 300 times more potent as greenhouse gases than carbon dioxide, respectively. The EPA attributes manure management as the fourth leading source of nitrous oxide emissions and the fifth leading source of methane emissions (EPA, 2009).

The type of manure storage system used contributes to the production of greenhouse gases. Many CAFOs store their excess manure in lagoons or pits, where they break down anaerobically (in the absence of oxygen), which exacerbates methane production. Manure that is applied to land or soil has more exposure to oxygen and therefore does not produce as much methane. Ruminant livestock, such as cows, sheep, or goats, also contribute to methane production through their digestive processes. These livestock have a special stomach called a rumen that allows them to digest tough grains or plants that would otherwise be unusable. It is during this process, called enteric fermentation, that methane is produced. The U.S. cattle industry is one of the primary methane producers. Livestock production and meat and dairy consumption has been increasing in the United States, so it can only be assumed that these greenhouse gas emissions will also rise and continue to contribute to climate change.

Odors

One of the most common complaints associated with CAFOs are the odors produced. The odors that CAFOs emit are a complex mixture of ammonia, hydrogen sulfide, and carbon dioxide, as well as volatile and semi-volatile organic compounds (Heederik et al., 2007). These odors are worse than smells formerly associated with smaller livestock farms. The anaerobic reaction that occurs when manure is stored in pits or lagoons for long amounts of time is the primary cause of the smells. Odors from waste are carried away from farm areas on dust and other air particles. Depending on things like weather conditions and farming techniques, CAFO odors can be smelled from as much as 5 or 6 miles away, although 3 miles is a more common distance (State Environmental Resource Center, 2004).

Because CAFOs typically produce malodors, many communities want to monitor emissions and odors. Quantifying odor from industrial farming can be challenging because it is a mixture of free and particle-bound compounds, which can make it hard to identify what specifically is causing the odor. Collecting data on specific gases, such as hydrogen sulfide, can be used as a proxy for odor levels.

CAFO odors can cause severe lifestyle changes for individuals in the surrounding communities and can alter many daily activities. When odors are severe, people may choose to keep their windows closed, even in high temperatures when there is no air conditioning. People also may choose to not let their children play outside and may even keep them home from school. Mental health deterioration and an increased sensitization to smells can also result from living in close proximity to odors from CAFOs. Odor can cause negative mood states, such as tension, depression, or anger, and possibly neurophysciatric abnormalities, such as impaired balance or memory. People who live close to factory farms can develop CAFO-related post traumatic stress disorder, including anxiety about declining quality of life (Donham et al., 2007).

Ten states use direct regulations to control odors emitted by CAFOs. They prohibit odor emissions greater than a set standard. States with direct regulations use scentometers, which measure how many times an odor has to be doused with clean air before the smell is undetectable. An additional 34 states have indirect methods to reduce CAFO odors. These include: setbacks, which specify how far CAFO structures have to be from other buildings; permits, which are the most typical way of regulating CAFOs; public comment or involvement periods; and operator or manure placement training.

Insect Vectors

CAFOs and their waste can be breeding grounds for insect vectors. Houseflies, stable flies, and mosquitoes are the most common insects associated with CAFOs. Houseflies breed in manure, while stable and other flies breed in decaying organic material, such as livestock bedding. Mosquitoes breed in standing water, and water on the edges of manure lagoons can cause mosquito infestations to rise. Flies can change from eggs to adults in only 10 days, which means that substances in which flies breed need to be cleaned up regularly.

Flies are typically considered only nuisances, although insects can agitate livestock and decrease animal health. The John Hopkins Bloomberg School of Public Health found evidence that houseflies near poultry operations may contribute to the dispersion of drug-resistant bacteria (Center for Livable Future, 2009). Since flies are attracted to and eat human food, there is a potential for spreading bacteria or pathogens to humans, including microbes that can cause dysentery and diarrhea (Bowman et al., 2000). Mosquitoes spread zoonotic diseases, such as West Nile virus, St. Louis encephalitis, and equine encephalitis.

Residences closest to the feeding operations experience a much higher fly population than average homes. To lower the rates of insects and any accompanying disease threats, standing water should we cleaned or emptied weekly, and manure or decaying organic matter should be removed twice weekly (Purdue Extension, 2007). For more specific insect vector information, please refer to NALBOH's vector guide (*Vector Control Strategies for Local Boards of Health*).

Pathogens

Pathogens are parasites, bacterium, or viruses that are capable of causing disease or infection in animals or humans. The major source of pathogens from CAFOs is in animal manure. There are over 150 pathogens in manure that could impact human health. Many of these pathogens are concerning because

they can cause severe diarrhea. Healthy people who are exposed to pathogens can generally recover quickly, but those who have weakened immune systems are at increased risk for severe illness or death. Those at higher risk include infants or young children, pregnant women, the elderly, and those who are immunosuppressed, HIV positive, or have had chemotherapy. This risk group now roughly compromises 20% of the U.S. population.

Table 2 Select pathogens found in animal manure.

Pathogen	Disease	Symptoms
Bacillus anthracis	Anthrax	Skin sores, headache, fever, chills, nausea, vomiting
Escherichia coli	Colibacilosis, Coliform mastitis-metris	Diarrhea, abdominal gas
Leptospira pomona	Leptospirosis	Abdominal pain, muscle pain, vomiting, fever
Listeria monocytogenes	Listerosis	Fever, fatigue, nausea, vomiting, diarrhea
Salmonella species	Salmonellosis	Abdominal pain, diarrhea, nausea, chills, fever, headache
Clostirdum tetani	Tetanus	Violent muscle spasms, lockjaw, difficulty breathing
Histoplasma capsulatum	Histoplasmosis	Fever, chills, muscle ache, cough rash, joint pain and stiffness
Microsporum and *Trichophyton*	Ringworm	Itching, rash
Giardia lamblia	Giardiasis	Diarrhea, abdominal pain, abdominal gas, nausea, vomiting, fever
Cryptosporidium species	Cryptosporidosis	Diarrhea, dehydration, weakness, abdominal cramping

Sources of infection from pathogens include fecal-oral transmission, inhalation, drinking water, or incidental water consumption during recreational water activities. The potential for transfer of pathogens among animals is higher in confinement, as there are more animals in a smaller amount of space. Healthy or asymptomatic animals may carry microbial agents that can infect humans, who can then spread that infection throughout a community, before the infection is discovered among animals.

When water is contaminated by pathogens, it can lead to widespread outbreaks of illness. Salmonellosis, cryptosporidiosis, and giardiasis can cause nausea, vomiting, fever, diarrhea, muscle pain, and death, among other symptoms. *E.coli* is another serious pathogen, and can be life-threatening for the young, elderly, and immunocompromised. It can cause bloody diarrhea and kidney failure. Since many CAFO use sub-therapeutic antibiotics with their animals, there is also the possibility that disease-resistant bacteria can emerge in areas surrounding CAFOs. Bacteria that cannot be treated by antibiotics can have very serious effects on human health, potentially even causing death (Pew Charitable Trusts, n.d.).

There is also the possibility of novel (or new) viruses developing. These viruses generate through mutation or recombinant events that can result in more efficient human-to-human transmission. There has been some speculation that the novel H1N1 virus outbreak in 2009 originated in swine CAFOs in Mexico. However, that claim has never been substantiated. CAFOs are not required to test for novel viruses, since they are not on the list of mandatory reportable illness to the World Organization for Animal Health.

Antibiotics

Antibiotics are commonly administered in animal feed in the United States. Antibiotics are included at low levels in animal feed to reduce the chance for infection and to eliminate the need for animals to expend energy fighting off bacteria, with the assumption that saved energy will be translated into growth. The main purposes of using non-therapeutic doses of antimicrobials in animal feed is so that animals will grow faster, produce more meat, and avoid illnesses. Supporters of antibiotic use say that it allows animals to digest their food more efficiently, get the most benefit from it, and grow into strong and healthy animals.

The trend of using antibiotics in feed has increased with the greater numbers of animals held in confinement. The more animals that are kept in close quarters, the more likely it is that infection or bacteria can spread among the animals. Seventy percent of all antibiotics and related drugs used in the U.S. each year are given to beef cattle, hogs, and chickens as feed additives. Nearly half of the antibiotics used are nearly identical to ones given to humans (Kaufman, 2000).

There is strong evidence that the use of antibiotics in animal feed is contributing to an increase in antibiotic-resistant microbes and causing antibiotics to be less effective for humans (Kaufman, 2000). Resistant strains of pathogenic bacteria in animals, which can be transferred to humans thought the handling or eating of meat, have increased recently. This is a serious threat to human health because fewer options exist to help people overcome disease when infected with antibiotic-resistant pathogens. The antibiotics often are not fully metabolized by animals, and can be present in their manure. If manure pollutes a water supply, antibiotics can also leech into groundwater or surface water.

Because of this concern for human health, there is a growing movement to eliminate the non-therapeutic use of antibiotics with animals. In 2001, the American Medical Association approved a resolution to ban all low-level use of antibiotics. The USDA has developed guidelines to limit low-level use, and some major meat buyers (such as McDonald's) have stopped using meat that was given antibiotics that are also used for humans. The World Health Organization is also widely opposed to the use of antibiotics, calling for a cease of their low-level use in 2003. Some U.S. legislators are seeking to ban the routine use of antibiotics with livestock, and there has been legislation proposed to solidify a ban. The Preservation of Antibiotics for Medical Treatment Act (PAMTA), which was introduced in 2009, has the support of over 350 health,

consumer, and environmental groups (H.R. 1549/S. 619). The act, if passed, would ban seven classes of antibiotics important to human health from being used in animals, and would restrict other antibiotics to therapeutic and some preventive uses.

Other Effects – Property Values

Most landowners fear that when CAFOs move into their community their property values will drop significantly. There is evidence that CAFOs do affect property values. The reasons for this are many: the fear of loss of amenities, the risk of air or water pollution, and the increased possibility of nuisances related to odors or insects. CAFOs are typically viewed as a negative externality that can't be solved or cured. There may be stigma that is attached to living by a CAFO.

The most certain fact regarding CAFOs and property values are that the closer a property is to a CAFO, the more likely it will be that the value of the property will drop. The exact impact of CAFOs fluctuates depending on location and local specifics. Studies have found differing results of rates of property value decrease. One study shows that property value declines can range from a decrease of 6.6% within a 3-mile radius of a CAFO to an 88% decrease within 1/10 of a mile from a CAFO (Dakota Rural Action, 2006). Another study found that property value decreases are negligible beyond 2 miles away from a CAFO (Purdue Extension, 2008). A third study found that negative effects are largest for properties that are downwind and closest to livestock (Herriges, Secchi, & Babcock, 2005). The size and type of the feeding operation can affect property value as well. Decreases in property values can also cause property tax rates to drop, which can place stress on local government budgets.

Considerations for Boards of Health

Right-to-Farm Laws

With all of the potential environmental and public health effects from CAFOs, community members and health officials often resort to taking legal action against these industrial animal farms. However, there are some protections for farms in place that can make lawsuits hard to navigate. Right-to-farm laws were created to address conflicts between farmers and non-farming neighbors. They seek to override common laws of nuisance, which forbid people to use their property in ways that are harmful to others, and protect farmers from unreasonable controls on farming.

All 50 states have some form of right-to-farm laws, but most only offer legal protections to farms if they meet certain specifications. Generally, they must be in compliance with all environmental regulations, be properly run, and be present in a region first before suburban developments, often a year before the plaintiff moves to that area. These right-to-farm laws were originally created in the late 1970s and early 1980s to protect family farms from suburban sprawl, at a time when large industrial farms were not the norm. As industrial farms grew in size and number, the agribusiness industry lobbied for and achieved the passage of stricter laws in the 1990s, many of which are now being challenged in court by homeowners and small family farmers. Opponents to these laws argue that they deprive them of their use of property and therefore violate the Fifth Amendment to the Constitution.

Some state courts have overturned their strict right-to-farm laws, such as Iowa, Michigan, Minnesota, and Kansas. Others such as Vermont have rewritten their laws. Vermont's updated right-to-farm bill

protects established farm practices as long as there is not a substantial adverse effect on health, safety, or welfare.

Boards of health need to be aware of what legal protection their state offers farms. Right-to-farm laws can hinder nuisance complaints brought about by community members. State laws can prevent local government or health officials from regulating industrial farms.

Board of Health Involvement with CAFOs

Boards of health are responsible for fulfilling the three public health core functions: assessment, policy development, and assurance. Boards of health can fulfill these functions through addressing problems stemming from CAFOs in their communities. Specific public health services that can tackled regarding CAFOs include monitoring health status, investigating health problems, developing policies, enforcing regulations, informing and educating people about CAFOs, and mobilizing community partnerships to spread awareness about environmental health issues related to CAFOs.

Assessment: Board of health members should ensure that there is an effective method in place for collecting and tracking public complaints about CAFOs and large animal farms. Since environmental health specialists at local health departments are often responsible for investigating complaints, the board of health must take measures to ensure that they are properly trained and educated about CAFOs. It is possible that the board of health may be responsible or choose to do some investigations itself. Schmalzried and Fallon (2008) advocate that local health districts adopt a proactive approach for addressing public concerns about CAFOs, stating that health districts can offer some services that may help ease public frustration with CAFOs. A fly trapping program can establish a baseline for the average number of flies present prior to the start-up of CAFOs or large animal farms, which can then establish if a fly nuisance exists in the area. Testing for water quality and quantity can provide evidence if CAFOs are suspected of affecting private water supplies. Boards of health can also monitor exposure incidences that occur in emergency rooms to determine if migrant or farm workers are developing any adverse health conditions as a result of their work environments. Establishing these programs benefit both members of the community and provide information to future animal farm operators, and local boards of health should recommend them if they've been receiving complaints about CAFOs.

Policy Development: Boards of health in many states can adopt health-based regulations about CAFOs, however, they may be met with some resistance. Humbolt County, Iowa, adopted four health-based ordinances concerning CAFOs that became models for regulations in other states, but the Iowa Supreme Court ruled the ordinances were irreconcilable with state laws. Boards of health that choose to regulate CAFOs can also be subject to pressure from outside forces, including possible lawsuits or withdrawal of funding. Boards of health should also consider working with other local officials to institute regulations on CAFOs, such as zoning ordinances.

Assurance: Boards of health can execute the assurance function by advocating for or educating about better environmental practices with CAFOs. Board members may receive complaints from the public about CAFOs, and boards can hold public meetings to receive complaints and hear public testimony about farms. If boards of health are not capable of regulating industrial farms in their communities, they can still try to collaborate with other local agencies that have jurisdiction. Board of health members can educate other local agencies and public officials about CAFOs and spread awareness about the environmental and health hazards. They can request a public hearing with the permitting agency of the

CAFO to express their concerns about the potential health effects. They can also work with agricultural and farm representatives to teach better environmental practices and pollution reduction techniques.

In many states, boards of health are empowered to adopt more stringent rules than the state law if it is necessary to protect public health. Board of health members should examine their state laws before they take any action regarding CAFOs to determine the most appropriate course of action. Any process should include an investigative period to gather evidence, public hearings, and a time for public review of draft policies.

Board of Health Case Studies

Tewksbury Board of Health, Massachusetts

Locals have complained about Krochmal Farms, a pig farm, for many years, but complaints have increased recently. The addition of a hog finishing facility to the farm coincided with the time that community member complaints grew. Most complaints are centered on the odor coming from the farm. The complaints were originally just logged when phone calls were received; however, the health department added a data tracking system as the number of complaints increased. After a complaint is received, the sanitarian or health director does a site visit to investigate.

The health director in Tewksbury filed an order of prohibition against the farm, which is allowed under Massachusetts law 111, section 143, for anything that threatens public health. The order of prohibition was appealed and the matter was taken to the board of health for a grievance hearing. The board of health hearing included months of testimony about the pig farm. The board of health is also doing a site assignment, which determines if a location is appropriate for treating, storing, or disposing of waste, including agricultural waste. The site assignment process includes both the Department of Environmental Protection (DEP) and the local board of health. The board of health holds a public hearing process, while the DEP reviews the site assignment application. The board of health grants the site assignment only if it is concurrently approved by the DEP.

The health director in Tewksbury points out that the only laws the board of health is able to regulate the farm under are nuisance laws. There have been efforts by the community to do a home rule petition to address the air quality and pest management complaints. The home rule petition is currently working its way through the Massachusetts state house. The status of the petition is unknown.

The board of health has tried to work directly with the pig farm to manage complaints. The farm contains manure composting facilities and the health district has requested advance notice to warn the community before manure is treated or applied to the soil. The farm has adopted a new manure management system. This system uses Rapp technology to control odors and reduce ammonia and hydrogen sulfide levels. However, questions still remain as to whether this addition will fully solve the odor issue. Typically, systems using Rapp technology include an oil cap that floats on manure holding pools and helps seal odors inside. These techniques have been researched and proven to reduce odors. However, the Tewksbury farm did not install the oil cap, and it is unknown whether the exclusion of the cap will hinder the technology's ability to reduce odors.

The complaints about the farm primarily concern the odor that emanates from the farm. The complaints do include mention of health side effects, including nausea and burning eyes. The health director has also heard concerns about potential environmental effects from the pig manure. Community members are

worried the manure runoff is entering and contaminating Sutton Brook, since there has been flooding in that area. There has been no confirmation of this occurring. The board of health is aware that the farm has a nutrient management plan, but they are not allowed to request and find out what is incorporated in that plan.

The Tewksbury piggery is technically not classified as a CAFO, though it is believed to be the largest pig farm in the commonwealth of Massachusetts. The area around it has become densely populated and the community members state that they just want to live peacefully with the farm. The board of health has submitted multiple grant applications to study the health effects associated with the farm. After the site assignment process is complete, the board of health will decide how it will regulate the farm. At the beginning of 2010, the board of health was still working on drafting regulations for the pig farms.

Wood County Board of Health, Ohio

Wood County, Ohio, contains two existing large dairy farms, both of which were proposed in 2001 to be expanded to over 1500 cows each. It is also the site for three other proposed dairy farms. There is a large community effort that supports restricting the operation and expansion of these farms, mainly represented by the community group Wood County Citizens Opposed to Factory Farms. The Wood County Board of Health became involved in investigating these dairy farms through this community group and other local officials. The Trustees of Liberty Township requested assistance from the Wood County Board of Health in supporting a moratorium on factory farm operations until local regulations were in effect. The trustees believed that manure runoff from the farms could contaminate local waterways, lower the ground water table, increase the presence of insect vectors, and devalue local properties.

The Wood County Health Director, in cooperation with the board of health, contacted nearby counties to determine what actions they had taken against farms in their communities. While the health director and board of health investigated action in the form of a nuisance regulation against the farms, they were advised that nuisance lawsuits filed against farms in Ohio were held to a tough standard, and they would be forced to demonstrate with scientific proof that the farms have a substantial adverse effect on health. They found that no other board of health in Ohio had opted to regulate farming operations and relied on the enforcement of existing state laws.

The board of health held a public forum to hear public opinion regarding the industrial farms. Ultimately, the Wood County Board of Health took actions other than regulations to help protect the health and environment of its community. They helped community members protect the safety of their water wells by offering free and low cost water well testing and inspections. They tested area ditch and water ways for fecal coliform bacteria, phosphorous, and nitrates to monitor the impact of farm runoff. They also purchased fly traps to monitor and count fly types to determine if the farms have caused an increase in insect vectors. Board of health members also met with state officials from the Ohio EPA in an effort to facilitate cooperation regarding the factory farms. While the Wood County Board of Health and Health Department chose not to institute any local regulations, they continue to monitor the situation and respond to community complaints.

Cerro Gordo County Board of Health, Iowa

Officials in Cerro Gordo County, Iowa, began looking into regulating animal feeding operations after the number of hog farms in Iowa started to grow. Floods in North Carolina and new regulations in Colorado meant that many hog farms began relocating to Iowa. Many citizens had concerns over the effects of

CAFOs, and the Iowa State Association of Counties wanted to review air quality issues. Officials in Cerro Gordo County originally began working on a regulation that required inspections and was based on public health concerns, since farms were already exempt from any regulations related to zoning. However, Iowa state senators soon introduced legislation that passed and prevented any animal feeding operations from being regulated from a public health angle as well.

As Iowans were now prevented from regulating animal feeding operations in terms of zoning or public health, officials in Cerro Gordo County decided to place a moratorium on the construction of new animal feeding operations in that county. They wanted to temporarily stop the growth of animal feeding operations until they could get better science about their effects. Cerro Gordo County Ordinance #40, the "Animal Confinement Moratorium Ordinance," went into effect on May 14, 2002. Since the moratorium did not address public health or zoning, officials were able to get around the rules and still have a way to temporarily control animal feeding operation growth in their county. The ordinance placed "a 1-year moratorium on any new construction, expansion, or activity occurring on land used for the production, care, feeding, or housing of animals." The ordinance also afforded "local public health officials adequate time to appropriately assess health and environmental concerns that may be related to confined animal feeding operations and concentration of animals; establish objective measurable standards of enforcement; exercise the Board of Health's responsibility to protect and improve the health of the public; refrain from impacting farm operators unfairly; and provide penalties for violations of the provisions hereof pursuant to Chapter 137, Code of Iowa" (Cerro Gordo County, 2002).

The moratorium was first adopted by the Cerro Gordo County Board of Health. It was then presented to the county board of supervisors by the health director on behalf of the board of health. Before the board of health adopted the moratorium, they held an investigative meeting in which representatives from the Iowa Farm Bureau and other industry spokespeople exchanged opinions on the issue of animal feeding operations. The moratorium was created through a collaboration between local and county officials—health department staff, the board of health, and the board of supervisors. The moratorium did not receive any help or backing from state officials, who were concerned about the political nature of the ordinance. However it did receive backing from a *Globe Gazette* editorial.

The moratorium was immediately met with resistance from state officials. The Cerro Gordo County Board of Supervisors was contacted by a local legislator, and the Iowa Farm Bureau stated they would challenge the county budget. The Iowa Farm Bureau threatened to take the county to court. There were concerns over the cost of a court trial, which was estimated to be as high as $60,000. The county attorney doubted the legality of the moratorium and ultimately recommended removing it. The moratorium was in effect until June of 2005, when it was repealed by the county board of supervisors.

Since the moratorium was repealed there have been a few hog farms built in Cerro Gordo County, but the decline in pork prices has prevented any large growth of hog farms. Health officials believe that if the county had not implemented the animal confinement moratorium, there would have been many more farms built in their county, since many hog farms were built in counties south of Cerro Gordo County. There is now a process for siting new animal confinement operations in Iowa that uses a Master Matrix scoring system. The Cerro Gordo County Board of Supervisors tracks the Master Matrix system, but so far no animal feeding operations in Iowa who have applied using this system have been denied the right to build.

Conclusion

Concentrated animal feeding operations or large industrial animal farms can cause a myriad of environmental and public health problems. While they can be maintained and operated properly, it is important to ensure that they are routinely monitored to avoid harm to the surrounding community. While states have differing abilities to regulate CAFOs, there are still actions that boards of health can and should take. These actions can be as complex as passing ordinances or regulations directed at CAFOs or can be simply increasing water and air quality testing in the areas surrounding CAFOs. Since CAFOs have such an impact locally, boards of health are an appropriate means for action. Boards of health should take an active role with CAFOs, including collaboration with other state and local agencies, to mitigate the impact that CAFOs or large industrial farms have on the public health of their communities.

Appendix A: Regulatory Definitions of Large CAFOs, Medium CAFOs, and Small CAFOs

Animal Sector	Size Thresholds (number of animals)		
	Large CAFOs	Medium CAFOs[1]	Small CAFOs[2]
Cattle or cow/calf pairs	1,000 or more	300-999	Less than 300
Mature dairy cattle	700 or more	200-699	Less than 200
Veal calves	1,000 or more	300-999	Less than 300
Swine (over 55 pounds)	2,500 or more	750-2,500	Less than 750
Swine (under 55 pounds)	10,000 or more	3,000-9,999	Less than 3,000
Horses	500 or more	150-499	Less than 150
Sheep or lambs	10,000 or more	3,000-9,999	Less than 3,000
Turkeys	55,000 or more	16,500-54,999	Less than 16,500
Laying hens or broilers[3]	30,000 or more	9,000-29,999	Less than 9,000
Chickens other than laying hens[4]	125,000 or more	37.500-124,999	Less than 37,500
Laying hens[4]	82,000 or more	25,000-81,999	Less than 25,000
Ducks[4]	30,000 or more	10,000-29,999	Less than 10,000
Ducks[3]	5,000 or more	1,500-4,999	Less than 1,500

Data: Environmental Protection Agency

1 Must also meet one of two "method of discharge" criteria to be defined as a CAFO or must be designated.

2 Never a CAFO by regulatory definition, but may be designated as a CAFO on a case-by-case basis.

3 Liquid manure handling system

4 Other than a liquid manure handling system

CH_4 AND N_2O EMISSIONS FROM LIVESTOCK MANURE

ACKNOWLEDGEMENTS

This paper was written by Paul Jun, Michael Gibbs, and Kathryn Gaffney (ICF Incorporated).

ABSTRACT

Livestock are produced throughout the world and are a significant contributor to global methane (CH_4) emissions. Methane, a greenhouse gas, is produced from the decomposition of livestock manure under anaerobic conditions. These conditions often occur when large numbers of animals are managed in a confined area (e.g., dairy farms, beef feedlots, and swine and poultry farms) where manure is typically stored in large piles or disposed of in lagoons. Nitrous oxide, also a greenhouse gas, is produced during the nitrification-denitrification of nitrogen contained in livestock waste.

The *Revised 1996 IPCC Guidelines for National Greenhouse Gas Inventories* (*IPCC Guidelines*) provide a general guide to estimating methane emissions from livestock manure. Two approaches may be used to estimate emissions: the Tier 1 approach relies on default emission factors drawn from previous studies, while the more complex Tier 2 approach requires country-specific information on livestock manure characteristics and manure management practices. The Tier 2 approach is recommended when the data used to develop the default values does not correspond well with the country's livestock and manure management conditions or when a country has large dairy and swine populations.

To prepare methane estimates, livestock population data characterized by subgroup are required. For Tier 1 estimates, necessary population data should be readily obtainable within the country or from the Food and Agricultural Organization (FAO). The Tier 2 estimates require additional data on manure characteristics and manure management practices, for which country-specific data should be used. These data should be obtained through data collection activities. If necessary, IPCC default values can be used for some of the factors in the Tier 2 calculation.

Nitrous oxide estimates also require livestock population and manure management practice data. The value and source of these data should correspond with that used for estimating methane emissions.

Reporting of emission estimates for both methane and nitrous oxide is clearly described in the *IPCC Guidelines.* With few exceptions, confidentiality is not expected to pose a challenge.

Ensuring the quality of the inventory will be an important activity, particularly where Tier 2 methods are used. The most important aspect of QA/QC (quality assurance/quality control) is thorough and transparent documentation of the emissions calculation steps, including all activity data and emission factor values.

1 INTRODUCTION

1.1 Nature, magnitude, and distribution of source

1.1.1 Overview

Methane Generation

The principal factors affecting methane emission from livestock manure are the amount of manure that is produced and the portion of the manure that decomposes anaerobically. The total amount of manure produced can be estimated using an average amount of manure produced per animal and the number of animals. The type of manure management system used and the climate (primarily temperature) are the primary factors that determine the extent of anaerobic decomposition that takes place.

Some livestock producers reduce the amount of methane that escapes into the atmosphere by constructing lids or caps for lagoons or tanks where manure is kept. This recovered methane is often flared or used as a fuel in a boiler, heater, or an engine-generator.

Nitrous Oxide Generation

Production of N_2O during storage and treatment of animal wastes can occur via combined nitrification-denitrification of nitrogen contained in the wastes. The amount of N_2O released depends on the system and duration of waste management. Because N_2O production requires an initial aerobic reaction and then an anaerobic process, it is theorized that dry, aerobic management systems may provide an environment more conducive for N_2O production.

1.1.2 Process description

Methane

Livestock manure is primarily composed of organic material and water. Under anaerobic conditions, the organic material is decomposed by anaerobic and facultative bacteria. The end products of anaerobic decomposition are methane, carbon dioxide, and stabilized organic material. The methane production potential of manure depends on the specific composition of the manure, which in turn depends on the composition and digestibility of the animal diet.

The amount of methane produced during decomposition is influenced by the climate and the manner in which the manure is managed. The management system determines key factors that affect methane production, including contact with oxygen, water content, pH levels, and nutrient availability. Climate factors include temperature and rainfall. Optimal conditions for methane production include an anaerobic, water-based environment, a high level of nutrients for bacterial growth, a neutral pH (close to 7.0), and warm temperatures.

The key factors affecting methane production from livestock manure are the quantity of manure produced, manure characteristics, the manure management system, and climate.

Quantity of Manure Production

Manure production varies by animal type and is proportional to the animal's weight and feed intake.

Manure Characteristics

The portion of manure that can generate methane is the volatile solids portion (VS)[1]. The VS portion depends on livestock type and diet, which also affect the quantity of methane that can be produced per kilogram of volatile solids (VS) in the manure.

Manure Management System

Methane production depends on the type of manure management system, which can be broadly divided into "liquid" and "dry" systems. Dry systems include solid storage, dry feedlots, deep pit stacks, and daily spreading of the manure. In addition, unmanaged manure from animals grazing on pasture falls into this category. Liquid

[1] Volatile solids (VS) are the organic fraction of total solids in manure that will oxidize and be driven off as gas at a temperature of 600°C.

management systems often use water to facilitate manure handling. These systems include tanks and lagoons which store manure until it is applied to cropland. Liquid systems create the ideal anaerobic environment for methane production. Detailed descriptions of these systems are provided in Table 10 in Annex 2.

Climate

Manure decomposes more rapidly when the climate encourages bacterial growth. For liquid manure systems, warm temperatures increase methane generation. For solid systems, rainfall can affect methane production, with wet climates having higher emissions than arid climates. In either case, emissions from solid systems tend to be very low.

Nitrous Oxide

Nitrous oxide is produced from the combined nitrification-denitrification process that occurs on the nitrogen in manure. The majority of nitrogen in manure is in ammonia (NH_3) form. Nitrification occurs aerobically and converts this ammonia into nitrate, while denitrification occurs anaerobically, and converts the nitrate to N_2O. Temperature, pH, biochemical oxygen demand (BOD), and nitrogen concentration affect N_2O generation. BOD is the amount of dissolved oxygen used by aerobic microorganisms to completely consume the available organic matter.

Increasing aeration initiates the nitrification-denitrification reactions, and hence makes release of N_2O possible. Therefore, as fresh dung and slurry is highly anoxic and well-buffered with near neutral pH, N_2O production is expected to increase with increasing aeration. However, the denitrification process that produces N_2O requires an anaerobic environment. Currently, there is not enough quantitative data to derive a relationship between the degree of aeration and N_2O emissions. This makes N_2O emissions estimates from this source highly uncertain.

2 METHODOLOGICAL ISSUES

2.1 Selection of good practice methods

The *IPCC Guidelines* provides a general approach to estimate methane emissions from livestock. The three main steps used to estimate methane emissions from livestock manure are as follows: a) collect activity data for livestock population groups and subgroups; b) estimate emissions factors for each subgroup or use default emission factors; and c) multiply the emission factor by the population to obtain total methane emission estimate for the population. The total emissions estimates should be reported in gigagrams (Gg). Because the emission factors are reported in kilograms per head per year, the total emissions in Gg is estimated as follows:

Emission Factor (kg/head/yr) • Population (head) / (10^6 kg/Gg) = Emissions Gg/yr.

To execute this process in the most efficient manner, the *IPCC Guidelines* recommends two approaches to estimate methane emissions from livestock manure.

The **Tier 1** approach is simplified so that only readily available animal population data are needed to estimate emissions. Default emission factors are presented for each of the recommended population subgroups.

The **Tier2** approach provides a more detailed method for estimating methane emissions from manure management systems. This approach is recommended for countries with large livestock populations managed under confined conditions because the Tier 1 method will not accurately account for the higher level of emissions that are generally produced in confined facilities. This method requires detailed information on animal characteristics and the manner in which manure is managed. Using this additional information, emission factors specific to the conditions of the country are estimated and the default emission factors from Tier 1 are not used.

Countries are encouraged to carry out emissions inventory calculations at a finer level of detail beyond Tier 2 if possible. This can include conducting regional analyses of emissions to account for differences in livestock and manure characteristics, climate, and manure management practices across specified regions.

For N_2O, the *IPCC Guidelines* recommends an approach similar to the Tier 2 methane approach. Information on how manure is managed is used to identify default emission factors. These are used with nitrogen excretion estimates for each livestock group based on animal population data to estimate N_2O emissions.

N_2O emissions from all waste management systems are reported under this emissions source category with three exceptions:

- Manure that is applied to agricultural soils (e.g., daily spread);
- Manure deposited by grazing animals on fields (pasture range and paddock), and

- Manure used for fuel.

N_2O emissions from manure that is managed in these systems are instead accounted for in the methodology for estimating direct emissions from agricultural soils, direct soil emissions of N_2O from animal production, and manure used as fuel, respectively. The class "used for fuel" is not included here as a source of N_2O because it is considered an energy-related emission. Currently, this class incorrectly includes manure managed in anaerobic digesters.

2.2 Emissions factors

Methane

Emission factors are estimates of methane produced in kilograms per animal. Emission factors help to standardize emissions across many different livestock groups so that relatively correct total emission estimates can be made.

Tier 1 In this step, emission factors that are most appropriate for the country's livestock characteristics are selected. The *IPCC Guidelines* include default emission factors, which have been drawn from previous studies and are organized by region (Tables 4.5 and 4.6 from the *IPCC Guidelines* are included in Annex 1).

The Tier 1 emission factors incorporate assumptions about manure composition, climate, and manure system usage for developed and developing countries, as described in the Tier 2 discussion below.

The climate data collected as part of the activity data is used to select the appropriate emission factors. If a country manages livestock in more than one climate zone, a weighted average emission factor for each animal type should be computed by multiplying the percentages of the animal populations in each climate region by the emission factor for each climate region.

Weighted Emission Factor = Percentage of Animal Population in Climate • Climate Emission Factor

Tier 2 The Tier 2 emission factors are calculated based on country-specific data on manure composition, manure methane producing capacity, climate, and waste system usage. The major components of the emission factor calculation are as follows:

- *Volatile Solids (VS)* is the portion of the manure that produces methane. Often, data on average daily VS excretion are not available. Therefore, the VS values may need to be estimated from feed intake levels and characteristics. Feed intake data for cattle should be determined by selecting a representative animal from each animal type. The IPCC's suggested methodology for estimating VS using feed data is shown in Annex 2, which reprints Equation 15 from the *IPCC Guidelines.*
- *Methane Producing Potential (B_O)* is the maximum amount of methane that can be produced from a given quantity of manure. The methane producing potential varies by animal type and diet. The *IPCC Guidelines* provide default values for each major global region. The values determined for US livestock are used for all of the developed country regions, and a slightly modified value is used for some categories in the developing country regions. Using country-specific B_O factors based on recent measurement data or research should improve the reliability of the resulting emissions factor.
- *Methane Conversion Factor (MCF)* defines the portion of the methane producing potential (B_O) that is achieved. The MCF varies with the manner in which the manure is managed and the climate, and can theoretically range from 0 to 100 percent. Manure managed as a liquid under warm conditions has a high MCF of 65 to 90 percent. Manure managed as dry material in cold climates has a low MCF at 1 percent. Default MCFs by manure system have been developed from previous studies; the IPCC's recommended MCF's are shown in Annex 2, in Table 11, which was taken from the *IPCC Guidelines.* Incorporating additional research on methane production under various management scenarios may improve the accuracy of these factors.
- *Fraction of Manure in Management System (MS%)* describes the portion of each livestock group's manure that is handled by a specific manure management technique. This factor is collected as activity data, discussed in Section 2.3.

These four variables are used in the equation to calculate emission factors as follows:

EQUATION 1

$$EF_i = VS_i \bullet 365 \text{ days/yr} \bullet B_{oi} \bullet 0.67 \text{ kg/m}^3 \bullet \sum_{jk} MCF_{jk} \bullet MS\%_{ijk}$$

Where:

EF_i: annual emission factor (kg) for animal type i (e.g., dairy cows);

VS_i: daily VS excreted (kg) for animal type i;

B_{oi}: maximum methane producing capacity (m^3/kg of VS) for manure produced by animal type i;

MCF_{jk}: methane conversion factors for each manure management system j by climate region k; and

$MS\%_{ijk}$: fraction of animal type i's manure handled using manure system j in climate region k.

Nitrous Oxide

Nitrous oxide emission factors are estimates of kilogram of nitrous oxide nitrogen produced per kilogram of nitrogen excreted. These factors vary by waste management system, as shown in Table 1

TABLE 1

TENTATIVE DEFAULT VALUES FOR N_2O EMISSION FACTORS FROM ANIMAL WASTE PER ANIMAL WASTE MANAGEMENT SYSTEM (KG N_2O - N/KG NITROGEN EXCRETED)

Animal Waste Management System	Emission Factor EF
Anaerobic lagoons	0.001 (<0.002)
Liquid systems	0.001 (<0.001)
Daily spread[a]	0.0 (no range)
Solid storage and drylot[a]	0.02 (0.005-0.03)
Pasture range and paddock (grazing)[b]	0.02 (0.005-0.03)
Used as fuel[c]	Not Applicable
Other systems[b]	0.005

[a] Considered to be a part of direct soil emissions from agricultural fields after spreading.

[b] Considered to be a part of direct soil emissions from animal production.

[c] Considered to be a part of emissions from energy.

Source: IPCC, 1996.

2.3 Activity data

Activity data include data on livestock population, and manure management system usage. The Tier 1 methodology for methane emissions requires data on livestock population by livestock group. Both the Tier 2 methodology for methane and the nitrous oxide methodology require livestock population data and data on manure system usage.

Methane

Tier 1: The *IPCC Guidelines* recommend collecting the average annual population of livestock listed in Table 2. It is recommended that countries collect their own population data. The number of animals recorded depends on the time at which the census is taken. For example, a census taken before most calves are born yields a lower number of animals than a census taken after most calves are born. Data should represent an average estimate for the entire year. If population data cannot be collected, it can be obtained from an outside source such as the Food and Agriculture Organization (FAO) or similar country-specific livestock census reports.

TABLE 2 DOMESTIC LIVESTOCK INCLUDED IN THE TIER 1 METHODOLOGY
Livestock
Dairy Cattle
Non-Dairy Cattle
Buffalo
Sheep
Goats
Camels
Horses
Mules and Asses
Swine
Poultry

As shown in Table 2, IPCC recommends recording data on dairy cattle separate from other cattle. Dairy cattle are defined as mature cows producing milk in commercial quantities for human consumption, and are managed differently from non-dairy cattle. This generally results in differences in composition and methane production potential between dairy and non-dairy cattle manure. Additionally, dairy cattle manure is often managed differently from cattle manure.

In some countries, there are two types of dairy cows: high-producing, “improved” breeds in commercial operations and low-producing breeds managed with traditional methods. If possible, countries can separate the dairy cow population into two groups. The dairy cow group does not include cows used mainly for producing calves or for draft power. These cows are accounted for in non-dairy cattle data.

In addition, livestock populations must be described in terms of warm or cool temperature climates for purposes of estimating livestock manure emissions. Data on the annual average temperature of the regions where livestock are managed should be used as follows:

- Areas with annual average temperatures less than 15° C are defined as cool;
- Areas with annual average temperatures from 15° C to 25° C inclusive are defined as temperate, and
- Areas with annual average temperatures greater than 25° C are defined as warm.

The fraction of each livestock population should be estimated for each climate. This data can be developed from country-specific climate maps and livestock census reports. To the extent possible, the temperature data should reflect the locations where the livestock are managed.

Tier 2: In addition to the livestock population data described for Tier 1, the Tier 2 approach also requires data on the percentage of manure managed with each management system. Data should be collected for each management system. Table 12 in Annex 2 summarizes the main types of manure management systems, which can be broadly divided into "wet" and "dry" systems. If specific management system data does not exist, there should be at least a division of manure production into wet and dry systems. The IPCC provides default manure management practice data for major regions based on Safley, et al. (1992). If country-specific data exists or can be collected, it should be used. Additionally, if the current data predates known changes in manure management practices, they should be updated to reflect the current practices.

Nitrous Oxide

In addition to livestock population and manure management system data (described above), the nitrous oxide emissions estimation approach also requires nitrogen excretion data by animal type. It is recommended that country-specific data be collected and used. This may require manure composition analysis, which should be coordinated with any research to determine volatile solids content. If this is not feasible, regional default values can be used. These are provided in Table 3.

TABLE 3

TENTATIVE DEFAULT VALUES FOR NITROGEN EXCRETION PER HEAD OF ANIMAL PER REGION (KG/ANIMAL/YR)

Region	Type of Animal					
	Non-Dairy Cattle	Dairy Cattle	Poultry	Sheep	Swine	Other Animals
North America	70	100	0.6	16	20	25
Western Europe	70	100	0.6	20	20	25
Eastern Europe	50	70	0.6	16	20	25
Oceania	60	80	0.6	20	16	25
Latin America	40	70	0.6	12	16	40
Africa	40	60	0.6	12	16	40

Asia & Far East	40	60	0.6	12	16	40

Source: IPCC, 1996.

2.4 Uncertainty

Parallel to the IPCC sector-specific meetings on good practice guidance, the IPCC is completing a programme of work on emissions inventory uncertainty. This work will result in recommendations to the United Nations Framework Convention on Climate Change (UNFCCC) on approaches to assessing and managing uncertainty. During the IPCC Inventory Experts Group Meeting in Paris (October 1998), technical experts in the uncertainty programme came up with a series of questions to be answered in the sector meetings. Specifically, the sector meetings should provide answers to these questions in the individual source context. The questions are listed in the general background paper.

Methane

Tier 1: Given that the emissions factors for Tier 1 are not based on country-specific data, they do not represent accurately the manure management system characteristics for any given country. The emissions factors are highly uncertain as a result. Emission factors should be updated for regions that have experienced significant changes in manure management practices.

Tier 2: One source of uncertainty in the Tier 2 emissions factors is the manure system usage data. The level of confidence in this data depends on the methods used to collect the data for each country. Additionally, there is uncertainty in the MCFs used to estimate the portion of the methane production potential that is realized in each manure management system. Conditions can vary significantly, particularly in liquid systems. The default MCFs may not account for all of the variability in methane production that can exist within systems. A secondary source of uncertainty lies in the equations used to calculate the emissions factor (presented in Annex 2). Generally, uncertainty in the equations is low compared to the uncertainty in the manure system usage data. Consequently, efforts undertaken to reduce uncertainty should focus first on improving this data.

Nitrous Oxide

In addition to the uncertainty in the manure system usage data, there is also uncertainty in the nitrogen excretion data. Similar to manure system usage, the level of uncertainty in nitrogen excretion data depends on the methods used to collect the data. As discussed before, there is also a high level of uncertainty in the emission factors that arises from a lack of data on N_2O production from manure.

2.5 Completeness

Given that the different livestock species are distinct and population data are generally available, each country is expected to create a complete inventory comprised of emissions estimates for each required livestock species. If population data are unavailable, countries can use data collected by FAO (FAO, 1999).

2.6 Other important issues

2.6.1 Baseline

An emission baseline is an important component of an inventory programme. Below is a description of issues related to creating a baseline for the methane and nitrous oxide methods recommended by the IPCC.

Methane

Tier 1: Developing a baseline for Tier 1 requires collecting and compiling animal population data during the baseline period. For the Tier 1 methodology, difficulties arise when

- Animal population data are not available for the baseline period;
- Animal population data during the baseline period are not broken down into the animal groups recommended by IPCC, and
- Changes in manure management practices over time affect methane emissions.

Approaches to overcoming these difficulties include collecting aggregate historical data from FAO and using current data to break out historical population data into the animal groups. If changes in manure management practices affect methane emissions significantly, the Tier 1 method is unreliable, and the Tier 2 method should be used.

Tier 2: Developing a baseline for Tier 2 requires the collection and compilation of manure management system usage data during or following the baseline period. In addition to the issues related to animal population data described for Tier 1, difficulties arise in the Tier 2 methodology when:

- Manure management system data are not available for the baseline period;
- Manure management system data during the baseline period are not broken down into the systems recommended by IPCC, and
- The Tier 2 methodology was not used throughout the baseline period.

Approaches to overcoming a lack of substantial management system data include applying a sample area or region's manure management practice trends to the entire country. If emission estimation methodologies have changed, historical data that are required by the current methodology should be collected and used to re-estimate emissions for that period. If these data do not exist, it may be appropriate to create a trend with recent data and use the trend to back-estimate management practices for the baseline period. Among other sources, publications, industry and university experts can be used to estimate trends for the livestock and feed characteristics.

Nitrous Oxide

The issues related to animal population and manure management practices described for methane also apply to emissions from nitrous oxide.

2.6.2 Accurate detection of mitigation measures

Efforts to reduce methane emissions through improved productivity, and thus declining livestock populations, would be reflected in the livestock population data. This decline would directly affect manure and volatile solids production, as well as nitrogen production. All other factors kept constant, decreases in volatile solids and nitrogen production would reduce methane and nitrous oxide emissions.

Shifts in manure management practices towards dry systems would have a similar affect on methane emissions. On a weight basis, manure in dry systems produces significantly less methane than liquid systems. Even with increased manure production, shifts toward dry systems could decrease methane emissions dramatically. Based on default emission factors, such shifts would presumably have an opposite effect on nitrous oxide emissions. However, the high uncertainty associated with these factors may diminish any effects of such changes.

The current methodology accounts for manure handled in anaerobic digesters. The IPCC default MCF for these digesters is 5-15%, which is much lower than the MCF values for anaerobic lagoons (90%) and liquid/slurry systems (10-65%). Thus, increased handling of manure in such systems could significantly decrease methane emissions.

2.6.3 Consistency with inventory for livestock digestive systems

The livestock characterization used to estimate methane and nitrous oxide emissions from livestock manure should be consistent with the characterization used for methane emissions from livestock digestive systems. If there are conflicts or inconsistencies, these should be resolved as soon as possible.

3 REPORTING AND DOCUMENTATION

A recent report from the UNFCCC Secretariat "Methodological Issues Identified While Processing Second National Communications" (UNFCCC/SBSTA/1998/7) noted that almost all countries reported methane emissions from manure, and all countries, with the exception of two countries, reported emissions from manure separately from enteric fermentation emissions. Specifically, Belgium included emissions from manure with emissions from enteric fermentation and Estonia reported methane emissions from all agriculture rather than separating each agricultural source (Estonia, 1998).

In reporting emissions, countries should include all activity data, and document the source of the data. Countries using the methane Tier 2 approach should also explicitly show the emission factor calculation method. This includes the calculation method and steps to determine the respective emission factors that are weighted and aggregated across manure management systems to produce a single factor for each livestock category.

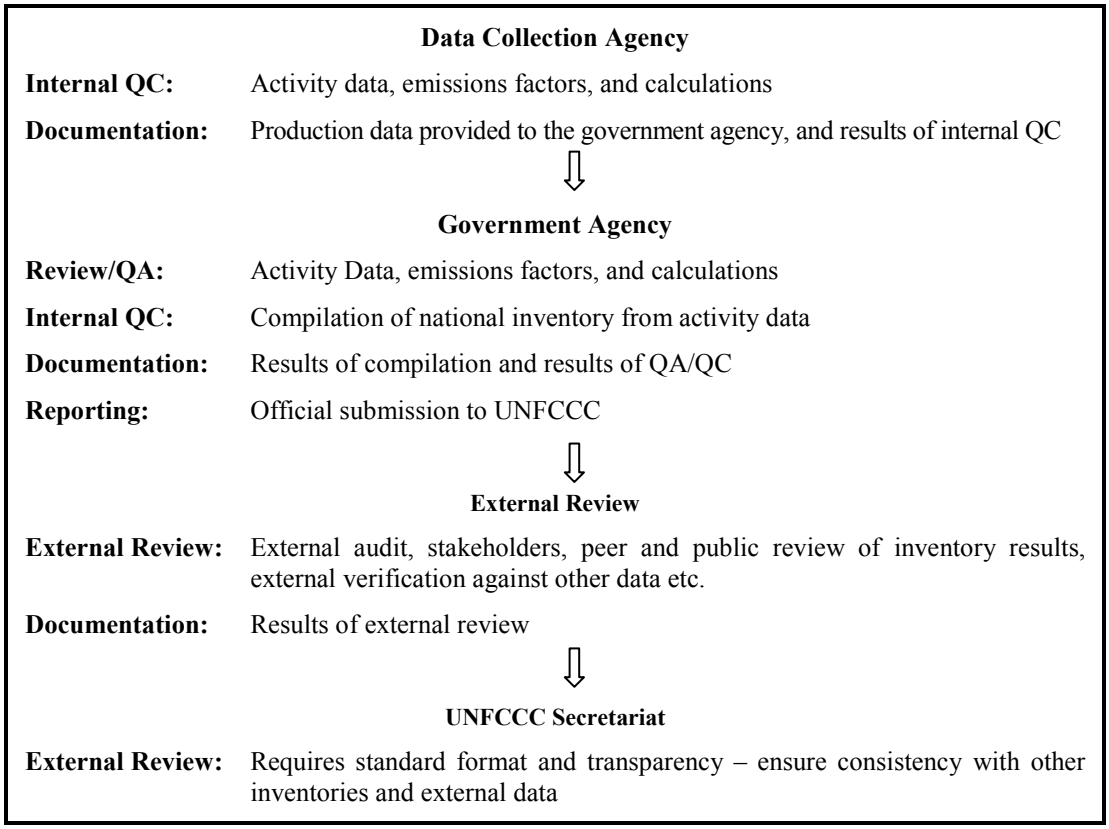
3.1 Current IPCC reporting guidelines

The *IPCC Guidelines* are used to guide countries in the preparation and submissions of annual greenhouse gas emissions inventories to the UNFCCC Secretariat. The Guidelines establish:

- Standard tables, definitions, units, and time intervals for reporting all types of emissions;
- Necessary documentation to enable comparison of national inventories, including worksheets, major assumptions, methodological descriptions, and enough data to allow a third party to reconstruct the inventory from national activity data and assumptions, and
- An uncertainty assessment.

Both methane and nitrous oxide emissions from livestock manure are reported in Table 4, Volume 2 of the *IPCC Guidelines* - Sectoral Report for Agriculture. This table requires recording emissions from each livestock source, and also across the major manure management systems.

3.2 Confidential business information



In isolated cases, reporting population data and information on management practices may be a problem in regions with a small number of large, commercial operations. Confidentiality is not expected to be a significant issue for this source.

4 INVENTORY QUALITY

4.1 Introduction

Inventory quality assurance and quality control (QA/QC) is a process integral to the development of a credible inventory. A well-developed and well-implemented quality assurance programme fosters confidence in the final inventory results regardless of the purpose and goal of the inventory. A successful quality assurance programme requires internal quality control procedures and an unbiased, external review and audit. The internal QC activities are designed to ensure accuracy, documentation, and transparency. The external review process is designed to minimize errors that occur in the preparation of emissions inventories, and reduce or eliminate potential inherent bias. Figure 1 outlines the flow of information and processes followed at each step.

Figure 1 Inventory QA/QC Process

4.2 Internal inventory QA/QC systems

4.2.1 Emissions factors

Emissions Factors QC

Methane

Tier 1: The emissions factors are based on default data. QC procedures include reviewing the available default values and documenting the rationale for selecting specific values. Other QC procedures are not required.

Tier 2: QC procedures for the Tier 2 emissions factors involve checking the equations and calculations used to calculate the emissions factor. The Tier 2 emissions factors are based on country-specific information on animal and feed characteristics. QC procedures on these data are described below in the Activity Data section.

Nitrous Oxide

The emissions factors are based on default data. QC procedures include reviewing the available default values and documenting the rationale for selecting specific values. Other QC procedures are not required.

Emissions Factors Documentation

Documentation is a crucial component of the review process because it enables reviewers to identify mistakes and suggest improvements. Among other elements, a detailed description of the equations used to estimate emissions factors is needed. In addition, a standardized reporting form is recommended to provide transparent information on the steps taken to calculate the emissions factors. Each step should contain the numbers used in each calculation, including the source of any data collected.

4.2.2 Activity data

Activity Data QC

Tier 1 and Tier 2 ***Livestock Population Data:*** The annual livestock population data are generally collected by a country's ministry of agriculture or a similar organization focused on the agriculture sector. The personnel that

collect data are responsible for reviewing the data collection methods, checking the data to ensure they were collected and aggregated correctly, and cross-checking the data with previous years to ensure the data are reasonable. The basis for the estimates, whether statistical surveys or "desk estimates," must be reviewed and described as part of the QC effort.

Tier 2 ***Manure Management Practices Data:*** There are generally two approaches to collecting manure management system usage data: a) a government agency or related body collects the data by surveying farms; or b) the agency or related body interviews industry and university experts. The QC activities for the two approaches are described below:

- *Farm Survey*: Government agencies, such as the ministry of agriculture or a related body, collect the animal and feed characteristics data required for the inventory. The personnel collecting the data are responsible for reviewing the collection methods, checking to ensure the data were collected and aggregated correctly, and comparing data with data from previous years to ensure the data are reasonable.
- *Industry and University Experts*: Manure system usage data may be obtained by surveying and interviewing industry and university experts. The personnel collecting the data are responsible for reviewing surveys used to collect the data to make sure the survey is appropriate for the data needs. Questions used in interviews should also be reviewed.

Activity Data Documentation

Documentation is a crucial component of the review process, because it enables reviewers to identify mistakes and suggest improvements. Among other information, the following is needed for the reviewing/auditing agency:

- A highly detailed description of the methods used to collect the activity data, and
- A discussion of potential areas of bias in the data, including a discussion of whether the manure management practices are representative of the country.

4.2.3 Inventory agency level activities

Inventory Agency Review of Activity Data QA

Before accepting the activity data, the inventory agency should assess them, including all data on the animal population and manure management practices. This review involves close cooperation with the personnel responsible for collecting, compiling, and analyzing the data. The assessment should include a review of the detailed methods used to collect the data, including a review of any surveys and interviews performed to collect the data. In addition, the assessment should include a comparison of the activity data with historical data, a discussion of the potential for bias, and recommendations for improvement.

Inventory Agency QC on Compiling National Emissions

In addition to a thorough quality assessment of data discussed above, the inventory agency should ensure that the process of aggregating data to develop the national inventory undergoes quality control. This should include, among other things:

- Cross-referencing the aggregated population data with the national totals;
- Back-calculating national and regional emissions factors from the Tier 2 management system usage data (if using Tier 2);
- Ensuring that the manure management practices are representative of the country (if using Tier 2);
- Ensuring that all farms are included in the population data, and
- Comparing with national trends to look for anomalies.

Inventory Agency Documentation on Compiling National Emissions

For the CH_4 emission inventory for enteric fermentation, a QA/QC management plan should address the specific items needed to perform audits and reviews. Examples of the types of information needed for documentation and external audit include:

- A detailed description of the inventory methodology;
- Identification of the input parameters that are needed and how the input parameters are obtained, and
- Frequency of data collection and estimation and results of determinations of accuracy and precision.

4.3 External inventory QA/QC systems

External QA activities include a planned system of review and audit procedures conducted by personnel not actively involved in the inventory development process. The key concept is an independent, objective review to assess the effectiveness of the internal QC programme, the quality of the inventory, and to reduce or eliminate any inherent bias in the inventory processes. Several types of external reviews, or audits, may be appropriate for the inventory of CH_4 and N_2O emissions from livestock manure.

- **Third party audit by an accredited organization, expert, independent third party:** An audit of the documentation and calculations ensures that each number is traceable to its origin.
- **Expert (peer) review:** Although a detailed peer review would be appropriate when a procedure for determining CH_4 emissions is first adopted or revised; it would not be needed on an annual basis. Such a review is designed to ensure that the methodology is rigorous, accurate, and that the data and assumptions reflect the best available information.
- **Stakeholder review:** Review by industrial organizations and government can provide a forum for review of the methods used.
- **Public review:** Some countries make their entire inventory available for public review and comment. This process may result in a range of comments and issues broader than those from other review processes.

Confidential Business Information Issues

Confidentiality is not a major issue when private parties review the data. However, in areas with several large, commercial producers, there may be opposition to releasing the activity data to the public.

5 UPDATES TO ESTIMATION METHODS

At the IPCC workshop on Good Practices in Inventory Methods held in the Netherlands on February 24-26, 1999, participants recommended updates to the Tier 2 method used to estimate methane emissions from livestock manure. These updates included the following:

- Modifications to the maximum methane producing capacity of cattle, poultry, and swine based on recent research;
- New MCF values for liquid/slurry and pit storage manure management systems;
- Revised definitions for several management systems, and
- The addition of new manure management systems into the IPCC list of systems.

Recent work by Zeeman and Gerbens (1999) showed that B_o values for swine manure may be lower than the IPCC default value. The latter would suggest an unrealistic high biodegradability of 92% (Zeeman and Gerbens, 1999), in contradiction to the observed biodegradability of 70% (Zeeman, 1994). Therefore it is proposed that the estimated B_o (Zeeman and Gerbens, 1999) values should be used as the default values in the *IPCC Guidelines*. A comparison of these values is shown in Table 4.

TABLE 4

RANGE IN B_O VALUES REPORTED BY SAFLEY ET AL.(1992) AND ESTIMATED B_O VALUES FOR DEVELOPED AND DEVELOPING COUNTRIES (ZEEMAN AND GERBENS,1999) IN COMPARISON TO IPCC DEFAULT VALUES (M^3 CH_4/KG VS)

	IPCC (1996) Developed Countries	IPCC (1996) Developing Countries	Safley et al. (1992)	Zeeman and Gerbens (1999) Developed	Zeeman and Gerbens (1999) Developing
	Default	Default	range	estimated	estimated
Non-dairy	0.17	0.10	0.17-0.33		
Dairy	0.24	0.13	0.10-0.24	0.25	0.14[1]
Poultry	0.32	0.24	0.24-0.39		
Swine	0.45	0.29	0.32-0.52	0.34	0.22[1]

Estimated B_o values for developing countries (Zeeman and Gerbens, 1999) are proportionally lower and similar to the IPCC estimate for B_o values for developinged regions.

The participants also proposed using revised MCF values based on values observed by Zeeman(1994) shown in Table 5.

TABLE 5

COMPARISON BETWEEN IPCC DEFAULT MCF VALUES AND PROPOSED MCF VALUES

Manure management Strategy	Climatic condition	MCF (%) (IPCC, 1995)	MCF (%) (Zeeman and Gerbens, 1999)
Liquid/slurry	Cool	10	39
	Temperate	35	45
	Warm	65	72
Pit < 1 month	Cool	5	0
	Temperate warm	18 33	0 30
Pit > 1 month	Cool	10	39
	Temperate	35	45
	Warm	65	72

In addition, it was recommended that digesters and anaerobic lagoons be subdivided to account for recovery, flaring and use of the biogas including the gas produced/emitted during manure storage after digestion. The proposed revisions to the manure management system definitions and MCF values are shown in Table 6. The proposed additional management systems are shown in Table 7.

TABLE 6

MANURE MANAGEMENT SYSTEMS (BLANK MEANS NO CHANGE FROM CURRENT IPCC DEFINITIONS/MCFS)

System	Definition	MCFs by Climate			Comments
		Cool	Temperate	Warm	
Pasture/Range/ Paddock					
DailySpread	Dung and urine is collected by some means such as scraping. The collected waste is applied to fields.				
Solid Storage	Dung and urine are excreted in a stall. The solids (with or without litter) are collected and stored in bulk for a long time (months) before disposal, with or without liquid runoff into a pit system.				
Drylot					
Liquid/Slurry	Dung and urine are collected and transported in liquid state to tanks for storage. Liquid may be stored for a long time (months). To facilitate handling water maybe added.	39%	45%	72%	When slurry tanks are used as fed-batch storage/digesters, MCF should be calculated according to formula 1.
Anaerobic Lagoon		0-100%	0-100%	0-100%	Should be subdivided in different categories, considering percentage recovery of the biogas and flaring of the biogas.
Pit Storage Below Animal Confinements	Combined storage of dung and urine below animal confinements <1 month >1 month	0-39%	0-45%	30%-72%	When pits are used as fed-batch storage/digesters, MCF should be calculated according to formula 1. The stable temperature, not the ambient temperature, is to be used for determining the climatic conditions.

TABLE 6 (CONTINUED)

MANURE MANAGEMENT SYSTEMS (BLANK MEANS NO CHANGE FROM CURRENT IPCC DEFINITIONS/MCFS)

System	Definition	MCFs by Climate			Comments
		Cool	Temperate	Warm	
Drylot					
Anaerobic Digester	The dung and urine in liquid/slurry is collected and anaerobically digested. Methane may be burned flared or vented.	0-100%	0-100%	0-100%	Should be subdivided in different categories, considering amount of recovery of the biogas, flaring of the biogas and storage after digestion .
Burned for Fuel	The dung and urine are excreted on fields. The sun dried dung cakes are burned for fuel.				

TABLE 7

PROPOSED NEW MANURE MANAGEMENT SYSTEMS

Recommended Additional Systems	Definition	MCFs by Climate			Comments
		Cool	Temperate	Warm	
Cattle Deep Litter	Cattle dung and urine is excreted on stall floor. The accumulated waste is removed after a long time.	10%	35%	65%	MCF's are similar to liquid/slurry; temperature dependant.
Composting – Intensive	Dung and urine is collected and placed in a vessel or tunnel, there is forced aeration of the waste.	0.5%	0.5%	0.5%	MCF's are less than half of solid storage. Not temperature dependant.
Composting – Extensive	Dung and urine collected, stacked and regularly turned for aeration.	0.5%	1%	1.5%	MCF's are slightly less than solid storage. Less temperature dependant.
Poultry manure with bedding	Manure is excreted on floor with bedding. Birds walk on waste.	1.5%	1.5%	1.5%	MCF's are similar to solid storage but with generally constant warm temperatures.
Poultry manure without bedding	Manure is excreted on floor without bedding. Birds do not walk on waste.	1.5%	1.5%	1.5%	MCF's are similar to dry lot at a warm climate.
Aerobic Treatment	Dung and manure is collected as a liquid. The waste undergoes forced aeration, or treated in aerobic pond or wetland systems to provide nitrification and denitrification.	0.1%	0.1%	0.1%	MCF's are near zero.

6 CONCLUSIONS

The key issues for estimating emissions from manure management relate to the actual methodology as well as to the creation of a baseline for methane and nitrous oxide emissions. Major issues concerning the Tier 1 methodology include lack of animal population data by animal groups. Approaches to overcoming this difficulty include collecting aggregate historical data from FAO and using current data to break out historical population data into the animal groups. For the Tier 2 methodology, the key issue is obtaining an accurate representation of manure management systems for any particular additional country. Approaches to overcoming this issue include applying a sample area or region's manure management practice trends to the entire country.

Issues to be addressed when developing a baseline include lack of available data, historic data not having been organized as recommended by IPCC, and changes in manure management practices over time that affect emissions results. The approaches for resolving issues include re-examination of historical data by means of the current methodology, the application of data from a representative region to the entire country as well as the creation of a trend with recent data and back-estimating historic data using this trend.

Updates to the Tier 2 method recommended at the IPCC Workshop in *Good Practices* in Inventory Methods held on February 24-26, 1999 in the Netherlands included the results of recent research such as modifications to the maximum methane producing capacity of livestock (B_o values), new MCF values for liquid slurry and pit storage as well as the revision and incorporation of the additional manure management systems currently being used (i.e. daily spread, solid storage, drylot, and anaerobic lagoon were revised; pit storage is a new system that has been incorporated).

ANNEX 1 TIER 1 EMISSION FACTORS

TABLE 8

MANURE MANAGEMENT EMISSION FACTORS (KG PER HEAD PER YR.)

	Developed Countries			Developing Countries		
Livestock	Cool	Temp.[a]	Warm	Cool	Temp.[a]	Warm
Sheep	0.19	0.28	0.37	0.10	0.16	0.21
Goats	0.12	0.18	0.23	0.11	0.17	0..22
Camels	1.6	2.4	3.2	1.3	1..9	2.6
Horses	1.4	2.1	2.8	1.1	1..6	2.2
Mules and Asses	0.76	1.14	1.51	0.60	0.90	1.2
Poultry[b]	0.078	0.117	0.157	0.012	0.018	0.023

The range of estimates reflects cool to warm climates. Climate regions are defined in terms of annual average temperature as follows: Cool = less than 15° C; Temperate = 15° C to 25° C inclusive; and Warm = greater than 25° C. The Cool, Temperate, and Warm regions are estimated using MCFs of 1% and 2%, respectively.

[a] Temp. = Temperate climate region.

[b] Chickens, ducks, and turkeys.

All estimates are ±20%.

Sources: Emission factors developed from: feed intake values and feed digestibilities used to develop the enteric fermentation emission factors; MCF, and B_O values reported in Woodbury and Hashimoto (1993). All manure is assumed to be managed in dry systems, which is consistent with the manure management system usage reported in Woodbury and Hashimoto (1993).

Source: IPCC, 1996 (Chapter 4, Table 4.5).

TABLE 9

TIER 1 MANURE MANAGEMENT EMISSION FACTORS FOR CATTLE, SWINE, AND BUFFALO

Regional Characteristics	Livestock Type	Emission Factor by Climate Region (kg/head/yr)		
		Cool	Temperate	Warm
North America: Liquid-based systems are commonly used for dairy and swine manure. Non-dairy manure is usually managed as a solid and deposited on pastures or ranges.	Dairy Cattle	36	54	76
	Non-dairy Cattle	1	2	3
	Swine	10	14	18
	Buffalo			
Western Europe: Liquid/slurry and pit storage systems are commonly used for cattle and swine manure. Limited cropland is available for spreading.	Dairy Cattle	14	44	81
	Non-dairy Cattle	6	20	38
	Swine	3	10	19
	Buffalo	3	8	17
Eastern Europe: Solid based systems are used for the majority of manure. About one-third of livestock manure is managed in liquid-based systems.	Dairy Cattle	6	19	33
	Non-dairy Cattle	4	13	23
	Swine	4	7	11
	Buffalo	3	9	16
Oceania: Virtually all livestock manure is managed as a solid on pastures and ranges. About half of the swine manure is managed in anaerobic lagoons.	Dairy Cattle	31	32	33
	Non-dairy Cattle	5	6	7
	Swine	20	20	20
	Buffalo			

TABLE 9 (CONTINUED)

TIER 1 MANURE MANAGEMENT EMISSION FACTORS FOR CATTLE, SWINE, AND BUFFALO

Regional Characteristics	Livestock Type	Emission Factor by Climate Region (kg/head/yr)		
		Cool	Temperate	Warm
Latin America: Almost all livestock manure is managed as a solid on pastures and ranges. Buffalo manure is deposited on pastures and ranges.	Dairy Cattle	0	1	2
	Non-dairy Cattle	1	2	1
	Swine	0	1	2
	Buffalo	1	1	2
Africa: Almost all livestock manure is managed as a solid on pastures and ranges.	Dairy Cattle	1	1	1
	Non-dairy Cattle	0	1	1
	Swine	0	1	2
	Buffalo			
Middle East: Over two-thirds of cattle manure is deposited on pastures and ranges. About one-third of swine manure is managed in liquid-based systems. Buffalo manure is burned for fuel or managed as a solid.	Dairy Cattle	1	2	2
	Non-dairy Cattle	1	1	1
	Swine	1	3	6
	Buffalo	4	5	5
Asia: About half of cattle manure is used for fuel with the remainder managed in dry systems. Almost 40% of swine manure is managed as a liquid. Buffalo manure is managed in drylots and deposited in pastures and ranges.	Dairy Cattle	7	16	27
	Non-dairy Cattle	1	1	2
	Swine	1	4	7
	Buffalo	1	2	3
Indian Subcontinent: About half of cattle and buffalo manure is used for fuel with the remainder managed in dry systems. About one-third of swine manure is managed as a liquid.	Dairy Cattle	5	5	6
	Non-dairy Cattle	2	2	2
	Swine	3	4	6
	Buffalo	4	5	5

The range of estimates reflects cool to warm climates. Climate regions are defined in terms of annual average temperature as follows: Cool = less than 15° C; Temperate = 15° C to 25° C inclusive; and Warm = greater than 25° C. All climate categories are not necessarily represented within every region. For example, there are no significant warm areas in Eastern or Western Europe.

Note: Significant buffalo populations do not exist in North America, Oceania, or Africa.

Source: IPCC, 1996 (Chapter 4, Table 4.6).

ANNEX 2 TIER 2 EMISSION FACTORS

IPCC VS Excretion Rate Equation (Equation 15 in the IPCC Guidelines)

EQUATION 15

$$VS\ (kg\ dm/day) = Intake\ (MJ/day) \bullet (1kg\ dm / 18.45\ MJ) \bullet (1 - DE\% / 100) \bullet (1 - ASH\% / 100)$$

Where:

VS: VS excretion per day on a dry weight basis;

dm: dry matter;

Intake: the estimated daily average feed intake in MJ/day;

DE%: the digestibility of the feed in percent;

ASH%: the ash content of the manure in percent.

TABLE 10

MANURE MANAGEMENT SYSTEMS AND METHANE CONVERSION FACTORS (MCFS)

System		MCF by Climate			Source
		Cool	Temperate	Warm	
Pasture/Range/Paddock: the manure from pasture and range grazing animals is allowed to lie as is, and is not managed.		1%	1.5%	2%	b
Daily Spread: manure is collected in solid form by some means such as scraping. The collected manure is applied to fields regularly (usually daily).		0.1%	0.5%	1%	b
Solid Storage: manure is collected as in the daily spread system, but is stored in bulk for a long period of time (months) before any disposal.		1%	1.5%	2%	b
Drylot: in dry climates animals may be kept on unpaved feedlots where the manure is allowed to dry until it is periodically removed. Upon removal, the manure may be spread on fields.		1%	1.5%	5%	b
Liquid/Slurry: these systems are characterized by large concrete-lined tanks built into the ground. Manure is stored in the tank for six or more months until it can be applied to fields. To facilitate handling as a liquid, water may be added to the manure.		10%	35%	65%	b
Anaerobic Lagoon: anaerobic lagoon systems are characterized by flush systems that use water to transport manure to lagoons. The manure resided in the lagoon for periods from 30 days to over 200 days. The water from the lagoon may be recycled as flush water or used to irrigate and fertilize fields.		90%	90%	90%	c
Pit Storage: liquid swine manure may be stored in a pit while awaiting final disposal. The length of storage time varies, and for this analysis is divided into two categories: less than one month or greater than one month.	<1 month	5%	18%	33%	b
	> 1 month	10%	35%	65%	b
Anaerobic Digester: the manure, in liquid or slurry form, is anaerobically digested to produce methane gas for energy. Emissions are from leakage and vary with the type of digester.		5-15%	5-15%	5-15%	d
Burned for Fuel: manure is collected and dried in cakes and burned for heating or cooking. Emissions occur while the manure is stored before it is burned. Methane emissions associated with the combustion of the manure are not considered here. Combustion-related emissions are estimated in the *Traditional Biomass Fuels* Section of the *Energy* chapter.		5-10%	5-10%	5-10%	e

a The range of estimates reflects cool to warm climates. Climate regions are defined in terms of annual average temperature as follows: Cool = less than 15° C; Temperate = 15° C to 25° C inclusive; and Warm = greater than 25° C.

Greenhouse gas emissions from ruminant supply chains
A global life cycle assessment

This report presents results from a broad assessment carried out to improve the understanding of greenhouse gas (GHG) emissions along livestock supply chains. The analysis was conducted at the Animal Production and Health Division of FAO and co-financed by the Mitigation of Climate Change in Agriculture (MICCA) programme. The following persons and institutions contributed to this work:

Study team:

- Pierre Gerber (Team Leader – FAO)
- Carolyn Opio (Principal investigator – FAO)
- Theun Vellinga (Livestock modeller – Wageningen University)

USDA	United States Department of Agriculture

Definitions of commonly-used terms

Anaerobic	In the absence of oxygen, i.e. conditions conducive to the conversion of organic carbon into methane (CH_4) rather than carbon dioxide (CO_2).
Breeding overhead	Animals that are kept to maintain the herd/flock size, rather than to produce food.
By-product	Material produced during the processing including slaughtering of a crop or livestock product that is not the primary objective of production (e.g. meals and brans, offal or skins).
Carbon footprint	The total amount of GHG emissions associated with a product along its supply-chain, and sometimes includes emissions from consumption, end-of-life recovery and disposal. Usually expressed in kg or t of carbon dioxide equivalent (CO_2-eq).
CO_2-equivalent emission	The amount of CO_2 emissions that would cause the same time-integrated irradiative forcing, over a given time horizon, as an emitted amount of a mixture of GHGs. It is obtained by multiplying the emission of a GHG by its Global Warming Potential (GWP) for the given time horizon. The CO_2 equivalent emission is a standard metric for comparing emissions of different GHGs (IPCC, 4 AR 2007).
Coefficient of variation	The standard deviation expressed as a percentage of the mean.
Cohort	Class of animals within a herd defined by their age and sex (e.g. adult females, replacement females, males for fattening, etc.).
Co-product	Material generated by a production activity that generates more than one output (e.g. meat, eggs and manure are co-products of chicken production).
Crop residue	Materials left in an agricultural field after the crop has been harvested (e.g. straw or stover).

Dairy herd	For the purposes of this assessment, includes milking animals, replacement stock and surplus calves that are fattened for meat production.
Direct energy	Energy used on-farm for livestock production, e.g. for lighting, heating and cooling.
Embedded energy	Energy or emissions arising during the manufacture of farm inputs, such as fertiliser or steel.
Emission factor	Factor that defines that rate at which a greenhouse gas is emitted, e.g. kg CH_4 per animal per year or kg N_2O-N/kg manure N.
Emissions intensity	Mass of emissions per unit of product, e.g. kg CO_2/kg of meat/milk.
Fat and protein corrected milk (FPCM)	Milk corrected for its fat and protein content to a standard of 4.0 percent fat and 3.3 percent protein. This is a standard used for comparing milk with different fat and protein contents. It is a means of evaluating milk production of different dairy animals and breeds on a common basis.
Feed conversion ratio	Measure of the efficiency with which an animal converts feed into tissue, usually expressed in terms of kg of feed per kg of output (e.g. CW, milk or protein).
Feed material	Individual feed type (e.g. maize grain or wheat straw).
Fieldwork	General term for the field operations undertaken during crop cultivation, e.g. ploughing, drilling, spreading, etc.
Geographical Information System	A computerized system organizing data sets through the geographical referencing of all data included in its collections.
Globalwarming potential	Defined by the Intergovernmental Panel on Climate Change (IPCC) as an indicator that reflects the relative effect of a GHG in terms of climate change considering a fixed time period, such as 100 years, compared with the same mass of carbon dioxide.
Grassland-based livestock systems	Livestock production systems in which more than 10 percent of the dry matter fed to animals is farm-produced and in which annual average stocking rates are less than ten livestock units per hectare of agricultural land (FAO, 1996).

Manure N	Nitrogen in manure.
Methane conversion factor	The percentage of the manure's maximum methane producing capacity (Bo) that is achieved during manure management
Mixed farming systems	Livestock production systems in which more than 10 percent of the dry matter fed to livestock comes from crop by-products and/or stubble or more than 10 percent of the value of production comes from non-livestock farming activities (FAO, 1996).
Monte Carlo analysis	Method that uses repeated random sampling for estimating uncertainty in results.
Pixel	The smallest unit of information in GIS raster data, usually square in shape. In GIS dataset, each pixel represents a portion of the earth, and usually has an attribute value associated with it, such as soil type or vegetation class. Pixel is often used synonymously with cell.
Ration	The combination of feed materials constituting the animal's diet.
Synthetic N	Nitrogen in the form of manufactured fertilisers, such as ammonium nitrate.
Tier levels	Defined in IPCC (2006), these correspond to a progression from the use of simple equations with default data (Tier 1 emission factors), to country-specific data in more complex national systems (Tier 2 & 3 emission factors). Tiers implicitly progress from least to greatest levels of certainty as a function of methodological complexity, regional specificity of model parameters, spatial resolution and the availability of activity data.

Executive summary

BACKGROUND AND PURPOSE

In decades to come, the global demand for livestock products will continue to increase driven by growing populations, incomes and urbanization. As a consequence the sector needs to produce more but in a context of increasing natural resource scarcity and challenges posed by climate change.

In 2010, the ruminant sector contributed about 29 percent to global meat production (equivalent to 81 million tonnes) of which 79 percent is from the cattle sector and the remaining from buffalo and small ruminants. Global milk production in 2010 was 717 million tonnes with milk production from the cattle sector contributing the bulk, about 83 percent of global production.

While ruminants play an important role in providing high quality protein essential for human diets, they are an important source of greenhouse gas (GHG) emissions. The demand for bovine meat, mutton and milk is forecasted to grow at a rate of 1.2 percent, 1.5 percent and 1.1 percent, respectively, during the period 2006-2050. To avoid significant increases in total GHG emissions from the sector, a reduction of the intensity of emissions is required.

This report presents a life cycle analysis of the GHG emissions arising from ruminant supply chains around the year 2005. This first comprehensive and disaggregated global assessment of emissions enables the understanding of emission pathways and hotspots. This is a fundamental and initial step to identify mitigation strategies and inform public debate.

Two similar reports on the emissions from pig and chicken supply chains and on the emissions from the dairy sector are also available. An overall report providing an overview of results and exploring mitigation potential and options is also available.[1]

METHODOLOGY

This assessment is based on a life cycle assessment (LCA) and includes all main sources of emissions along the supply chain starting from land use and the production of feed, through emissions from animal production to emissions related to processing and transportation of products to the retail distribution point.

GHG emissions arising from land-use change (LUC) associated with livestock production were also assessed. Land-use change emissions considered include the transformation of forest to cropland and of forest to pasture in Latin America and the Caribbean. Given the year of reference (2005), latest trends could not be fully reflected (e.g. reduction of deforestation rates in LUC). A sensitivity analysis was conducted, showing that the period of the analysis has an important influence on results.

[1] FAO. 2010. Greenhouse gas emissions from the dairy sector – A life cycle assessment. FAO, Rome.
FAO. 2013a. Tackling climate change through livestock – A global assessment of emissions and mitigation opportunities. FAO, Rome.
FAO. 2013b. Greenhouse gas emissions from pig and chicken supply chains – A global life cycle assessment. FAO, Rome.

Due to the lack of globally validated model and databases, sequestration and losses of soil C arising from pasture management could not be included in the assessment but can be significant. The effect of this was tested in the case of Western Europe; carbon sequestration could mitigate about 5 percent of total ruminant emissions in the region, but with a high degree of uncertainty.

This analysis covers emissions from the three major GHGs in agriculture, namely methane (CH_4), nitrous oxide (N_2O) and carbon dioxide (CO_2), omitting gases of minor importance.

The analysis was undertaken using the Global Livestock Environmental Assessment Model (GLEAM). This model quantifies GHG emissions arising from production of the main livestock commodities: meat and milk from cattle, sheep, goats and buffalo; meat from pigs; and meat and eggs from chickens.

The model calculates total emissions and (commodity) production for a given farming system within a defined area. The emissions per unit of product can be calculated for combinations of different commodities/farming systems/locations at different spatial scales.

In a complex analysis such as this, results are not definitive, but rather the best assessment that could be made and subject to improvement in subsequent revisions. Methodological developments are being developed within the context of the LEAP Partnership (Livestock Environmental Assessment and Performance),[2] to harmonize metrics and approaches used in the assessment of environmental performance of livestock supply chains, including future updates of this report.

KEY FINDINGS

Overall sectoral contribution to global GHG emissions

Globally, ruminant supply chains are estimated to produce 5.7 gigatonnes CO_2-eq *per annum* representing about 80 percent of the livestock sector emissions. Emissions from beef and milk production represent respectively 35 and 30 percent of the livestock sector emissions (equivalent to 4.6 gigatonnes CO_2-eq). Buffalos and small ruminants supply chains have a much lower contribution, representing respectively 8.7 percent and 6.7 percent of sector emissions.

Main emission sources

The largest source of GHG emissions in ruminant production is methane (CH_4) from enteric fermentation, which accounts for about 47 percent of the sector's emissions and more than 90 percent of the total CH_4 emissions. Nitrous oxide (N_2O) emissions originating mainly from feed production and N deposited during grazing represent 24 percent of the sector's GHG emissions.

Emissions from land-use change associated with the expansion of grassland into forest account for 14.8 percent of total emissions related to beef production.

While LUC contributes a significant amount to total emissions; and particularly so in certain regions, these estimates vary greatly depending on the assumptions made, data and approach applied.

[2] http://www.fao.org/ag/againfo/livestock-benchmarking/en/.

Emission intensities (emission of GHG per unit of product) per commodity

Average emission intensity for products from ruminants were estimated at 2.8, 3.4 and 6.5 kg CO_2-eq/kg fat and protein corrected milk (FPCM) for cow milk, buffalo and small ruminant milk, respectively, and 46.2, 53.4, and 23.8 kg CO_2-eq/kg carcass weight (CW) for beef, buffalo and small ruminant meat, respectively.

EMISSION INTENSITIES PER PRODUCTION SYSTEMS AND REGIONS

There are variations in emission intensities across regions and production systems for each commodity. These variations are largely driven by differences in production goals (specialized versus non-specialized production) and management practices, including animal husbandry methods, animal health and genetics which influence levels of productivity.

In addition, there is a wide divergence in emission intensity for different commodities produced within the same region under comparable conditions (production systems and climatic zones) pointing to the existence of a considerable emission intensity gap (Section 4.4).

Variation by production systems

Globally, mixed systems provide the bulk of the meat and milk output: about 79 percent of the beef, 85 percent of cow's milk and 70 and 68 percent of small ruminant milk and meat is produced in this system. In addition, mixed systems also supply about 97 and 96 percent of buffaloes' milk and meat, respectively.

On average, mixed systems have slightly lower emission intensities than grassland-based systems. This difference is explained by several factors such as reproductive efficiency (higher fertility rates, lower age at calving,) animal health (lower mortality rates), management (higher slaughter weights, reduced time to slaughter), and better feed quality in mixed farming systems. All these factors combine to result in higher productivity and lower emission intensity.

Variation by region

World regions show highly diverse emission intensities which are to large extent explained by their contribution to production, their production systems and management practices.

Cattle

Regional emission intensity of milk ranges from 1.6 kg CO_2-eq/kg FPCM to 9.0 kg CO_2-eq/kg FPCM. Generally, milk production in low productive systems has higher emission intensities than in high production systems of most affluent counties where better animal feeding and nutrition results in lower enteric and manure emissions and emission intensity at animal level. Improved genetics and animal health care and animal husbandry combine with better feeding to reduce the breeding overhead (i.e. animals kept to maintain the herd) thus further reducing emission intensity at herd level. In North America, manure management emissions are relatively high due to the use of liquid manure management systems that produce greater quantities of methane emissions.

Emission intensity of beef at regional level show a great deal of diversity; ranging from 14 kg CO_2-eq/kg CW in Eastern Europe and the Russian Federation to 76 kg CO_2-eq/kg CW in South Asia. Beef production has the highest emission intensi-

ties in South Asia, sub-Saharan Africa, Latin America and the Caribbean, and East and Southeast Asia. The quality and type of feed, low reproduction efficiency, poor herd management practices, genetics and animal health (high mortality) explain the higher emission intensities in these regions. In addition, in Latin America and the Caribbean, almost one third of the emissions from beef production are related to pasture expansion into forested areas. This figure is however associated with a high level of uncertainty as a result of methodological uncertainty and data gaps.

Regions with the lowest emission intensity such as Europe, North America and Oceania are not necessarily characterized by similar production systems. For example, in Europe about 80 percent of the beef is produced from dairy surplus calves and culled cows which explains the relatively low emission intensity of beef. In North America and Oceania, production is generally characterized by a high level of specialization and higher productivity, which results in lower emission intensities. However, in these two regions, beef cattle may be reared either intensively or extensively (on grain or grass).

Buffalos

Global buffalo milk and meat production is concentrated in three major world regions: South Asia, Near East & North Africa and East & Southeast Asia. South Asia alone produces as much as 90 percent and 70 percent of the global buffalo milk and meat, respectively. Milk produced in South Asia has lower emission intensity, explained by high milk yields compared to Near East & North Africa and East & Southeast Asia. Emission intensity of buffalo meat production is particularly high in East & Southeast Asia as productivity of the animals is low due to poor feed resources (largely based on low quality feed resources such as crop residues and pasture) and low reproductive efficiency. With the exception of a few countries in the Mediterranean region, buffalo production in industrialized world regions plays a very minor role.

Small ruminants

With the exception of small ruminant milk production in Western Europe and lamb and mutton production in Oceania and Western Europe, meat and milk from small ruminants is generally more important in developing world regions. Emission intensity for small ruminant milk is however highest in developing regions such as NENA and East & Southeast Asia, SSA and South Asia due to poorer production conditions in which animals are for the most part reared for subsistence purposes. In contrast, in industrialized countries where small ruminant milk production is important, emission intensity is low due to the specialization of production.

The contribution to global small ruminant meat production is characterized by a dichotomy between regions; global lamb and mutton production is largely concentrated in Western Europe and Oceania while production of meat from goats takes place in developing regions. Emission intensity for small ruminant meat is lowest in Oceania and Western Europe and highest in developing regions.

This difference in emission intensity of small ruminant meat and milk is due to variations in reproductive efficiency (resulting in a smaller "breeding overhead"), feed quality, and management practices that are generally poorer in developing regions.

FACTORS DRIVING EMISSION INTENSITY LEVELS

Differences in emission intensities are driven by a combination of factors.

- At animal level emission intensity is influenced by: (i) digestibility, quality and composition of the feed ration which influence the level of enteric methane emissions and manure emissions (lower release of nitrogen and volatile solids) per unit of product produced (milk or weight gain); and (ii) improved genetics and animal health contribute to better conversion of feed into animal products further reducing emission intensity at animal level.
- At animal level, emission intensity is influenced by feed quality combined with genetics, animal health, reproduction strategies (replacement, age at first calving) reducing the relative number of unproductive animals in the herd and thus emissions per unit of product generated at herd level.
- Land-use change, i.e. pasture and feed crop expansion, is a major driver of emissions. Feed originating from areas where LUC takes place has higher emission intensities.
- Manure management practices influence the release of methane and nitrous oxide.

CONCLUSIONS

The range of emission intensity within supply chains suggests that there is room for improvement. The areas with mitigation potential are the following:

- Improving feeding practices and digestibility of diets;
- Improving yields through genetics, feeding practices and animal health, and overall management;
- Reducing land-use change arising from feed crop cultivation and pasture expansion;
- Improving manure management – reducing the use of uncovered liquid manure management systems (MMSs), particularly in dairy systems;
- Improving the efficiency of feed crop production, particularly improving fertilization management.

This report focuses on one measure of environmental performance: kg CO_2-eq/kg commodity. When evaluating GHG mitigation measures, attention should also be paid to their potential impacts on other environmental dimensions, for example on water quality, as well as on broader development objectives, such as food security and poverty reduction.

1. Introduction

1.1 BACKGROUND

The global livestock sector is faced with a three-fold challenge: the need to increase production to meet demand, adapt to a changing and increasingly variable economic and natural environment and, at the same time, improve its environmental performance. While positive effects of grazing systems are locally verified on biodiversity and landscapes, major concerns have been raised about the potential consequences associated with livestock sector growth, including increasing natural resource use and degradation, contribution to global warming, water resource depletion, biodiversity erosion and habitat change. These concerns have resulted in a widespread interest from governments, consumers and industry in the assessment of the environmental performance of livestock production.

The evidence of human-induced climate change (IPCC, 2006) and the important contribution of the livestock sector to total anthropogenic emissions highlight the urgent need to better understand the sources of the livestock sector's greenhouse gas (GHG) emissions and related mitigation options. Starting in 2009, the Animal Production and Health Division of FAO has been engaged in a comprehensive assessment of livestock-related GHG emissions aimed at identifying low-emission development pathways for the livestock sector. The undertaking follows two broad objectives: first, to improve and break down the initial estimates of livestock sector's overall emissions provided in *Livestock's long shadow – Environmental issues and options* (FAO, 2006) and, second, to identify the major available mitigation options along livestock supply chains.

This report presents an update of the *Livestock's long shadow* assessment of GHG emissions from ruminant supply chains. It should be understood as a step in a series of assessments to measure and guide progress regarding the sector's GHG emissions.

1.2 SCOPE OF THIS REPORT

Livestock commodities differ in resource use and emission profile. These variations reflect fundamental differences in the underlying biology and modes of production. The reporting structure reflects this by bringing together species with important shared features concerning their emission profile. This report quantifies the main sources of GHG emissions, and estimates GHG emissions for major ruminant products, predominant ruminant production systems, main world regions and agro-ecological zones (AEZs), and major stages in the supply chains.

The assessment takes a supply chain approach in estimating emissions generated during: (a) the production of inputs for the production process; (b) crop and animal production; and (c) subsequent transport and processing of the outputs into basic products. Given the global scope of the assessment and the complexity of livestock supply chains, several hypotheses and generalizations had to be made to keep data requirements of the assessment manageable. They are documented in the report and their impact on results is analysed. Emissions related to the consumer (the purchase, storage and preparation of food) and food losses that take place at retail and consumer level are not included.

This report addresses a technical audience in private and public organizations, academia and LCA practitioners. Policy-makers and the informed general public will find a comprehensive review of results, methods and the mitigation potential in the livestock sector in an overview report published in parallel to this report (FAO, 2013a).

By providing the most accurate information available on a global scale, this assessment helps to identify priority areas for mitigation and technical options that can reduce GHG emissions from the ruminant sector. It also provides a benchmark against which future trends can be measured.

This report focuses on GHG emissions only; other environmental dimensions, such as water resources, land, biodiversity and nutrients, have not been considered. GHG emissions from the livestock sector cannot be taken as an indicator of environmental sustainability in general. There are important synergies and trade-offs among competing environmental criteria that require fuller assessment.

The base year selected for assessment is 2005. This year was chosen because at the start of the assessment, the available spatial data, and in particular information on the predicted livestock densities, were based on 2005 data.

1.3 THE GLOBAL LIVESTOCK ENVIRONMENTAL ASSESSMENT MODEL

This assessment is based on a newly-developed analytical framework: the Global Livestock Environmental Assessment Model (GLEAM). GLEAM intends to pull together the existing knowledge on production practices and emissions pathways and create a framework for disaggregation and comparison of emissions on a global scale. The model is developed for six animal species (cattle, buffalo, sheep, goats, pigs and chicken) and related edible products. It recognizes two farming systems for ruminant species (mixed and grazing), three for pigs (backyard, intermediate and industrial) and three for chicken (backyard, industrial egg and industrial meat). Overall, this amounts to over 14 000 theoretical supply chains, defined here as unique sets of commodity, farming system, country and climatic zone. The physical area corresponding to each of these sets is further decomposed in cells on a map.

Four publications present the results of this work:

- This technical report addressing the world's cattle, buffalo and small ruminant (sheep and goat) sectors.
- A report addressing the world's pig and chicken (meat and eggs) sectors, published in parallel to this report (FAO, 2013b).
- An earlier technical report published in 2010, addressing the world's dairy sector (FAO, 2010).
- An overview report, summarizing the above at the sector level and providing additional cross-cutting analysis of emissions and mitigation potential, published in parallel to this report (FAO, 2013a).

Since the publication of the FAO report on GHG emissions from the dairy sector (FAO, 2010), GLEAM has been improved to include additional GHG emissions sources such as direct on-farm energy use and indirect energy embodied in farm buildings and equipment. In addition, new data (herd parameters, feed rations) has also been made available, so this report presents an update of the results on dairy production presented in 2010.

1.4 OUTLINE OF THIS REPORT

This report consists of six sections (including this introductory section). Section two starts with a brief introduction to the global ruminant sector describing production systems and their contribution to global ruminant milk and meat production.

Section 3 gives an overview of the approach used in the estimation of GHG emissions in this assessment, providing basic information on the LCA approach. The section presents a description of the functional units used, system boundary, allocation to co-products and sources of GHG emissions. The section also provides an overview of ruminant production system typology applied, the tool (GLEAM) and methods as well as broad information on data sources and management. Detailed description of the approach and methods can be found in the appendices.

The results (total emissions and emission intensities) of this assessment are presented in Section 4 followed by a discussion on the main important sources and drivers of emissions from ruminant species as well as a discussion on uncertainty and assumptions likely to influence the results (Section 5). It also presents the results of a Monte Carlo uncertainty analysis performed in this study.

Section 6 presents the conclusions and recommendations that can be drawn from this work as well as provides direction on areas for improvement.

The appendices in this report provide a detailed description of the GLEAM model, methods applied (on quantifying carbon losses from land-use change, on-farm direct and indirect energy use and post farmgate emissions) and data. The appendices also explore different computation approaches (e.g. for estimating LUC emissions and allocation of emissions to slaughter by-products) presenting their impact on emission intensity.

2. Overview of the global ruminant sector

In this report, the ruminant sector comprises cattle, sheep and goat, and buffalo. The global ruminant population in 2010 was estimated to be 3 612 million (FAOSTAT, 2012), with cattle making up nearly 40 percent, sheep and goat 55 percent, and buffalo the remaining 5 percent. Within the ruminant sector, the cattle sector is by-far the most important: contributing about 64 and 600 million tonnes of meat and milk, respectively; about 79 and 83 percent of total meat and milk production from ruminants. Small ruminant products constitute a relatively small share of globally-produced ruminant meat and milk, about 17 percent and 4 percent, respectively.

Ruminants are mainly reared in either grazing or mixed systems and the relative global importance of mixed systems compared with grazing systems is reflected by the fact that about 73 percent of all ruminants are reared in mixed farming systems. This study estimates that globally about 79 percent of the beef and 85 percent of cattle milk and 70 percent and 68 percent of the small ruminant milk and meat, respectively, is produced in mixed systems. Mixed systems also supply the bulk of products from buffalo; about 97 and 96 percent of milk and meat, respectively. Within these two systems, there is a wide variation in farming practices of which is subject to several factors such as climatic conditions, availability of fodders, market demand, etc.

Agro-ecological conditions are important determinants of the characteristics of ruminant production and estimates of the relative importance of ruminant meat and milk production within the AEZs varies between cattle, buffalo, and small ruminants (see Maps 1, 2, 3, 4 and 5 in Appendix G). In cattle production, temperate zones contribute 50 percent and 38 percent of the milk and beef compared with 21 percent and 33 percent from humid zones and 29 percent and 29 percent from arid zones.

On the other hand, arid zones contribute the bulk of milk and meat production from small ruminants and buffalo; 69 percent and 52 percent of small ruminant milk and meat, and 84 percent and 70 percent of buffalo milk and meat. The humid and temperate zones contribute 12 percent and 18 percent of small ruminant milk and 18 and 29 percent of the meat.

The relative importance of the different species varies enormously – while economic conditions play a key role, factors such as biophysical conditions and cultural values are also important.

Beef production is the most diverse form of all ruminant meat production. It is produced in extremely diverse production systems, ranging from grazing to mixed livestock-crop systems. Beef is either produced in "dedicated" beef herds, where beef is the only main product, or as a co-product from dairy production, i.e. surplus calves from dairy herds are raised for beef and culled cows are used for meat.

Specialized beef production units may take many forms: breeding and growing beef enterprises, breeding and finishing, growing and finishing on pasture or in feedlots, etc. Such forms of production are usually located in the industrialized

world regions and Latin America. However, in many parts of the world, particularly in the developing regions, this distinction between dairy and specialized beef production is subtle especially where cattle are considered multifunctional producing both milk and meat as well as other valuable non-edible products and services such as manure, hides and skin, and are used for draught power.

Despite their small contribution to global milk and meat output, sheep and goat farming plays a larger role in some specific economies. In many marginal rural areas, it plays a significant socio-economic role. An important attribute of small ruminants is that they are able to thrive and produce on unfavourable land and are generally suited to harsh climatic conditions where cattle would perform poorly. Sheep and goats are better converters of low-quality fibrous feed into meat and milk due to their better digestive ability to utilize poor quality roughages. In this regard, about 56 percent of the world's small ruminants are located in arid zones and 27 percent and 21 percent in the temperate and humid zones, respectively. However, these animals also adapt very easily to intensive production systems and can produce meat and milk efficiently.

Milk and meat products from sheep and goats have two purposes: they are used for subsistence at household level or are sold as niche products. Meat and milk from sheep is usually obtained from high yielding animals kept under intensive conditions e.g. dairy intensive systems in the Mediterranean region, lamb production in New Zealand and Australia. In Northern Europe and Oceania (particularly New Zealand), sheep are kept mainly for meat production while in the Mediterranean region almost all sheep and goats belong to dairy breeds where milk is the main output of production and meat considered as a by-product.

Similar to other ruminant species, systems of buffalo production vary widely through the different regions of the world and are determined by several interacting factors that include climate (tropical or temperate, humid or arid), location (rural, peri-urban or urban), cropping systems (rain-fed or irrigated, annual or perennial crops), type of operation (small or large farm, subsistence or commercial), and primary purpose for buffalo production and/or management (milk, meat, draught power or mixed).

In South Asia, North Africa and the Near East, buffalo are mainly kept for milk and meat production. In East & Southeast Asia, draught power and meat are important, while in Europe, buffalo are kept on large commercial farms under modern intensive systems for milk and meat production (Perera, 2011).

Buffalo provide milk, meat, hides and draught power. Among the different products obtained from buffalo, meat and hides are more important, although buffalo play an important role in milk production in Asian countries and few countries in the Mediterranean region. Global milk production is concentrated in two countries, India and Pakistan, which together account for 92 percent of the world's total milk production. Buffalo have an inherent ability to produce milk of high fat contents (ranging from 6 to 8.5 percent) and, because of this, buffalo milk is preferred over cow milk in some regions of the world such as South Asia. In 2010, about 98 percent of the global buffalo meat production was produced in South, East and Southeast Asia with the bulk contributed by India and Pakistan. This is easily explained by the fact that the two countries have 73 percent of the global buffalo population. Besides edible products, ruminants also produce a host of non-edible products such

as manure, hides and skin, and natural fibre (wool, cashmere and mohair). While farm mechanization has resulted in significant reduction in the use of animals for draught power, farmers in many parts of the world still rely on cattle and buffalo as a source of draught power.

3. Methods

3.1 CHOICE OF LIFE CYCLE ASSESSMENT (LCA)

The use of Life Cycle Assessment (LCA) to assess food production is becoming increasingly common. This trend is driven by the need of policy-makers, producers and consumers for reliable and comprehensive environmental information to identify environmentally and economically sustainable agricultural products and practices.

The LCA approach, which is defined in ISO standards 14040 and 14044 (ISO, 2006), is now widely accepted in agriculture and other industries as a method for evaluating the environmental impact of production, and for identifying the resource and emission-intensive processes within a product's life cycle. The main strength of LCA lies in its ability to provide a holistic assessment of production processes in terms of resource use and environmental impacts, as well as to consider multiple parameters (ISO, 2006).

LCA also provides a framework to broadly identify effective approaches to reduce environmental burdens and is recognized for its capacity to evaluate the effect that changes within a production process may have on the overall life-cycle balance of environmental burdens. This enables the identification and exclusion of measures that simply shift environmental problems from one phase of the life cycle to another.

However, LCA also presents significant challenges, particularly when applied to agriculture. First, the data-intensive nature of the method places limitations on the comprehensive assessment of complex food chains and biological processes. Limited data availability can force the practitioner to make simplifications, which can lead to losses of accuracy.

A second difficulty lies in the fact that methodological choices and assumptions such as system boundary delineation, functional units, and allocation techniques may be subjective and affect the results. These complications call for a thorough sensitivity analysis.

3.2 GENERAL PRINCIPLES OF LCA

The LCA method was originally applied to analyse industrial process chains, but is increasingly being used to assess the environmental impacts of agriculture. It involves the systemic analysis of production systems to account for all inputs and outputs associated with a specific product within a defined system boundary. The system boundary largely depends on the goal of the study.

The reference unit that denotes the useful output of the production system is known as the functional unit, and it has a defined quantity and quality. The functional unit can be based on a defined quantity, such as 1 kg of product, or it may be based on an attribute of a product or process, such as 1 kg of fat and protein corrected milk (FPCM) or 1 kg of carcass weight (CW).

The application of LCA to agricultural systems is often complicated by the multiple-output nature of production, because major products are usually accompanied by the joint production of by-products. This requires appropriate partitioning of

environmental impacts to each product from the system according to an allocation rule, which may be based on different criteria such as economic value, mass balances, product properties, etc.

3.3 USE OF LCA IN THIS ASSESSMENT

In the last five years, an increasing number of LCA studies have been carried out for livestock production, mostly in Organisation for Economic Cooperation and Development (OECD) countries (Leip *et al*., 2010; Ledgard *et al.,* 2011; Beauchemin *et al*., 2010; de Vries and de Boer, 2010; Verge *et al*., 2008; Foley *et al*., 2011). Although LCA methods are well defined, the studies vary considerably in their level of detail, their definition of system boundaries, the emission factors (EFs) they use, and other technical aspects such as the allocation techniques and functional units they employ.

This assessment sets out to perform a complete LCA for the global livestock sector, using consistent calculation methods, modelling approaches, data and parameters for each production system within the sector. In contrast to previous LCA studies carried out for the livestock sector, which have primarily concentrated on either farm level or the national level emissions in OECD countries, this study is global in scope and includes both developed and developing countries.

As a consequence of its global scope, the approach developed for this study has had to overcome onerous data requirements by relying on some simplifications that result in a loss of accuracy, particularly for systems at lower levels of aggregation.

This assessment follows the attributional approach, which estimates the environmental burden of the existing situation under current production and market conditions, and allocates impacts to the various co-products of the production system. This differs from the consequential LCA approach, which considers potential consequences of changes in production, and relies on a system expansion analysis to allocate impacts of co-products (Thomassen *et al*., 2008).

The current assessment is based on the methodology for LCA, as specified in the following documents:

- ISO, 2006. *Environmental management – Life Cycle Assessment- Requirements and guidelines* - BS EN ISO 14044.
- British Standards Institute PAS 2050; 2008. Specification for the assessment of the life cycle greenhouse gas emissions of goods and services (BSI, 2008).

3.3.1 Functional unit

Ruminant production systems produce a mix of goods and services:

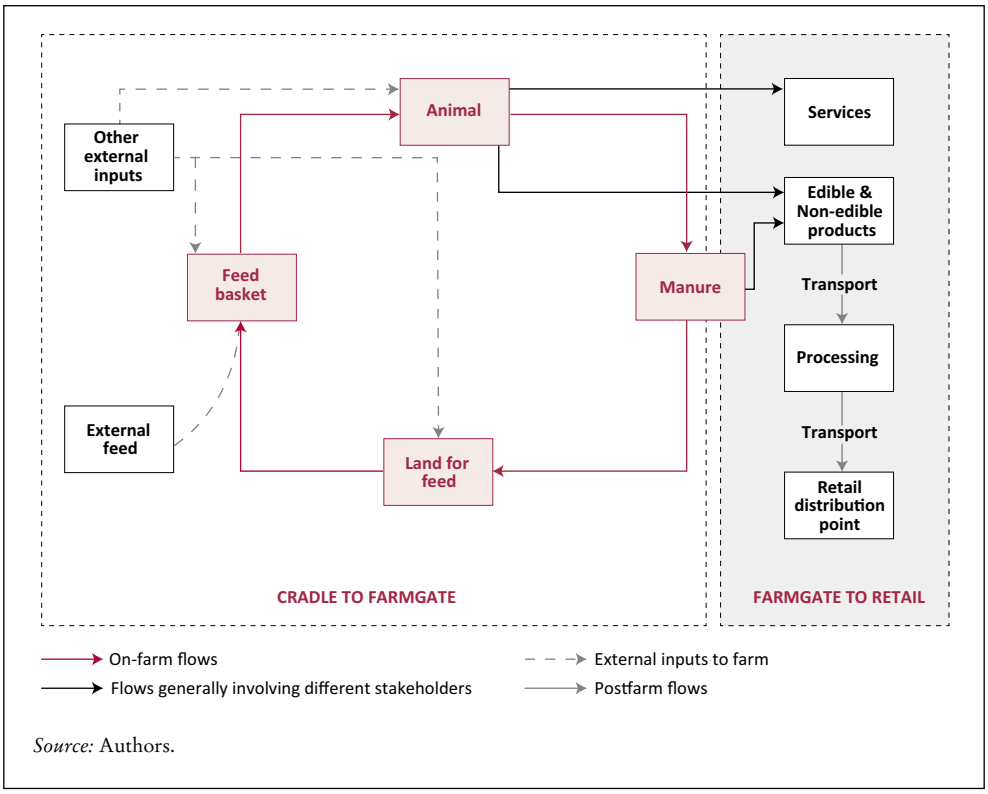
- Edible products: meat and milk.
- Non-edible products and services including natural fibre (wool, cashmere, mohair), draught power, hides and skin, manure and capital.

In this assessment, the functional units used to report GHG emissions for meat are expressed as a kg of carbon dioxide equivalents (CO_2-eq) per kg of carcass weight (CW) and emissions from milk are reported in CO_2-eq per kg of FPCM. FPCM is a method used to standardize milk produced in different systems with varying qualities. Appendix A provides details of the equations used in the standardization of milk from ruminants.

3.3.2 System boundary

The assessment encompassed the entire livestock production chain, from feed production through to the final processing of product, including transport to the retail distribution point (see Figure 1).

The cradle to retail system boundary is split into two subsystems:



- *Cradle to farmgate* includes all upstream processes in livestock production up to the farmgate where the animals or products leave the farm, i.e. production of farm inputs and on-farm production activities.
- *Farmgate to retail* includes transport of animals and product (milk) to processing plants (dairies and slaughter plants) or directly to market, processing into primary products, refrigeration during transport and processing, production of packaging material, and transport to the retail distributor.

All aspects related to the final consumption of milk and meat products (i.e. consumer transport to purchase product, food storage and preparation, food waste and waste handling of packaging) lie outside the defined system, and are thus excluded from this assessment.

To calculate GHG emissions from cradle to farmgate, a simplified description of livestock production systems (derived from Oenema *et al.*, 2005; Schils *et al.*, 2007; Del Prado and Scholefield, 2008) was developed (Figure 1).

Livestock production is complex, with a number of interacting processes that include crop and pasture production, manure handling, feed processing and transport, animal raising and management, etc. This requires modelling the flow of all

Figure 1.
System boundary as defined for this assessment

Table 1. Sources of GHG emissions included and excluded in this assessment

Food chain	Activity	GHG	Included	Excluded
Upstream	Feed production	N_2O	Direct and indirect N_2O from: • Application of synthetic N • Application of manure • Deposition of manure on pasture, ranges • Crop residue management	• N_2O losses related to changes in C stocks • Biomass burning • Biological fixation • Emissions from non-N fertilizers and lime
		CO_2	• Energy use in field operations • Energy use feed transport and processing • Fertilizer manufacture • Feed blending • Land-use change related to deforestation soybean and pasture expansion	• Changes in carbon stocks from land use under constant management practices
	Non-feed production	CO_2	• Indirect (embedded) energy related to the manufacture of on-farm buildings and equipment	• Production of cleaning agents, antibiotics and pharmaceuticals
Animal production unit	Livestock production	CH_4	• Enteric fermentation • Manure management	
		N_2O	• Direct and indirect N_2O from manure management	
		CO_2	• Direct on-farm energy use for milking, cooling, ventilation and heating	
Downstream	Post farmgate	CO_2; CH_4; HFCs	• Transport of live animals and product to slaughter and processing plant • Transport of processed product to retail point • Refrigeration during transport and processing • Primary processing of meat into carcasses or meat cuts and raw milk and dairy products • GHGs related to leakage of refrigerants during transportation • Manufacture of packaging	• On-site waste water treatment • Emissions from animal waste or avoided emissions from on-site energy generation from waste • Emissions related to slaughter by-products e.g. rendering material, offal, hides and skin • Retail and post-retail energy use • Waste disposal at retail and post-retail stages

Source: Authors.

products through internal chains on the farm and also allowing for imports and exports from the farm. The model therefore provides a means of integrating all these processes and linking all components in a manner that adequately captures major interactions among biological and physical processes. The flows are represented as directional lines between compartments in the system.

- "*Land for feed*" is the land used for feed production, on the farm itself or within the vicinity of production site (with negligible emissions related to the transport of feed to the animal rearing site).
- "*External feed*" originates from off-site production and includes by-products from the food industry and feed crops produced and transported over longer distances, e.g. soybeans; in most situations, the external feed is concentrate feed.
- "*Manure*" is shown partly outside the 'cradle-to-farmgate' system boundary in order to illustrate situations where manure is used as a fertilizer on food crops, either on- or off-farm, or where manure is used as fuel.
- "*Other external inputs*" refers to the inputs into production such as energy, fertilizer, pesticides, on-farm machinery, etc.

The connection of the four compartments shown in Figure 1 requires the devel-

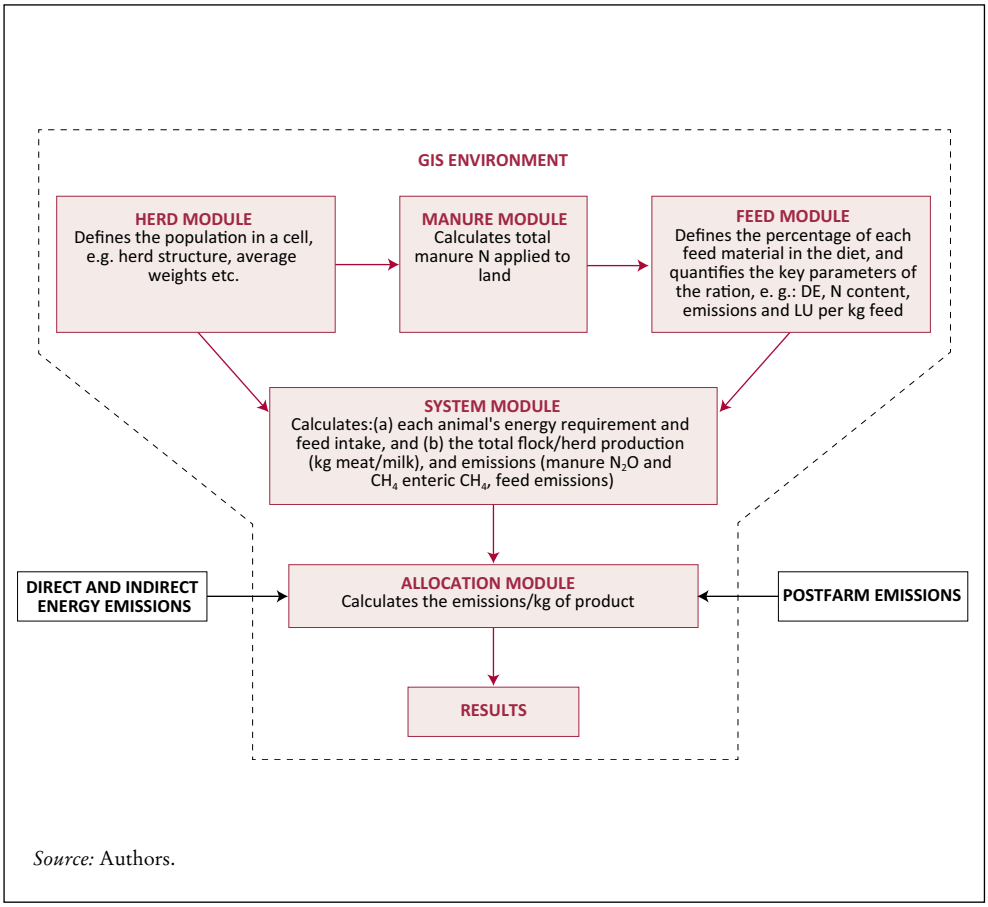
opment of specific models (see Appendix A) and attribution techniques (see Section 3.6 and Appendix A) for the allocation of emissions among different processes, uses and outputs. These compartments not only represent different activities in the production process such as animal production, feed production, manure management, etc., but also define the inter-linkages among production processes such as the link between animal performance (genetics, management), animal feed requirements (energy and protein requirements) and the production of outputs such as edible and non-edible products and services, and emissions.

3.3.3 Sources of GHG emissions

This study focuses on emissions of the three major GHGs associated with animal food chains – methane (CH_4), nitrous oxide (N_2O) and carbon dioxide (CO_2) – as well as GHGs related to refrigerants. The following emission sources were included and further grouped into pre- and post farmgate sources, and a number of potential GHG emissions and sinks were excluded from the analysis (Table 1).

Table 1 also illustrates a number of processes and activities in the livestock food chain that have been excluded due to:

- lack of global databases, e.g. on the production of co-products at slaughterhouse, post retail emissions, etc.;
- lack of methodology or consensus on quantification approach, e.g. changes in soil carbon stocks from LU; and
- limited contribution of the processes to the carbon footprint, e.g. use of production of cleaning agents, antibiotics and pharmaceuticals.



Emission categories and a description of the emissions included in each category are presented in Table 2.

Table 2. Description of emission categories used in this assessment

Category		Description
Feed N_2O		Direct and indirect N_2O emissions from manure deposited on pasture Direct and indirect N_2O emissions from organic and synthetic N applied to crops and pasture
Feed CO_2	blending and transport	CO_2 arising from the production and transportation of compound feed
	fertilizer production	CO_2 from energy use during the manufacture of urea and ammonium nitrate (and small amounts of N_2O)
	processing and transport	CO_2 from energy use during crop processing (e.g. oil extraction) and transportation by land and (in some cases) sea
	field operations	CO_2 arising from the use of energy for field operations (tillage, fertilizer application). Includes emissions arising during both fuel production and use.
Feed LUC CO_2		CO_2 from LUC associated with soybean cultivation and pasture expansion
Indirect (embedded) energy CO_2		CO_2 arising from energy use during the production of the materials used to construct farm buildings and equipment
Manure N_2O		Direct and indirect N_2O emissions arising during manure storage prior to application to land
Manure CH_4		CH_4 emissions arising during manure storage prior to application to land
Enteric CH_4		CH_4 arising from enteric fermentation
Direct energy CO_2		CO_2 arising from energy use on-farm for heating, ventilation etc.
Post farmgate		Energy use in processing and transport

3.4 OVERVIEW OF CALCULATION METHOD

A specific model and related databases were developed to carry out this assessment. The Global Livestock Environmental Accounting model (GLEAM) was designed to represent processes and activities from the production of inputs into the production process to the farmgate, the point at which products and animals leave the farm. It consists of five main modules: *herd module, manure module, feed basket module, system module and allocation module* and two additional modules for the calculation of direct and indirect on-farm energy and post farmgate emissions (Figure 2). Appendix A provides a detailed explanation of GLEAM.

3.4.1 Spatial variation and the use of Geographic Information System

A challenge faced in conventional LCA modelling is the complexity and variation in biophysical characteristics (such as soil and climate) as well as production processes. Data on farming activities and farming system parameters were collected at different levels of aggregation: production system, country level, AEZs, or a combination thereof (e.g. information on manure storage in developing countries was available for a combination of production systems and AEZs). Additional data, such as livestock numbers, pasture and availability of feedstuff was available in the form of Geographical Information System (GIS) grids (raster layers), with a spatial resolution not coarser than 5 arc minutes (ca. 10 km x 10 km at the equator). For

the outputs of GLEAM, a spatial resolution of 3 arc minutes (ca. 5 km x 5 km at the equator) was used.

GIS can store observed data for specific locations (e.g. soil types, climate factors), can model new information from these data and can also calculate regional summaries such as total area, emissions, etc. GIS was used to analyse spatially varied data (such as crop yields, livestock species distribution), generate location-specific input data required for LCA modelling (e.g. define the typology of livestock production systems, and calculate location-specific feed-crop availability, classification of dominant soil types in forested areas and location-specific temperature to estimate EFs such as CH_4 conversion factors for MMS) and store numerical model input and output data in a GIS database.

The use of GIS allowed the incorporation of spatial heterogeneity into the modelling process which brought with it the benefit of enhancing the reliability of data used as well as results. Furthermore, it produced a more spatially accurate inventory of emissions, particularly CH_4 emissions which are modelled based on animal cohorts and feed intake. In this way, emissions were estimated at any location of the globe, based on available information, and then aggregated along the desired category, e.g. farming systems, country group, commodity and animal species. This assessment thus demonstrates the potential of coupling GIS technology with LCA for assessing GHG emissions from the livestock food chain.

3.4.2 Emission factors

The GHG EFs applied for the various emission sources in this study are specified in Appendix B of this report. A combination of IPCC (2006) Tier 1 and Tier 2 approaches and EFs were used in the estimation of emissions.

Despite the existence of country-specific EFs, the study applied the same approach to all countries. The use of a unified approach was preferred for the assessment, to ensure consistency and comparability of results across regions and farming systems.

IPCC Tier 2 approaches were used in the characterization of livestock population, to calculate emissions related to enteric fermentation as well as manure management and storage. The Tier 1 method was used where data was generally lacking, e.g. estimation of carbon stocks from LUC and N_2O emissions from feed production.

Global Warming Potentials (GWPs) with a time horizon of 100 years based on the 4th Assessment Report of the IPCC (IPCC, 2007) were used to convert N_2O and CH_4 to CO_2-eq terms. Consequently, GWP of 25 and 298 were used for CH_4 and N_2O, respectively.

3.4.3 Land use and land-use change

Assessment of changes in carbon stocks for agricultural land remaining in the same land use category requires dynamic process models and/or detailed inventory measurements. According to IPCC (2006), these models should be able to represent all relevant management practices and their driving variables compatible with available country data. Their validity should also be reported in empirical assessments. As no models satisfy these criteria and are validated on a global scale, this analysis doesn't incorporate C stock changes under constant land use. Nevertheless, a discussion on the effect of this simplification is provided in Appendix C, in particular about the role of grasslands in C sequestration.

Land-use change (LUC) is a highly complex process. It results from the interaction of drivers which may be direct or indirect[3] and which can involve numerous transitions, such as clearing, grazing, cultivation, abandonment and secondary forest re-growth. The debate surrounding the key drivers of deforestation is a continuing one and the causal links (direct and indirect) are both complex and unclear.

In this assessment, LUC considered are the transformation of forest to cropland and of forest to pasture. The former focuses on deforestation associated with soybean production in Brazil and Argentina. This choice results from the use of 2005 as year of reference and from the following observations of trends in LU transitions and crop expansions:

- In the period 1990-2006,[4] which is used as the reference time period in this study, the main global cropland expansions were for maize and soybean production;
- Maize and soybean expansion occurred in different regions of the world but only in Latin America can it be linked to a decrease in forest area during the same period; and
- Within Latin America, Brazil and Argentina account for 91 percent of the total soybean area. Over the period 1990–2006, 90 percent of the soybean area expansion in Latin America took place in these two countries.

LUC emissions were then attributed to only those countries supplied by Brazil and Argentina for soybean and soybean cake, proportionally to the share on imports from these two countries in their soybean supply. This study also provides an analysis of sensitivity to these assumptions, in particular on the reference time period, the expansion of soybean at the expense of other land types including forestland (arable and perennial cropland and grassland) and the assumption that all traded soybean and soybean cake is associated with LUC (see Appendix C).

The second LU transformation focuses on deforestation associated with pasture expansion in Latin America. This choice results from the observation that, during the period 1990-2006, significant pasture expansions and simultaneous forest area decrease occurred in Latin America and Africa. However, due to the lack of reliable data and information, it is difficult to draw conclusions on the land-use conversion trends in Africa.

LUC emissions associated with the expansion of pasture into forest areas in Latin America are attributed to beef production in those countries in which the conversion occurred. Appendix C provides an elaboration of the approach applied.

3.5 DATA SOURCES AND MANAGEMENT

The availability of data varies considerably within and among key parameters. In general, the OECD countries possess detailed statistics, supported by several scientific and technical publications. In contrast, there is a severe paucity of data in non-OECD countries. Where detailed and accurate data are available, they are often outdated and/or lack supporting metadata. Appendix B presents some of the data utilized in this assessment.

[3] Direct drivers include conversion of forest areas for plantation crops or cattle ranching, rural settlements, mining and logging. Indirect drivers include subsidies for agribusiness, investment in infrastructure, land tenure issues, absence of adequate surveillance by the government and demand for forest products, such as timber.

[4] 1990 is chosen as the initial year because it is the most recent available year with a consistent forest dataset from the FAOSTAT database. This practically discounts 4 years of LUC related emissions, compared to the 20-year timeframe recommended by IPCC (IPCC, 2006).

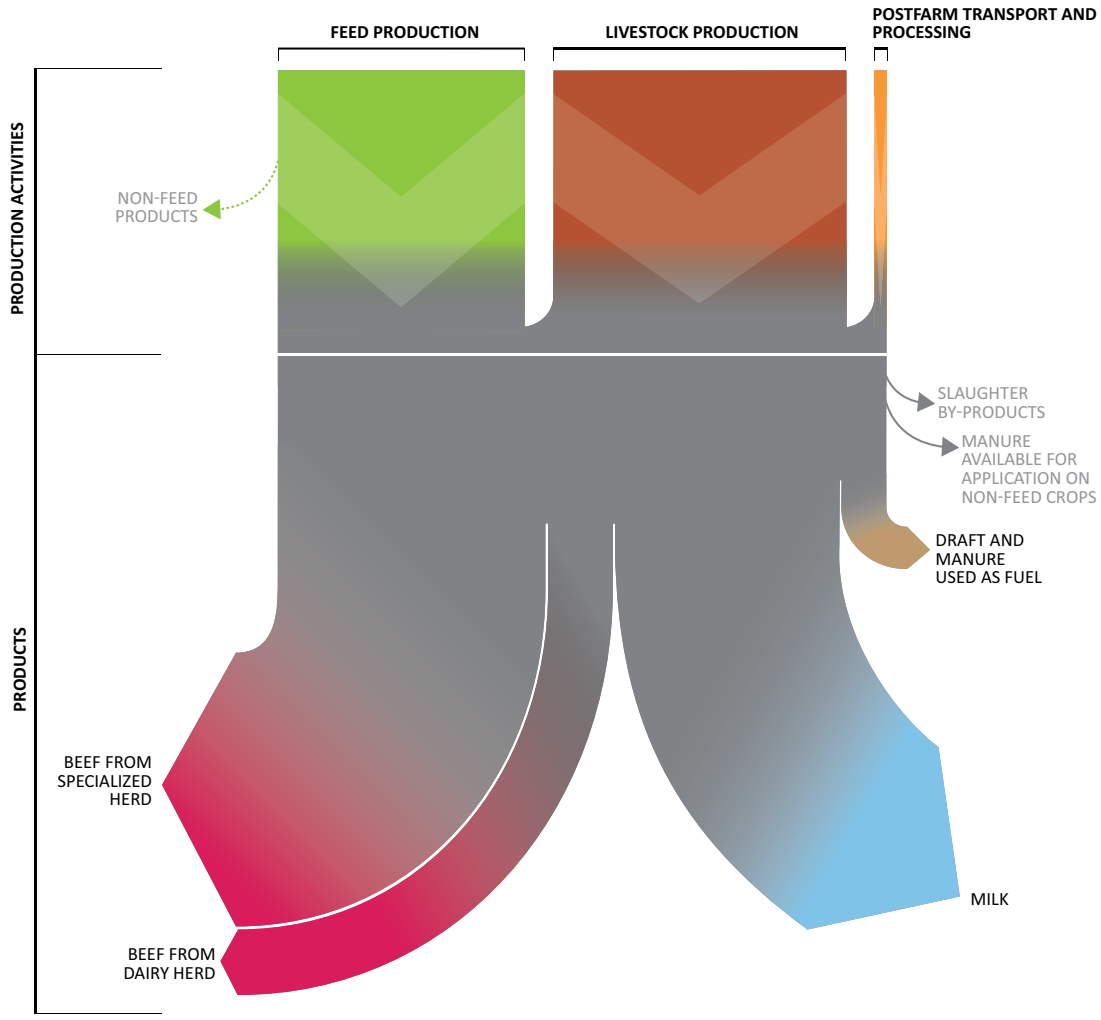
Table 3. Overview of the data sourced for the preparation of this assessment

Data groups	Data collection approach and sources
Herd (animal parameters)	Literature reviews, reports and surveys (see Appendix B)
Manure management	Literature reviews and reports (see Appendix B)
Feed basket	Literature reviews, reports; IFPRI (GIS based data)
LCI feed components	Literature reviews, reports; IFPRI (GIS based data), LCI databases Sweden and the Netherlands
Yield	Literature reviews and FAOSTAT
Non-edible products	Literature reviews and reports, FAOSTAT
Carbon stocks	Use of model based on Gross Primary Production (GPP)
Deforestation	FAO Forestry statistics, IPCC guidelines, literature and own calculations (see Appendix C)
Animal population characterization	Herd layer data, FAOSTAT and FAO Gridded Livestock of the World
Capital goods	Ecoinvent database and literature reviews

Source: Authors.

During the process of data collection, gaps initially encountered were addressed, to the extent possible, by extensive research of databases, literature sources and expert opinion. Assumptions were made when data could not be obtained. Data collection involved a combination of research, direct communication with experts, and access to public and commercially available life cycle inventory (LCI) packages such as Ecoinvent. The study's main data sources included:

- Gridded Livestock of the World (FAO, 2007).
- National Inventory Reports of Annex I countries (UNFCCC, 2009a).
- National Communications of non-Annex I countries (UNFCCC, 2009b).
- Geo-referenced databases on crop production from the International Food Policy Research Institute (You *et al.*, 2010).
- Above-ground net primary production (NPP) (Haberl *et al.*, 2007)
- Life Cycle Inventory (LCI) data from the Swedish Institute for Food and Biotechnology (Flysjö *et al.*, 2008), and Wageningen University, the Netherlands (I. de Boer, personal communication).
- Reports from the CGIAR research institutes.
- Statistics from FAO (FAOSTAT, 2009).
- Peer-reviewed journals.



The data have been organized into data groups or "basic data layers". Table 3 summarizes the data collection approach and sources for each main data group.

Further detail on data and data sources is given in Appendix B.

3.6 ALLOCATION OF EMISSIONS BETWEEN PRODUCTS, BY-PRODUCTS AND SERVICES

Livestock produce a mix of goods and services that cannot be disaggregated easily into individual processes. For example, a dairy cow produces milk, manure, draught power and capital services, and eventually meat when it is slaughtered. Given that multiple products are produced from each of the ruminant species, the environmental burden associated with production needs to be allocated for each of the products. In LCA, specific techniques are required to attribute relative shares of

Figure 3.
An illustration of production activities and partitioning of total emissions to products and services from cattle

Source: Authors.

GHG emissions to each of these goods and services. The ISO recommends avoiding allocation by dividing the main process into sub-processes, or by expanding the product system to include additional functions related to the co-products (ISO, 2006). In situations where allocation cannot be avoided (as is often the case in biological processes such as livestock production), GHG emissions can be allocated on the basis of causal and physical relationships.

Where physical relationships alone cannot be established or used as a basis for allocation, emissions should be allocated in a way which reflects other fundamental relationships. In the latter case, the most commonly used approach is economic allocation which, in the context of jointly produced products, allocates emissions to each product according to its share of the products' combined economic value. Other indexes, such as weight or protein content, can also be used (Cederberg and

Figure 4.
Classification of ruminant production systems used in the assessment

HERD TYPE	SYSTEM	CLIMATE	COUNTRY
Dairy herd *(producing milk and meat)*	Mixed[1] Grassland based[2]	Arid Humid Temperate/ tropical highlands	A B ...
Pure meat herd *(producing only meat)*	Mixed[1] Grassland based[2]	Arid Humid Temperate/ tropical highlands	A B ...

[1] Grassland-based livestock systems: Livestock production systems in which more than 10 percent of the dry matter fed to animals is farm-produced and in which annual average stocking rates are less than ten livestock units per hectare of agricultural land (FAO, 1996).
[2] Mixed farming systems: Livestock production systems in which more than 10 percent of the dry matter fed to livestock comes from crop by-products and/or stubble or more than 10 percent of the value of production comes from non-livestock farming activities (FAO, 1996).
Source: Authors.

Stadig, 2003). The allocation techniques used in this assessment to apportion emissions to products and services produced by ruminant systems are summarized below:

- Edible products (e.g. meat and milk): allocation based on protein content.
- Edible and non-edible products (e.g. milk, meat and fibre): allocation based on economic value of outputs.
- Slaughter by-products: no allocation is performed in this assessment. Appendix F explores the impact of allocating emissions to slaughter by-products.
- Manure: allocation based on sub-division of production process.
  - manure storage: emissions from manure management systems (MMS) allocated to livestock sector;
  - manure applied to feed: emissions allocated to livestock sector based on mass harvested and relative economic value;
  - manure applied to non-feed: no allocation to livestock sector; and
  - manure used for fuel: Emissions are deducted from the overall emissions and therefore are not allocation to livestock sector.
- Capital function: no allocation is performed in this assessment.
- Services (e.g. animal draught power): biophysical allocation based on extra-life time gross energy requirements for labour and emissions are deducted from the overall livestock emissions.

A detailed account of the application of the allocation technique is provided in Appendix A. Figure 3 illustrates flows of outputs from the cattle sector.

3.7 PRODUCTION SYSTEM TYPOLOGY

This assessment estimates emissions at global, regional and farming system levels. A farming system typology was thus adapted to provide a framework for examining GHG emission from different dairy farming systems. This typology is based on the classification principles set out by FAO (1996), namely, the feed-base and the agro-ecological conditions of production systems (Figure 4).

The following three AEZs were used:

- *"temperate": temperate regions*, where for at least one or two months a year the temperature falls below 5 ºC; and *tropical highlands*, where the daily mean temperature in the growing season ranges from 5 to 20 ºC.;
- *"arid": arid and semi-arid tropics and subtropics*, with a growing period of less than 75 days and 75-180 days, respectively; and
- *"humid": humid tropics and sub-humid tropics* where the length of the growing period ranges from 181-270 days or exceeds 271 days, respectively.

The widely-used classification approach developed by FAO (1996) that was used here has a number of advantages: it allows researchers to use the multiple databases developed using this structure [e.g. geo-referenced data on animal numbers in each livestock production system (LPS)]; it provides a conceptual framework to make estimates where data are lacking; and it enhances the compatibility of this work with other analyses using similar classification schemes.

4. Results

4.1 CATTLE

This study estimates that in 2005, total emissions from cattle production amount to 4 623 million tonnes CO_2-eq. These emissions include emissions associated with the production of meat and milk, emissions related to land-use change, emissions associated with post farmgate activities, and emissions related to non-edible products and services, draught power and manure used for fuel.

The following sub-sections present the emissions associated with edible products (meat and milk) as well as a disaggregated overview of the contribution of production systems and regions to emissions.

4.1.1 Total production, absolute emissions and emission intensities

In 2005, the global cattle sector produced approximately 508.6 million tonnes of milk and 61.4 million tonnes of beef, of which 56 percent of beef was produced by the specialized beef sector and 44 percent by the dairy herd. Table 4 reports the volume of production, absolute emissions and average GHG emissions per kg of milk and meat for the dairy and beef subsectors.

Globally, about 4 255.9 million tonnes of CO_2-eq were emitted by the global cattle sector in 2005; of this 1 419.1 million tonnes were associated with milk production and 2 836.8 million tonnes with beef production.[5] This is equivalent to 2.8 kg CO_2-eq per kg of fat and protein corrected milk and 46.2 kg CO_2-eq per kg of carcass weight.[6]

Regarding beef production from the cattle sector, there is a distinct difference in emission intensity between beef produced by the dairy herd and the specialized beef herd; the carbon intensity of beef from the specialized beef herds is almost fourfold that produced from the dairy herd (67.8 vs. 18.4 kg CO_2-eq per kg CW) (Table 4). The low emission intensity for dairy meat is caused by the fact that both milk and meat are produced by the dairy herd. Because a large proportion of the

Table 4. Global production, absolute GHG emissions and emission intensities for milk and beef

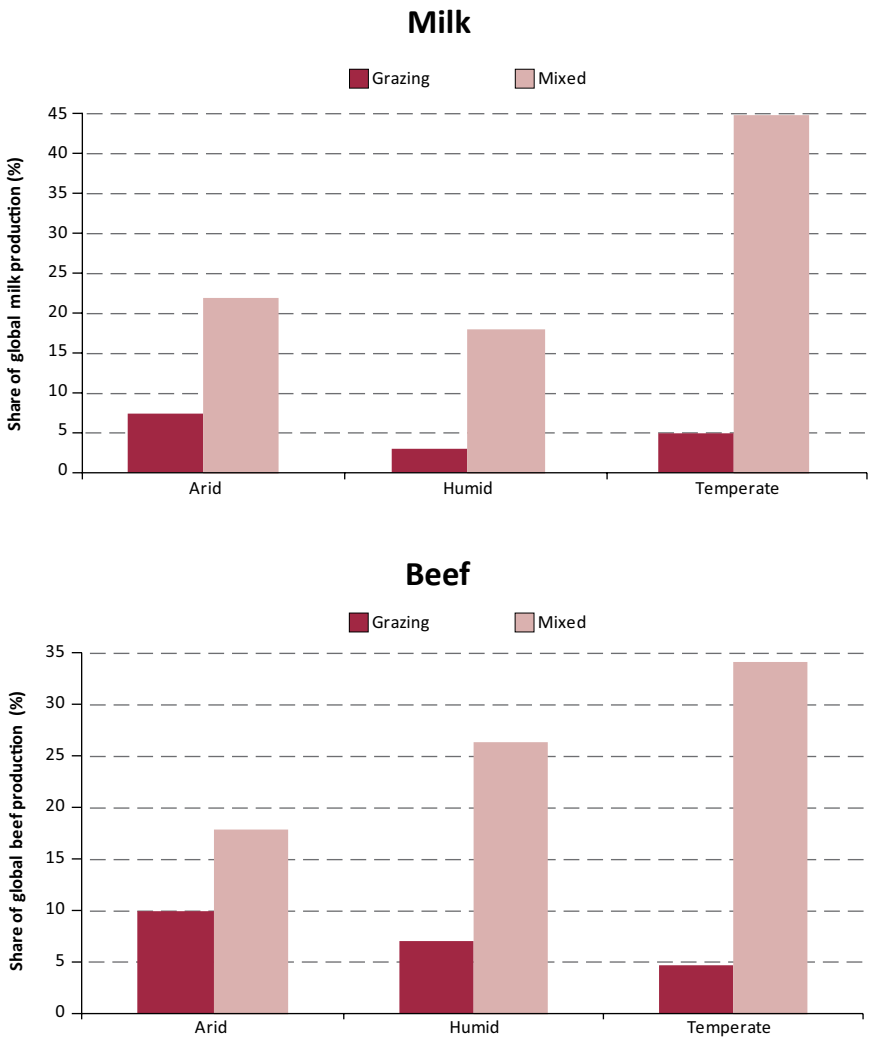
[5] Unless otherwise stated, the term "beef" refers to meat from dairy and specialized beef herds.

[6] Does not include emissions associated to slaughter by-products. See Appendix F for discussion of effects on results.

Figure 5.
Relative contribution of different processes to total GHG emissions from the global cattle sector



Source: GLEAM

total protein from the dairy herd originates from milk (see Map 6 in Appendix G), a greater proportion of the emissions from dairy herd is attributed to milk. Consequently, this reduces the GHG emissions attributed to meat from culled dairy cows and related meat production from surplus animals.

On the other hand, the specialized beef herd carries the entire burden of emissions because only one product is produced, while the reproductive overhead (cows, bulls and replacement animals) is almost the same. The overhead costs of the cow in dairy-based production systems are largely attributed to milk while in the specialized beef system the full costs are allocated to those animals destined for beef production.

Figure 6.
Contribution to total milk and beef production by production systems and agro-ecological zone[1]

[1] Excluding post farmgate and land-use change emissions (pasture expansion).
Source: GLEAM.

The relative contribution of production processes and gases to the emissions profile for milk and beef at global level is illustrated in Figure 5. A significant share of total GHG emissions is from CH_4 which accounts for 50 percent and 44 percent of the total emissions, with enteric fermentation contributing more than 92 percent and 97 percent of the total CH_4 emissions in dairy and beef production.

In both dairy and beef herds, N_2O emissions amounted to relatively similar proportions of the total carbon footprint – approximately 29 percent of the emissions. Main sources of N_2O emissions include N_2O from manure deposited during grazing and feed production.

On a global scale, CO_2 emissions represent 20 percent and 27 percent of the dairy and beef emission profiles, respectively. The difference in CO_2 emissions between

dairy and beef herds is due to the CO_2 emissions from land-use change associated with the expansion of grassland into forest areas which accounts for 14.8 percent of the total emissions related to beef production and 55 percent of the CO_2 emission.

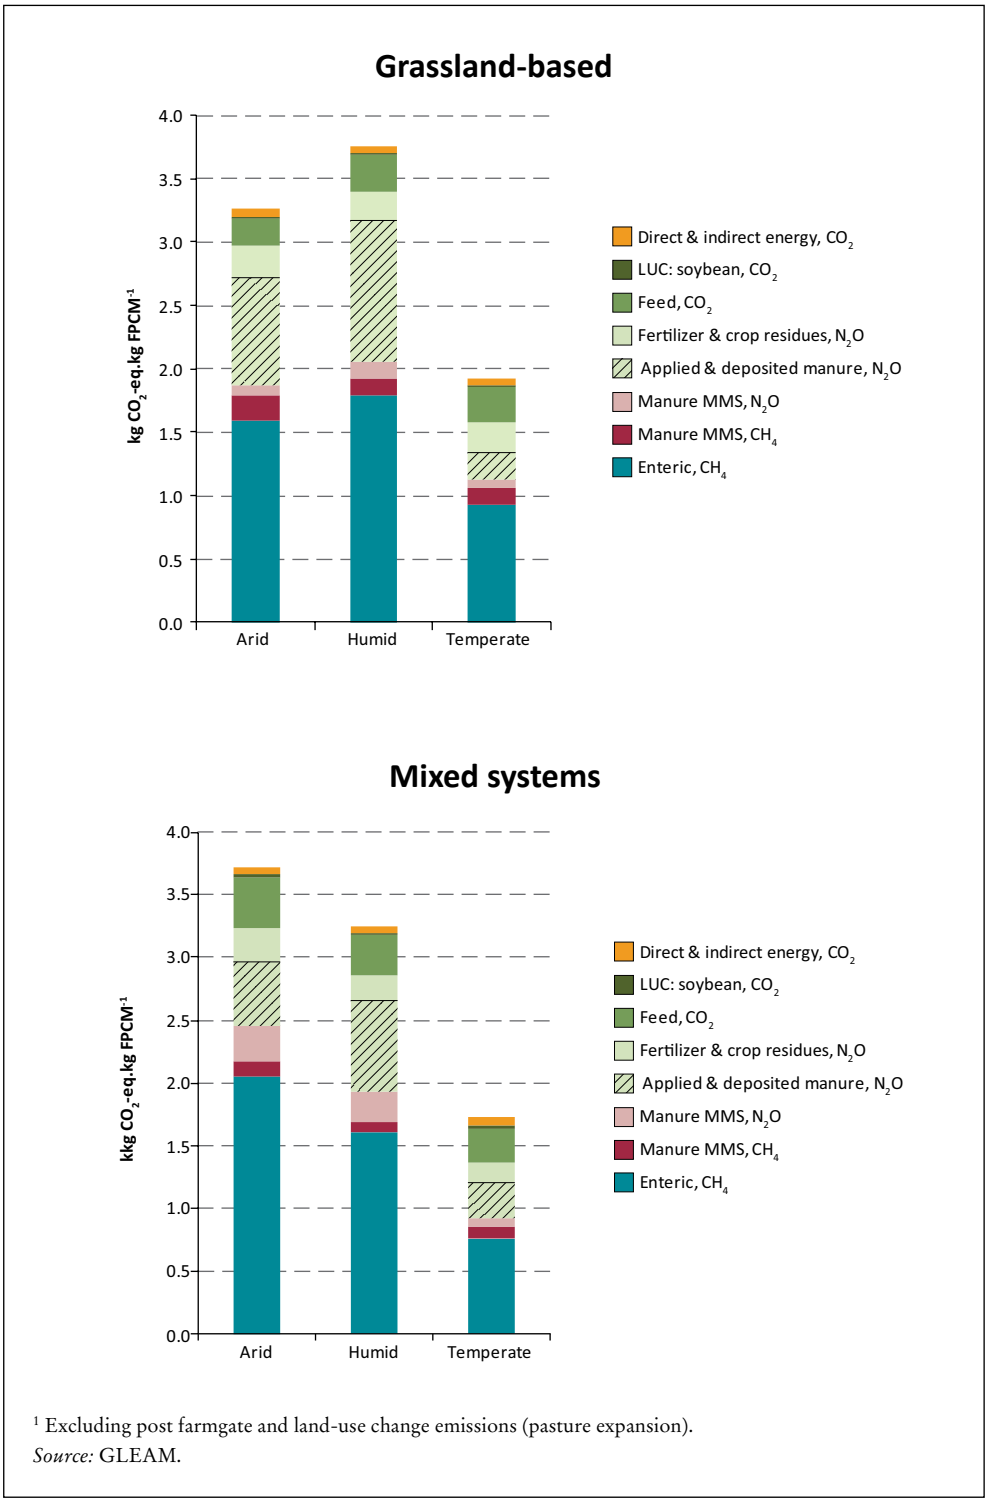
4.1.2 Emissions by production system and agro-ecological zone

Grass-based systems and mixed livestock production systems contribute 22 and 78 percent of global beef production, and 15 percent and 84 percent of global milk production, respectively (Figure 6).

Average emission intensities for milk and beef produced in grazing and mixed farming systems were estimated at 2.9 and 2.5 kg CO_2-eq/kg FPCM and 42.0 and 38.4 kg CO_2-eq/kg CW, respectively. The variation in emission intensity between the two systems is explained by several factors such as the generally higher slaughter weights, lower age at calving, reduced time to slaughter, and lower mortality rates and better feed quality in mixed farming systems.

Lowest emission intensity in milk and beef production corresponds to the temperate zones in both grassland-based and mixed farming systems (Figures 7 and 8), where productivity is rather high and CH_4 from enteric fermentation is low as a consequence of high digestibility of the feed in these zones. Concomitantly, temperate zones have slightly higher emissions associated with CO_2 feed compared with the humid and arid areas as a result of the high dependency on imported concentrate feed and synthetic fertilizer use in feed production. Lower emission intensity of beef produced in temperate zones is also related to the importance of dairy production in these areas; about 44 percent of the beef from the dairy sector is produced in temperate zones. Beef from the dairy sector as a consequence of the dairy system characteristics comes with discounted emissions because a large share of the emissions related to the meat from culled breeding animals is allocated to milk production.

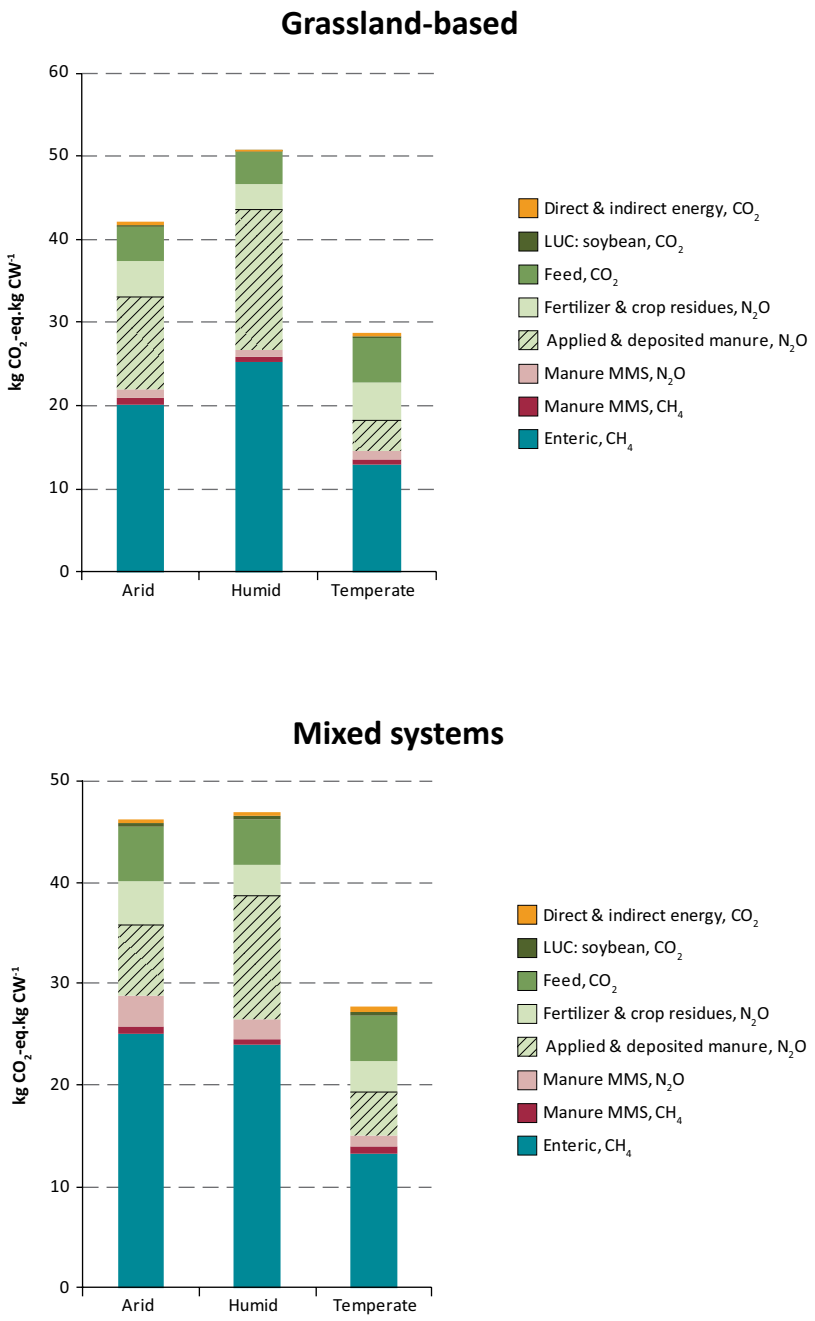
Enteric CH_4 is the largest source of emissions in all systems; however it is highest in arid and humid zones of both grazing and mixed farming systems where feed, for the most part, is of low quality.



Nitrous oxide emissions from feed production are dominant in both grazing arid and humid zones resulting from manure deposited on pasture during grazing, while in the mixed systems high N_2O emissions are not only associated with manure deposition but also use of synthetic fertilizer in feed production (see Section 5.2).

On the other hand, CH_4 emissions from manure management in both systems are negligible and this is explained by the high proportion of manure that is managed in dry MMS such as drylots or solid systems. Nitrous oxide from manure management is generally low especially in grazing systems because animals are grazing most of the time and manure is mostly deposited on pasture.

4.1.3 Regional emissions, production and emission intensities



In terms of total production, approximately 67 percent of the total protein from the global cattle sector is from milk. However, this global estimate obscures variations at regional level, where large differences exist both in terms of production and emissions. With the exception of Latin America and the Caribbean, the contribution of milk protein to the total protein from the cattle sector on average ranges from 56 percent in sub-Saharan Africa to 81 percent in Western Europe (Figure 9; Map 6 in Appendix G). In Latin America, meat protein contributes about 54 percent of the

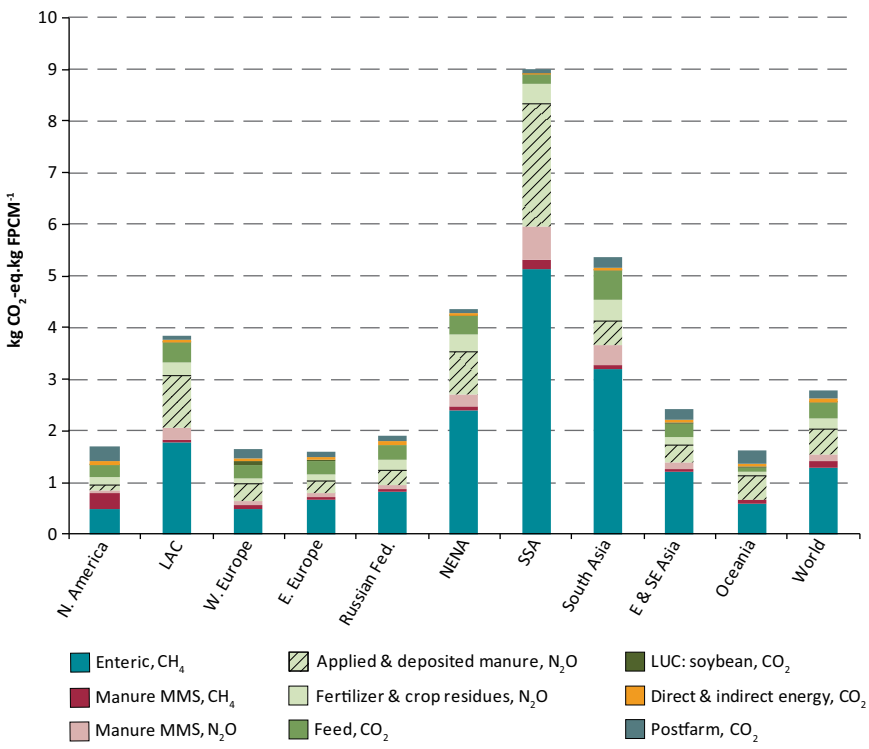
Emissions per kg meat and milk protein, comparing allocation of emissions to different outputs



Source: GLEAM.

total protein from cattle, mainly because the emphasis is on beef production rather than dairy. In the other world regions, meat protein ranges between 18 percent in Europe to 44 percent in sub-Saharan Africa.

Figure 10 presents a regional comparison of emission intensities for two computation approaches where (i) all emissions from cattle production are allocated to the main edible outputs from the system, milk and meat; and (ii) emissions related to other functions and processes, e.g. draught power and those related to the use of manure as a source of fuel, are deducted from the overall system emissions.

Figure 10 illustrates the difference in carbon equivalent impact and the extent to which production is specialized, i.e. whether it is meant for milk and meat production or whether animals are kept for other purposes. The starkest difference in emission intensity is shown for sub-Saharan Africa and South Asia where cattle herds are multi-purpose, producing not only edible products but also non-edible products and services that are utilized in other production processes within or outside the livestock sector boundary. In these regions, use of draught power is important as well as the use of manure as a source of fuel, and allocation of emissions to these products and services significantly lowers the emission intensity of edible products in these regions. In contrast, in industrialized regions, production is more specialized with cattle being specifically reared to produce meat and milk products. In these regions, emission intensity is generally lower, because production is more

Figure 11a.
Regional variation in GHG emission intensities for cow milk

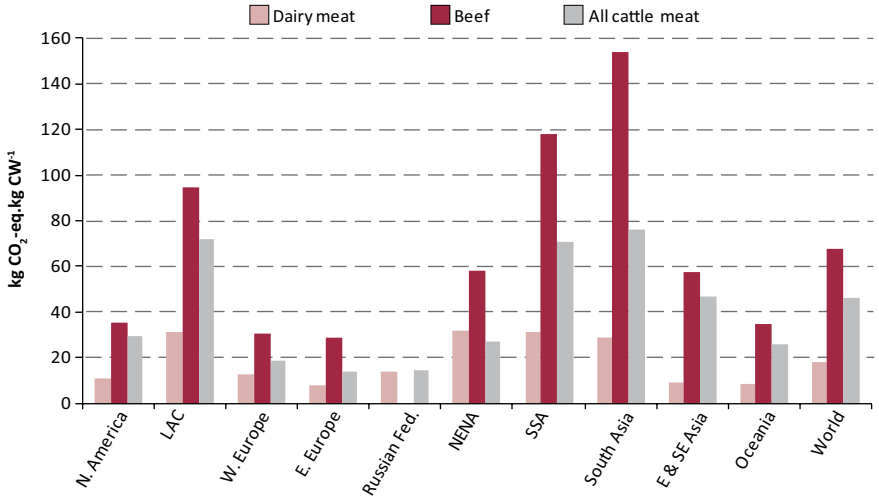
efficient, yields are higher, and animals are not kept for longer periods for other purposes such as draught power.

Figures 11a and 11b present regional variation in emission intensity for milk and meat (after allocation to draught and manure used for fuel) and the contribution of emission categories to the emission profile.

For milk, emission intensities vary from 1.6 kg CO_2-eq/kg FPCM in Eastern and Western Europe to 9 kg CO_2-eq/kg FPCM in sub-Saharan Africa (Figure 11a). Generally, industrialized regions of the world exhibit the lowest emission intensities per kg FPCM ranging between 1.6 and 1.7 kg CO_2-eq/kg FPCM, while in developing regions the range of emission intensity for milk is wider – 2.0 and 9.0 kg CO_2-eq/kg FPCM.



The main contribution to the GHG emission profile of milk in developing regions is enteric fermentation while in industrialized regions dominant emissions are largely related to feed production and processing. With regard to manure management, CH_4 emissions are highest in North America where on average 27 percent of manure from the dairy sector is managed in liquid systems that produce greater quantities of CH_4 emissions (see Section 5.3.1). In contrast, N_2O emissions from manure management are higher in developing regions as a result of the higher proportion of manure managed in dry systems.

Figure 11b.
Regional variation in GHG emission intensities for beef

Source: GLEAM.

Figure 12.
Regional comparison of emission intensity per kilogram of carcass

Source: GLEAM.

Regional variability in emission intensity for beef is presented in Figure 11b, with GHG emissions per kg carcass weight (CW) ranging from 14 kg CO_2-eq/kg CW in Eastern Europe and Russian Federation to 76 kg CO_2-eq/kg CW in South Asia. Highest emission intensities are found in developing regions: South Asia, sub-Saharan Africa, LAC and East and Southeast Asia. A key driver for the high emissions associated with beef is largely related to low feed digestibility, lower slaughter weights and higher age at slaughter. The carbon footprint of beef produced in Latin America comprises emissions related to land-use change from pasture expansion into forested areas. Consequently, land-use change is a major driver of emissions in the region, representing approximately one-third of the footprint (Figure 11b), equivalent to 24 kg CO_2-eq/kg CW. These LUC estimates are however associated with a high level of methodological uncertainty and do not capture recent deforestation trends (the period considered is 1990-2006).

The low emission intensities associated with beef in Europe (Western and Eastern Europe, and the Russian Federation) is explained by the large proportion of the beef produced from the dairy herd.[7] About 80 percent of the beef production in Europe is derived as a co-product from dairy production (from surplus calves and culled cows); in the Russian Federation, all beef is estimated to be produced by the dairy sector. The dairy sector therefore has a much higher impact on beef production in these regions and this is directly linked to the need for their dairy sectors to sustain milk production through production of calves in order to keep cows lactating. Figure 12 compares the regional emission intensity for beef produced by the dairy and beef herd and the average emission intensity of all beef produced by the cattle sector. The low emissions are also an artefact of the production characteristics of dairy herd (dual products) (see discussion on allocation techniques in Appendix A) and hence a large proportion of the emissions attribut-

[7] Table B22, Appendix B presents the contribution of dairy and beef herds to total beef production.

able to dairy cows is allocated to milk, resulting in a lower allocation to beef from the dairy herd.

The emission intensity for beef in Western Europe, North America and Oceania is lower than the global average mainly because these regions are key beef-producing regions characterized by high efficiency in production and high feed digestibility (Map 8 in Appendix G).

Table B13 in Appendix B illustrates average feed digestibility values for the average feed ration used in beef production in different regions. Highest feed digestility is found in industralized countries where feed rations are laregly composed of higher quality roughages and concentrates. The digestibility of average feed rations in developing regions is much lower, particulary in sub-Saharan Africa, South Asia and parts of East and Southeast Asia. Feed rations in this regions are laregly composed of roughages of low quality (grass, crop residues and leaves).

Regarding the contribution of different processes to the emission profile for beef, a distinct difference can be observed between the two broad regional groupings (developing and industrialized).

In developing regions, analogous to the dairy, the overall emission profile for beef is dominated by enteric CH_4 and N_2O emissions related to feed from manure deposited on pasture during grazing. The relatively higher N_2O emissions from manure management in sub-Saharan Africa, South Asia, and East and Southeast Asia reflects the higher share of manure managed in dry systems.

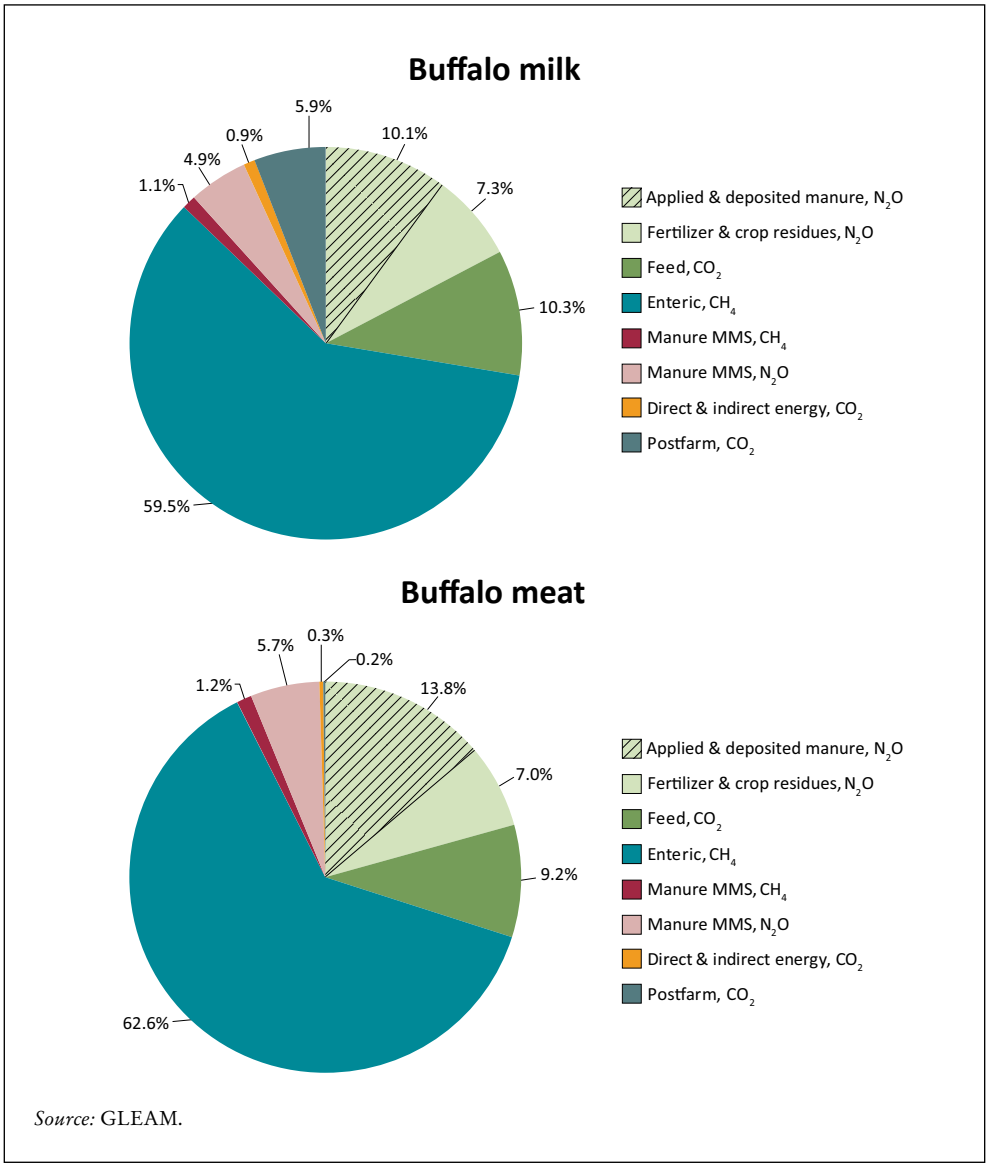
In contrast, enteric CH_4 emissions play a less important role in industrialized regions; however, this is compensated by high CO_2 and N_2O from feed emissions, reflecting a high dependence on feed imports, high fertilizer use in feed production and a higher level of mechanization (see Section 5.2).

4.2 BUFFALO

Milk and meat production from the global buffalo sector contributes an equivalent of 619 million tonnes CO_2-eq consisting of emissions from the production of meat and milk, emissions related to land-use change, emissions associated with post farmgate activities, and emission related to non-edible products and services, i.e. draught power and manure used for fuel.

4.2.1 Total production, absolute emissions, and emission intensities

In 2005, global buffalo milk and meat production amounted to 115.2 and 3.4 million tonnes, respectively, and associated with this, about 390 and 180.2 million tonnes CO_2-eq were emitted from the production of milk and meat from buffaloes, respectively (Table 5). On average, the emission intensity of buffalo milk and meat is estimated at 3.4 kg CO_2-eq/kg FPCM and 53.4 kg CO_2-eq/kg CW, respectively (Table 5). The emission intensity of meat produced by the dairy herd is significantly lower than that produced from the meat herd and the reasons are similar to those outlined in the previous sub-section on the cattle sector.



Enteric fermentation is by far the most important source of emissions, contributing over 60 percent of the emissions in both milk and meat production (Figure 13). Other important sources of emissions include emissions from feed production, particularly N_2O emissions from manure deposited largely determined by the long grazing period. Emissions from manure management (N_2O and CH_4 emissions) together contribute 6 percent and 7 percent of the total emissions from dairy and meat herds.

Table 5. Global production, emissions and emission intensity for buffalo milk and meat

Buffalo herd	Production *(million tonnes)*		Absolute emissions[1] *(million tonnes CO_2-eq)*		Average emission intensity *(kg CO_2-eq/kg product)*

Figure 13.
Relative contribution of different processes to GHG emission profile of buffalo milk and meat

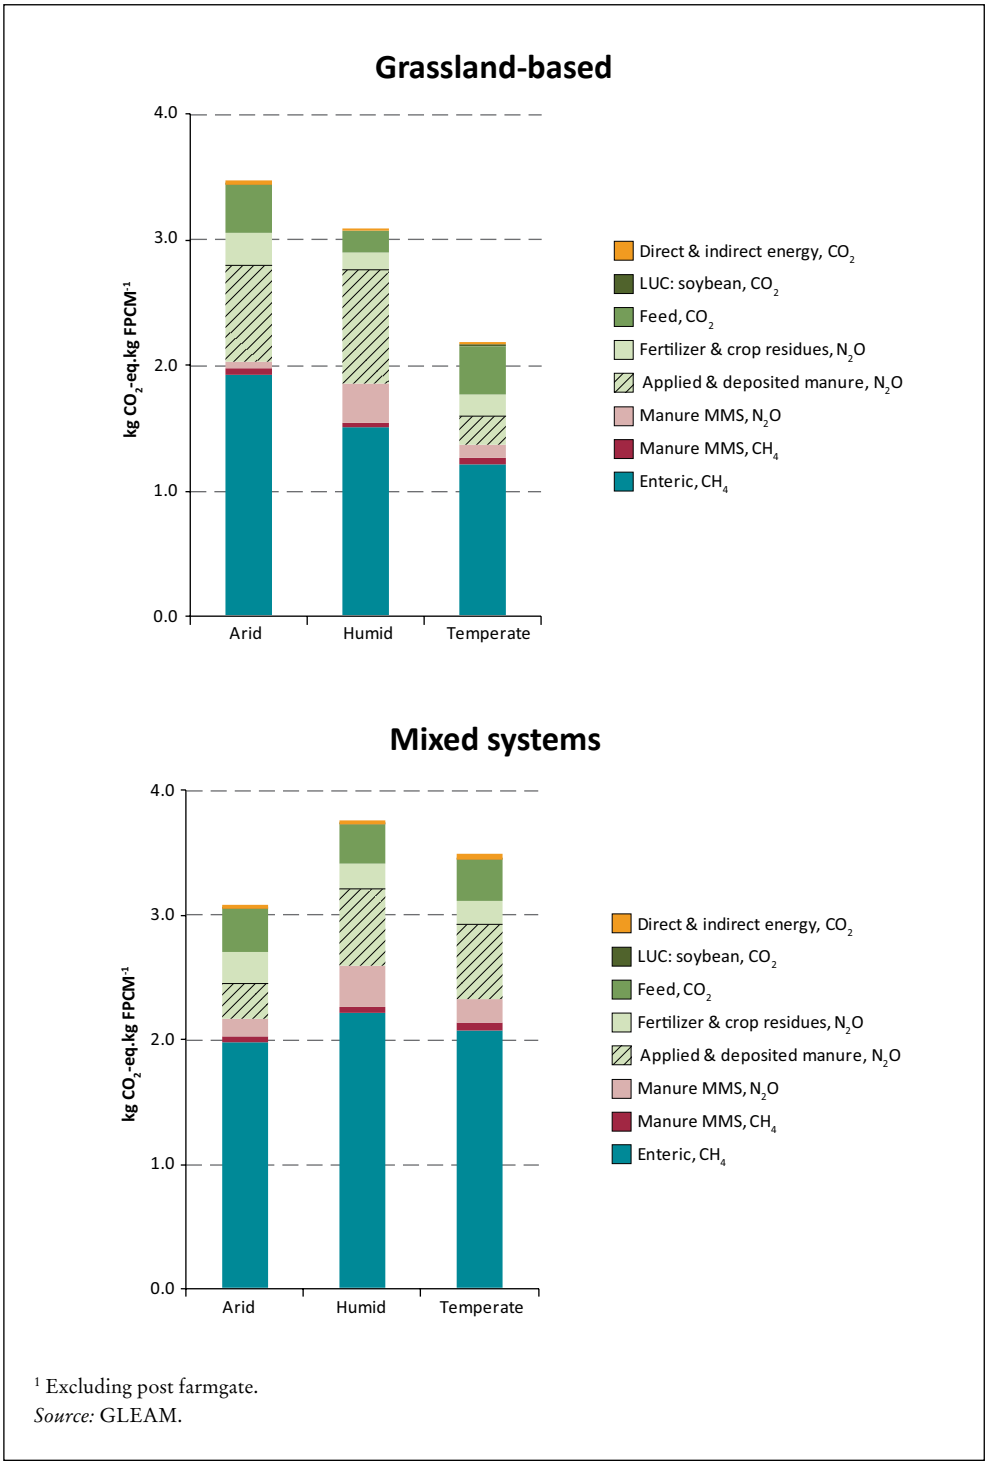
Source: GLEAM.

4.2.2 Emissions by production system and agro-ecological zone

Average emission intensity of buffalo milk from grazing and mixed farming systems is estimated at 3.4 and 3.2 kg CO_2-eq/kg FPCM, respectively. On the other hand, the emission intensity of buffalo meat from grazing and mixed farming systems is 36.7 and 54.0 kg CO_2-eq/kg CW, respectively. About 82 percent and 67 percent of milk and meat production from buffalo is produced in the mixed arid zones. Production in the other ecological zones is unimportant.

Lowest emission intensities for milk are found in the grazing temperate and mixed arid production systems (Figure 14).

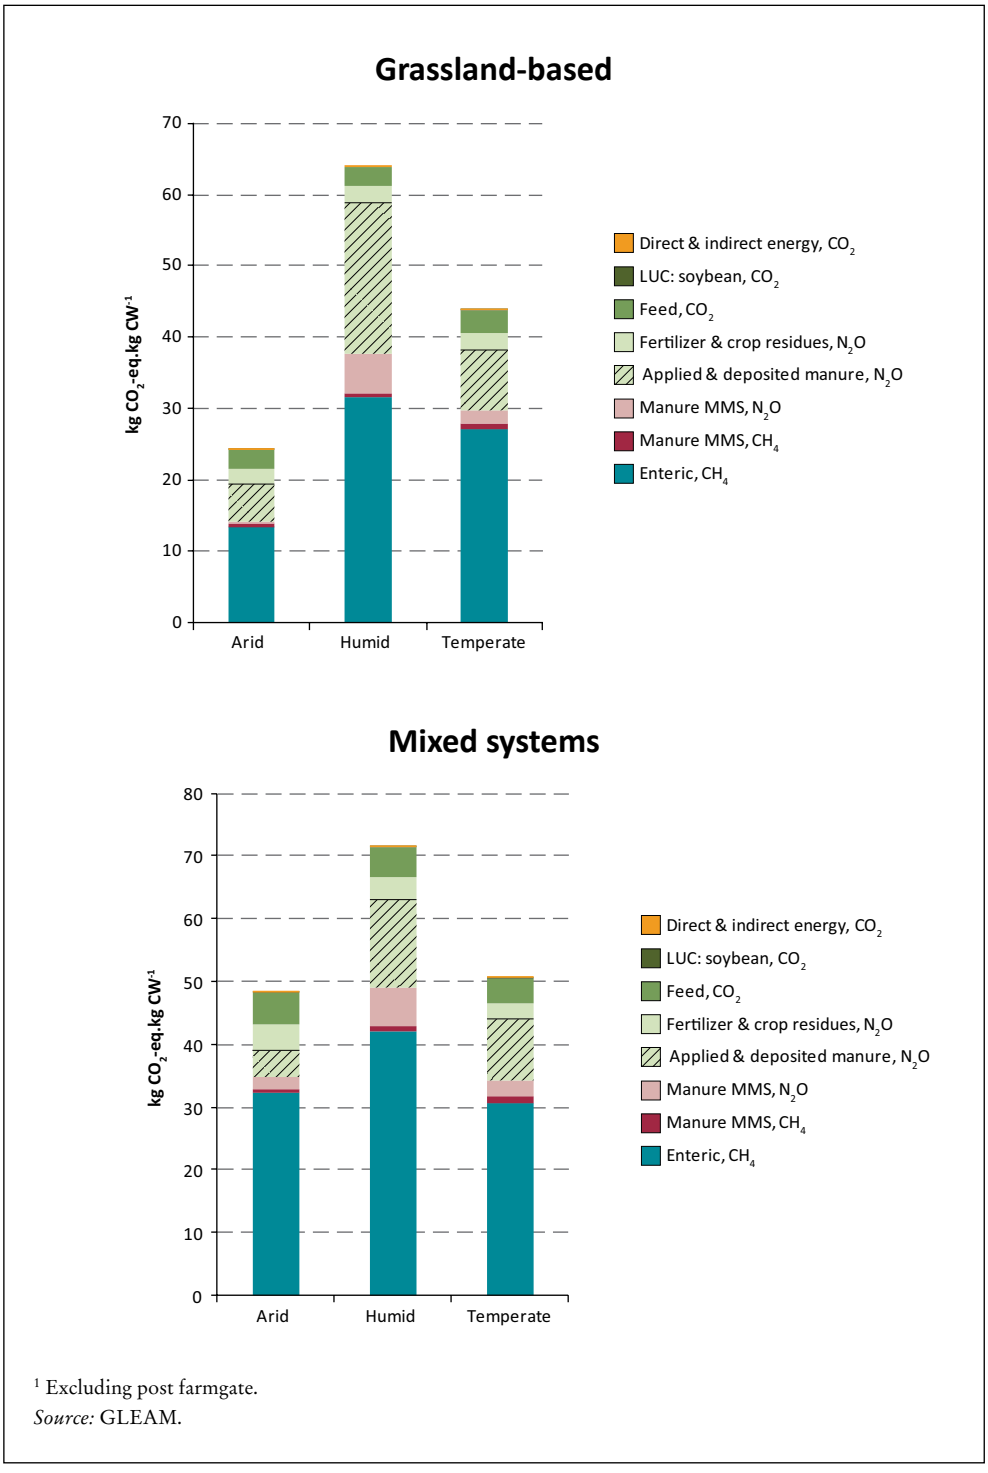
Lowest emission intensities for buffalo meat are found in the arid zones in both grazing and mixed systems (Figure 15), which contribute 70 percent of all buffalo meat, while humid zones in both systems have highest emission intensities. Important sources of emissions include: enteric fermentation, N_2O from feed production and grazing; and CO_2 emissions from feed production and processing. N_2O from manure and feed is an important source of emissions in the humid zones; these emissions are largely driven by the predominance of dry manure management systems and emissions from the deposition of manure on pasture. The remaining emissions are insignificant in terms of their contribution towards the carbon profile.



4.2.3 Regional production emissions and emission intensities

Global buffalo milk and meat production is important in three main world regions: South Asia, NENA and East & Southeast Asia; South Asia contributes 90 percent and 70 percent of the global buffalo milk and meat, respectively, and average milk emission intensity ranges from 3.2 to 4.8 kg CO_2-eq/kg FPCM (Figure 16a); milk produced in South Asia has the lowest emission intensity, explained by high yields. Emission intensity in South Asia is similar to the global average, explained by the fact that the bulk of buffalo milk (90 percent) is produced in the region.

On the other hand, the emission intensity of buffalo meat production at regional level ranges from 21 kg CO_2-eq/kg CW in NENA to 70.2 kg CO_2-eq/kg CW in East & Southeast Asia (Figure 16b). Key buffalo meat producing regions include South Asia (producing 70 percent of the global production), East & Southeast Asia (20 percent) and NENA (5 percent).



Enteric CH_4 and feed N_2O emissions associated with feed production are the dominant sources of emissions. Key sources of emissions in the buffalo carbon profile comprise CH_4 from enteric fermentation (contributing more than half of the carbon footprint), and CO_2 and N_2O emissions associated with feed production. Nitrous oxide emissions from manure management are significant in East & Southeast Asia, where manure is managed in dry and solid systems.

4.3 SMALL RUMINANTS

The contribution of the small ruminant sector to GHG emissions is equivalent to 474 million tonnes CO_2-eq. These total emissions from the sheep and goat production comprise emissions from production of edible (meat and milk) and non-edible products (natural fibre) as well as emissions from post farmgate processes. The discussion in subsequent sections presents total emissions and emission intensities related to small ruminant production at global, farming system and regional grouping levels for edible products.

4.3.1 Total production, absolute emissions, and emission intensities

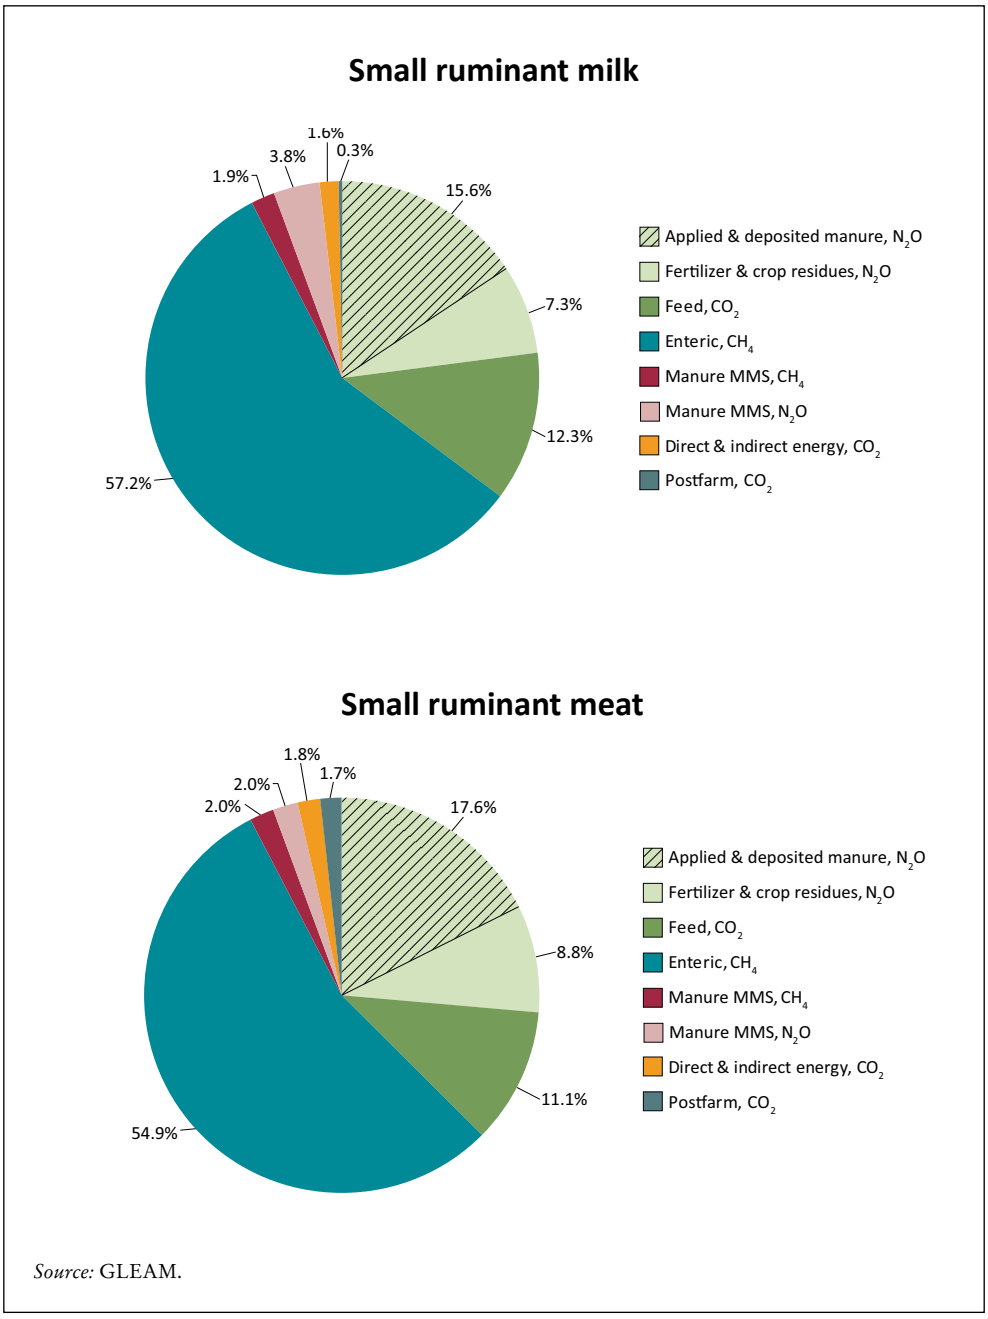
Globally, small ruminant production of meat and milk is responsible for 428.8 million tonnes CO_2-eq, of which 254.4 million tonnes CO_2-eq (59 percent) are associated with sheep production and 174.5 tonnes CO_2-eq (41 percent) are associated with goat production. Total production from the small ruminant sector amounts to 20.0 and 12.6 million tonnes of milk and meat, respectively. Goats contribute almost 60 percent of the milk produced by small ruminants, while sheep contribute 62 percent of the meat (Table 6).

On average, the emission intensity of small ruminant milk is 6.5 kg CO_2-eq/kg FPCM. In terms of emission intensity, goat's milk has lower emission intensity (5.2 kg CO_2-eq/kg FPCM compared with 8.4 kg CO_2-eq/kg FPCM for milk from sheep) due to higher yields compared with milk from sheep. Average emission intensity for small ruminant meat is 23.8 kg CO_2-eq/kg CW, while emission intensity for sheep and goats meat is quite similar – 24.0 and 23.5 kg CO_2-eq/kg CW, respectively (Table 6).

Similar to cattle and buffalo, CH_4 emissions are important, accounting for half of the total emissions associated with small ruminant production (Figure 17). Enteric fermentation is the single most important emission category in both milk and meat production, contributing 57 percent and 55 percent of the total GHG emissions from milk and meat production, respectively.

Nitrous oxide emissions amount to relatively similar proportions (27 percent and 28 percent) of the total carbon footprint for both milk and meat. Within this, N_2O emissions from manure storage and management are insignificant (4 percent and 2 percent for milk and meat, respectively), mainly because small ruminants are grazing most of the time and consequently a very small proportion of the manure is managed.

Table 6. Global production, emissions and emission intensity for small ruminants



Species	Production *(million tonnes)*		Absolute emissions[1] *(million tonnes CO_2-eq)*		Average emission intensity *(kg CO_2-eq/kg product)*	
	Milk[2]	Meat[2]	Milk	Meat	Milk[2]	Meat[2]
Sheep	8.0	7.8	67.4	186.9	8.4	24.0
Goats	12.0	4.8	62.4	112.5	5.2	23.5
Totals	**20.0**	**12.6**	**129.4**	**299.4**	**6.5**	**23.8**

[1] Absolute emissions include emissions from production and post farmgate emissions.

Source: GLEAM.

Figure 17.
Relative contribution of different processes to GHG emission profile of small ruminant milk and meat

Source: GLEAM.

Within the emissions profile, CH_4 from manure management is unimportant because virtually all manure is either deposited on pasture or managed in dry systems such as drylots and solid storage systems (see Table B19, Appendix B). Emissions associated with feed production comprising both N_2O (mainly from manure) and CO_2 emissions amount to 35 percent of the total emissions. Carbon dioxide emissions from on-farm energy use and embedded energy as well as post farmgate activities make a relatively small contribution towards the overall carbon footprint.

4.3.2 Emissions by production system and agro-ecological zone

Emission intensity for milk is higher in grazing systems with an average of 7.6 kg CO_2-eq/kg FPCM compared with 6.6 kg CO_2-eq/kg FPCM in mixed farming systems (Figure 18). A similar trend is found for small ruminant meat; average emission intensity per kg CW is 24.0 and 23.2 kg CO_2-eq/kg CW in grazing and mixed systems, respectively (Figure 19).

In small ruminant milk production in grazing systems, emissions intensity is highest in temperate zones, a trend which contrasts with the emission intensity trends for dairy cattle (see Figure 7). The higher emission intensity for small ruminant milk in grazing temperate zones is explained by a combination of factors: (i) total emissions are dominated by emissions from the temperate areas in regions such as Asia and Africa, where production conditions are poor for the most part; (ii) sheep milk production dominates small ruminant milk in the temperate zones, however milk yields from sheep are much lower compared with goats; and (iii) goats milk, which is characterized by higher yields per animal, mainly occurs in the arid areas.

On the other hand, for small ruminant meat there is no systematic trend across production systems; in grazing systems, highest emission intensity is found in temperate zones, while in mixed systems, meat produced in the arid zones has the highest emission intensity.

The difference in emission intensity of small ruminant meat is explained by a combination of factors: (i) high emission intensity in grazing temperate areas is related to the fact that in temperate zones small ruminants, particularly sheep, are reared for mainly for meat and therefore the carcass bears the whole burden of emissions; (ii) temperate grazing areas are also characterized by low yields, which are closely related to poor production conditions and low feed digestibility, hence the high emission intensity.

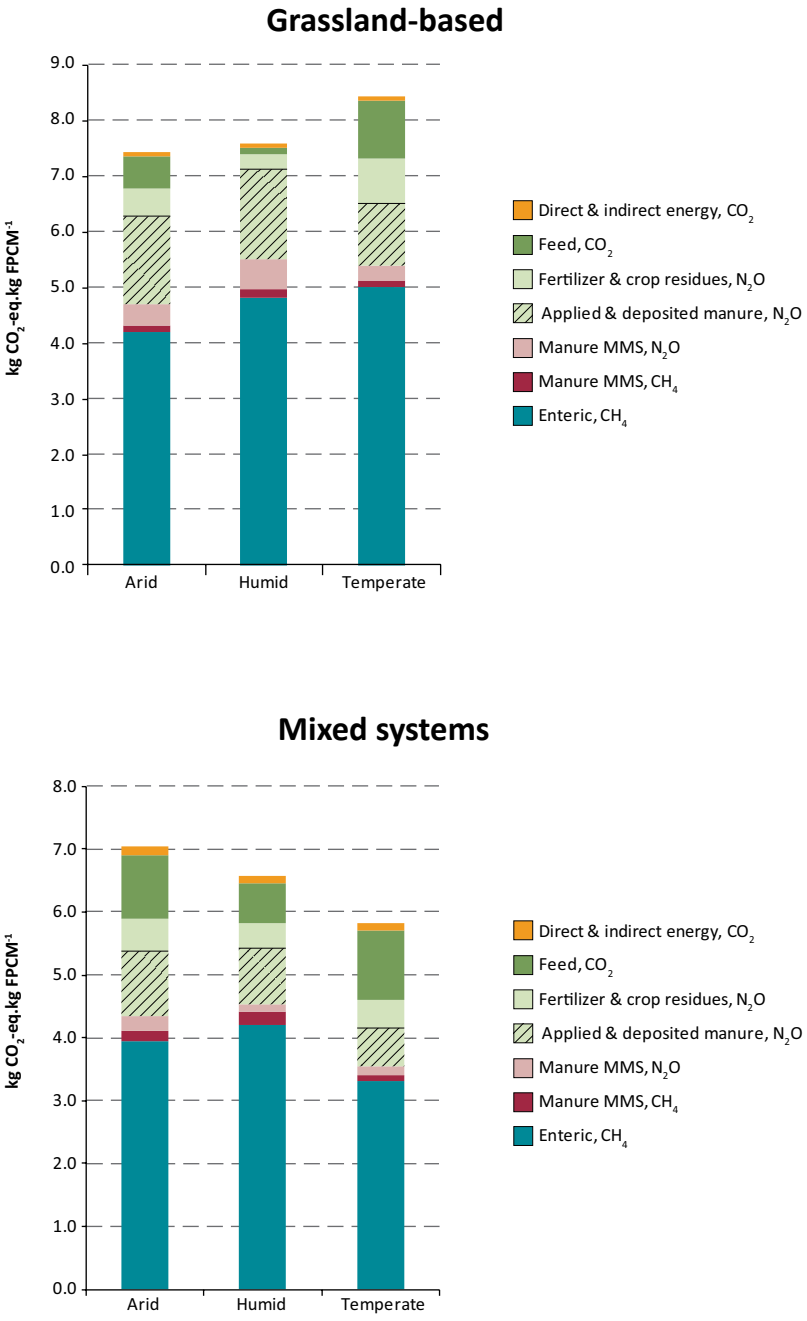

Figure 19, however, masks much of the variation that can be found within similar production systems and climatic conditions. Disaggregated emission intensity at production system level show temperate zones in grassland-based systems with highest emission intensity, about 27.5 kg CO_2-eq/kg CW. However, regions such as Oceania and W. Europe show a contrasting trend, with lowest emission intensities within this production system and AEZ typology (13.7 and 19.8 kg CO_2-eq/kg CW, respectively) as a result of their efficient production systems. Within temperate grassland-based systems, the predominance of other regions such as East & Southeast Asia, NENA and Latin America & Caribbean drive the emission intensities of the system. These high emissions are largely related to poor quality feed, poor performance of animals, and slower growth rates.

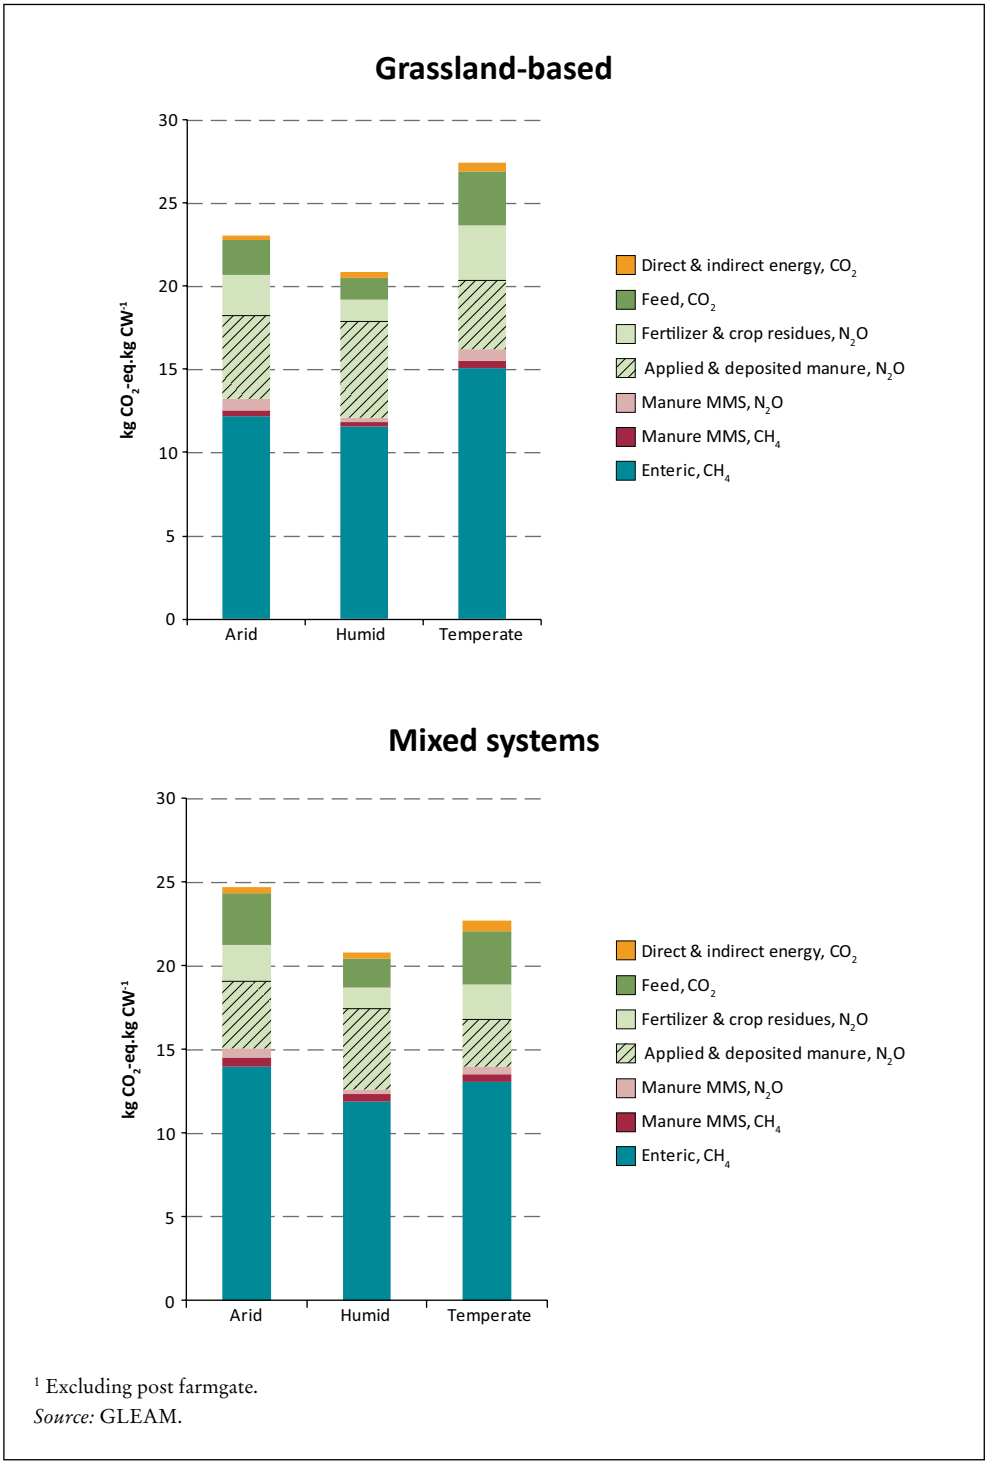
Methane emissions from enteric fermentation dominate the emission profile in both systems and across all three AEZs. Nitrous oxide emissions associated with feed production are relatively higher for grassland-based systems and this arises from the deposition of manure on pasture.

The high CH_4 emissions from manure management in the mixed farming systems relative to grazing systems indicate the management of manure in systems other than pasture-based systems.



CO_2 emissions related to feed production, transport and processing are important in the temperate areas in both systems, accounting for 12 percent and 19 percent, respectively, and 12 percent and 14 percent, respectively, of the average carbon footprint of small ruminant milk and meat produced in grazing and mixed temperate zones.

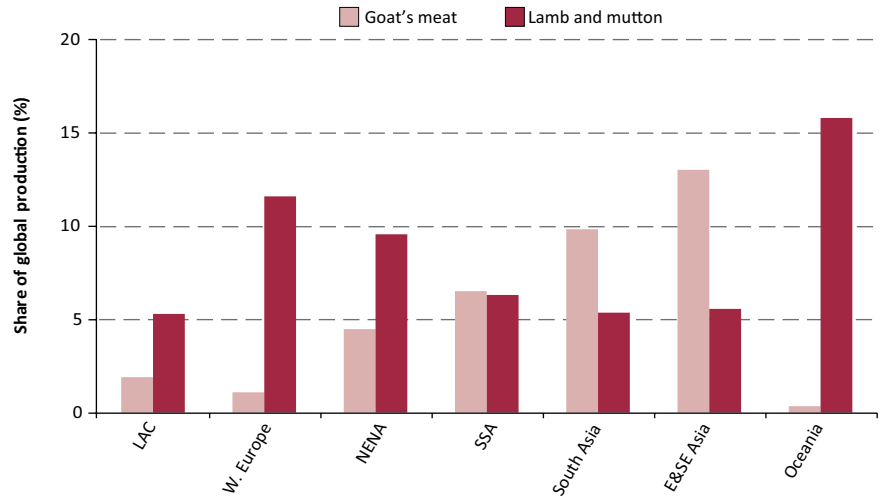
4.3.3 Regional production, emissions and emission intensities

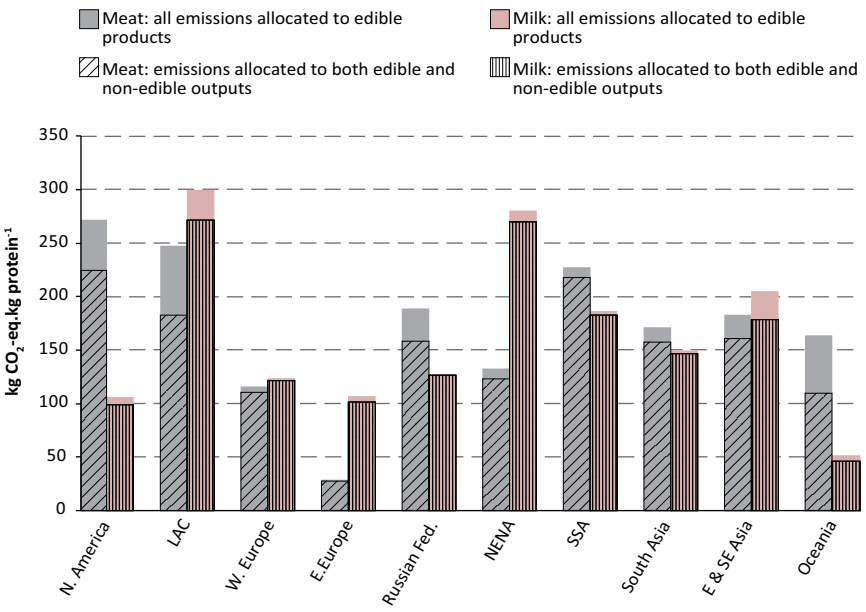
The production of small ruminant milk and meat is largely concentrated in developing regions. Figures 20a and 20b illustrate this trend; with the exception of small ruminant milk production in Western Europe and lamb and mutton production in Oceania and Western Europe, small ruminant production is generally more important in developing world regions.



Small ruminants produce not only edible products; other important co-products include natural fibre such as wool, cashmere and mohair. As mentioned in Section 3.6 of this report, we have applied an economic value allocation to partition total GHG emissions between the edible products (meat and milk) and non-edible products (natural fibre). Figure 21 illustrates the impact of allocation to co-products.

Figure 21 illustrates those regions where the natural fibre production is important and has a high economic value compared with edible products, such as North America, Latin America & Caribbean, Oceania, and East & Southeast Asia. In the other regions, natural fibre production is generally not profitable and of low economic value.

At a regional level, emission intensity for small ruminant milk ranges from 4.7 kg CO_2-eq/kg FPCM in Western and Eastern Europe to almost 8.9 kg CO_2-eq/kg FPCM in East & Southeast Asia. Emissions in NENA, sub-Saharan Africa and South Asia are 8.7, 6.9, and 4.9 kg CO_2-eq/kg FPCM, respectively (Figure 22a). Within the developing regions, South Asia has the lowest emissions explained by high milk productivity. Overall, across the regions, goats milk tends to have lower emission intensity mainly because of the higher productivity compared with sheep.



Methane from enteric fermentation is the dominant source of emissions in developing regions, ranging from 60 percent of the GHG emissions profile in South Asia to 69 percent in sub-Saharan Africa. For developing regions, N_2O emission related

to feed production is a significant source of emissions as a result of the deposition of manure during grazing (see Section 5.3 in Chapter 5). While CH_4 emissions from manure are negligible in most regions because manure is mainly managed in dry systems, in South Asia and East & Southeast Asia, CH_4 emissions from manure are slightly higher as a result of the higher temperatures in warmer climatic zones.

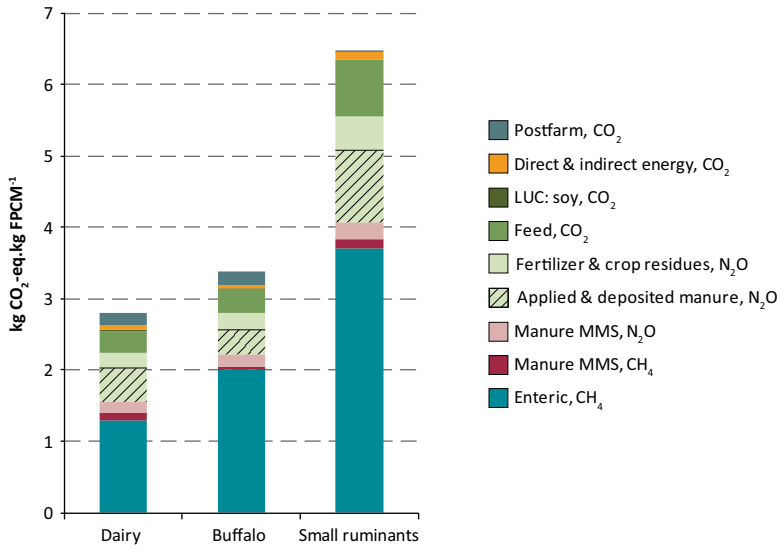
In most regions, N_2O from manure management is also negligible because a large proportion of the manure produced is deposited on pasture and these emissions are captured in feed production (in this analysis, manure deposited on pasture is considered as a fertilizer). However, NENA, sub-Saharan Africa, South Asia and East & Southeast Asia have relatively high N_2O emissions from manure because manure is not only deposited on pasture but also managed in other MMS such as drylot or solid systems which tend to have higher rates of conversion of N excreted to N_2O emissions.

Emissions of meat from small ruminants range from as low as 15 kg CO_2-eq/kg CW in Oceania to 31 kg CO_2-eq/kg CW in sub-Saharan Africa. Very little variation exists within the developing regions; emissions for East & Southeast Asia, Latin America, NENA and South Asia are 23.0, 25.5, 27.9 and 29 kg CO_2-eq/kg CW, respectively (Figure 22b). Contributions of different sources to emission intensity, differences among regions and the underlying reasons are very much the same as described above for milk.

Post farmgate emissions per kg carcass weight in Oceania are significant because of the importance of mutton and lamb exports from Australia and New Zealand. The two countries supply a major portion of global lamb and mutton exports, equivalent to 50 percent and 67 percent of their total production in 2005, respectively.

4.4 SUMMARY OF RESULTS

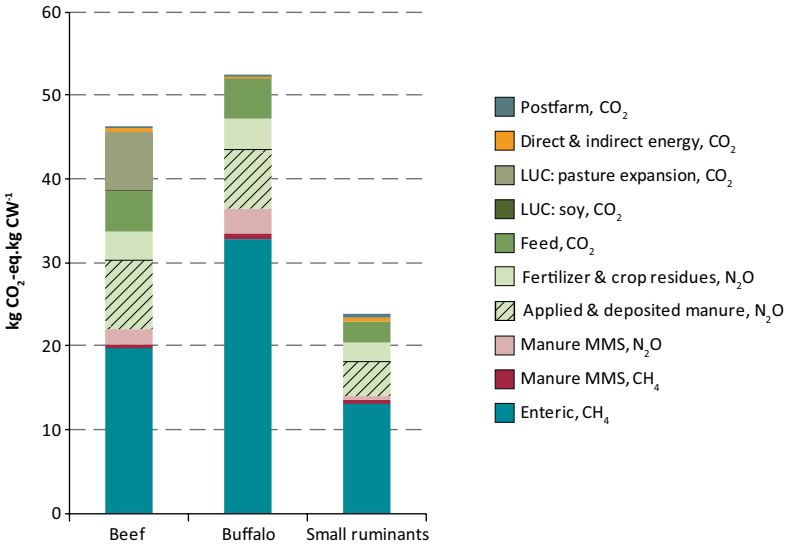
4.4.1 Comparison between ruminant species



Despite the similarities in emission profiles, there are differences among cattle, buffalo and small ruminant species. The carbon footprint for milk from small ruminants is more than double that of milk from dairy cattle and buffalo: 6.5 kg CO_2-eq/kg FPCM vs. 2.8 and 3.4 kg CO_2-eq/kg FPCM, respectively (Figure 23a). With regard to meat from ruminants, small ruminant meat has a smaller carbon footprint compared with that of beef; 23.8 kg CO_2-eq/kg CW vs. 46.2 and 53.4 kg CO_2-eq/kg CW for beef and buffalo meat, respectively (Figure 23b).

Among the edible commodities produced by ruminant systems, milk generally has the lowest emission intensity compared to meat suggesting that dairy systems are more efficient than pure meat systems. This is because dairy herds produce both milk and meat while beef systems are maintained mainly for calf production.

The difference in emission intensity among ruminant species can be attributed to a number of factors such as:



- Higher milk yields from dairy cattle and buffalo as opposed to small ruminants;
- Greater fecundity, and faster reproductive cycles and growth rates in small ruminants;
- Larger supporting breeding herds are required to sustain the production of beef; non-productive animals produce CH_4 and urinary-N without contributing to milk and meat production; and
- Whether LUC is associated with the production process.

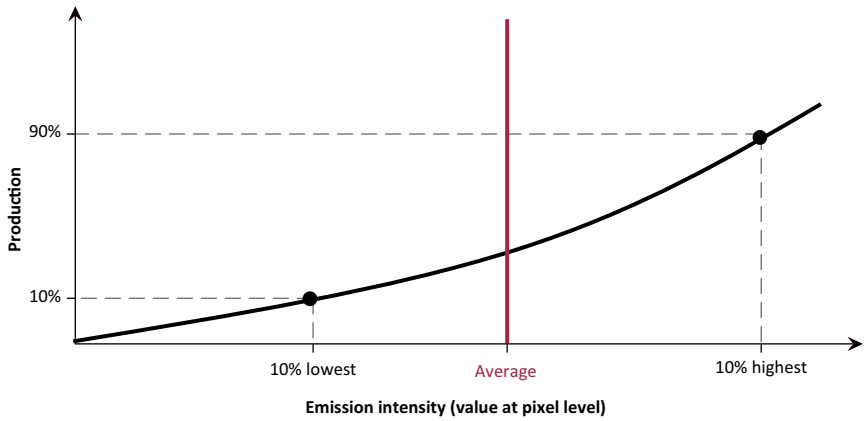
Figure 23a.
Average emission intensity for milk from cattle, buffalo and small ruminants

Source: GLEAM.

Figure 23b.
Average emission intensity for meat from cattle, buffalo and small ruminants

Source: GLEAM.

This assessment also found a wide diversity in emission intensity at regional and production system level. These variations are largely driven by differences in production goals (specialized versus non-specialized production) and management practices, including animal husbandry methods, animal health and genetics which influence levels of productivity.



4.4.2 Emission intensity gap within systems, climatic zones and regions

The comparison of emission intensity for ruminant commodities produced within the same region and comparable production conditions (production systems and agro-ecological zones) shows the existence of a considerable emission intensity gap. Average emission intesities within each region for each combination of production system and climatic zone as well as the lowest and highest emission intesity of pixels accounting for 10 percent of the production in the same system-region-AEZ were assessed. Figure 24 is a schematic representation of the analytical approach used to assess the emission intensity gap within regions, production systems and climatic zones.

Tables 7-9 provide an illustration of this variation in emission intensity for cattle (dairy and beef), buffalo milk and small ruminants (milk and meat). The emission intensity gap is particularly substantial in dairy and beef production. For example, in mixed temperate dairy systems in sub-Saharan Africa, the average emission intesity is 7.6 kg CO_2-eq/kg FPCM, compared to 1.6 and 13.3 kg CO_2-eq/kg FPCM in lowest and higher 10 percent, respectively (Table 7).

Within the dairy mixed and grassland-based systems in sub-Saharan Africa, Latin America and the Caribbean, and East and Southeast Asia, the emission intensity of the lowest 10 percent is comparable to other regions with similar production conditions. This is explained by the dominance of high productive countries within these systems and climatic zones. For example, in sub-Saharan Africa, within the dairy mixed and grassland-arid zones, South Africa alone accounts for almost 25 percent

of production in this regional-system-climatic zone with emission intensity ranging between 1.4 and 1.8 kg CO_2-eq/kg FPCM. Similarly, in mixed and grassland-based systems in temperate zones, South Africa contributes 20 and 70 percent of the regional production, respectively, with emission intensity ranging between 1.5 and 1.9 kg CO_2-eq/kg FPCM.

In Latin America and the Caribbean, milk production in Mexico in both grassland and mixed arid and temperate areas represents 30 percent of the production within these regional climatic zones and emission intensity ranges between 1.4 and 1.9 kg CO_2-eq/kg FPCM.

High milk productivity systems in countries such as Israel and Saudi Arabia within the arid zones result in low emission intensity (range between 1.2-1.5 kg CO_2-eq/kg FPCM for Israel and 1.1-2.0 kg CO_2-eq/kg FPCM for Saudi Arabia). About 23 percent of production within the mixed temperate dairy system in East and Southeast Asia occurs in Japan with a range of emission intensity 1.2 to 1.4 kg CO_2-eq/kg FPCM.

This variation highlights the heterogeneity within each production system and emphasizes the opportunities for reducing emission intensity particularly in low productive regions by bridging the gap in emission intensities between efficient producers and producers with a potential for improvement. This mitigation potential doesn't require changes in farming systems and can be based on already existing technologies and practices. It is estimated to 30% of the sector's total emissions and further explored in the overview report published in parallel to the current one (FAO, 2013a). This situation is completed by case study analysis to explore regional dimensions of mitigation in the sector.

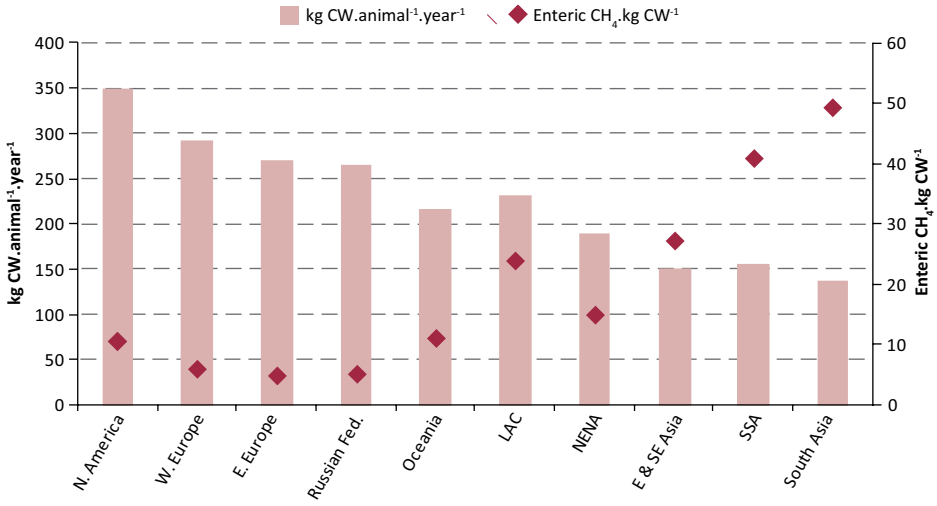
5. Discussion

This section discusses the key drivers of variation in emissions from major processes in the ruminant supply chain that contribute significantly to the carbon footprint of ruminant species, highlighting differences among species and world regions. The section also discusses some of the parameters and assumptions that could strongly influence the results.

5.1 METHANE EMISSIONS FROM ENTERIC FERMENTATION



Regardless of the species, the largest source of GHG emissions in ruminant production is CH_4, with more than 90 percent originating from enteric fermentation and the rest from manure. Globally, enteric fermentation from cattle, buffalo, and small ruminants contributes 2 448 million tonnes CO_2-eq, of which 76 percent is emitted by cattle and 14 percent and 10 percent by buffalo and small ruminants, respectively. The production of enteric CH_4 from ruminants is mainly affected by feed intake and feed quality which, in turn, defines the total energy and nutrient intake and consequently animal performance.

Many of these factors are interrelated, some of which affect net emissions and others emission intensity. At animal level, net emissions are influenced by feed intake and digestibility, while emission intensity is a function of net emissions, yield per animal, health and genetics. At herd level, factors affecting net emissions are similar to those cited above, while emission intensity is determined by issues such as reproductive and mortality rates, herd structure, management, etc. The following sections discuss some of the important factors that drive the variation in enteric CH_4.

Productivity. Productivity is an important factor in explaining the variation of emissions among different production typologies. Studies show a close correlation between carbon footprint and yield per animal (Capper *et al.*, 2008; Gerber *et al.*, 2011; Cederberg and Flysjo, 2004), highlighting the trend of decreasing emission intensity with increasing productivity. Regions and production systems with greater productivity have lower emission intensity partly because high yields shift the distribution of feed towards less feed for maintenance functions and more for production. As productivity per animal increases, CH_4 emissions per animal are typically higher because of higher feed intake. However, as the productivity of each animal increases, the farmer can reduce the herd size to produce the same amount of output.

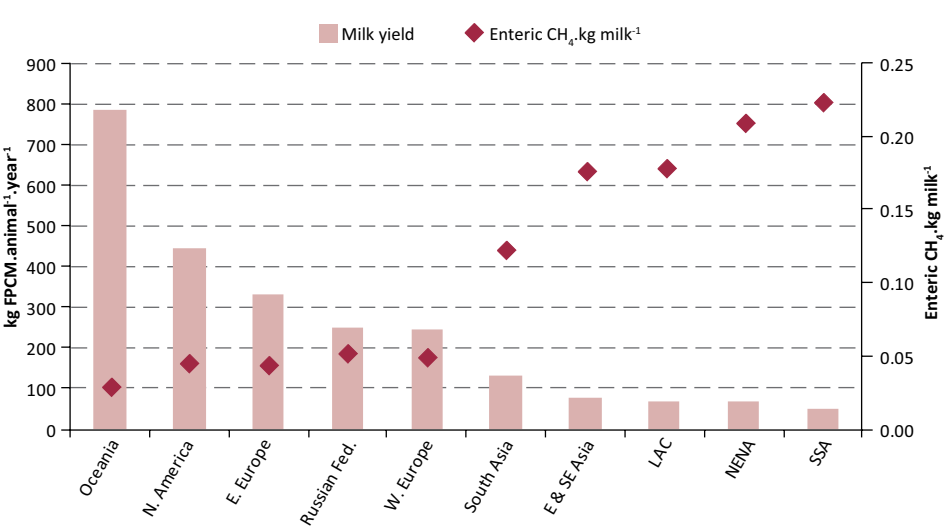


Figure 25a illustrates the differences in emission efficiency among the regions; the main reason for the differences is to be found in low productivity of the herd, which is in turn caused by low fertility, high mortality rates, low growth rates and low feed digestibility (see Appendix B). Gerber *et al.* (2011) have demonstrated the relationship between the carbon footprint of dairy cattle milk and productivity, and a similar trend has been established for small ruminants (Figure 25b). Lower-producing dairy animals tend to lose more feed energy as CH_4 per unit of milk produced. The benefits of improving animal productivity on CH_4 emissions results from the *dilution effect* of fixed maintenance where increasing productivity

Figure 25a.

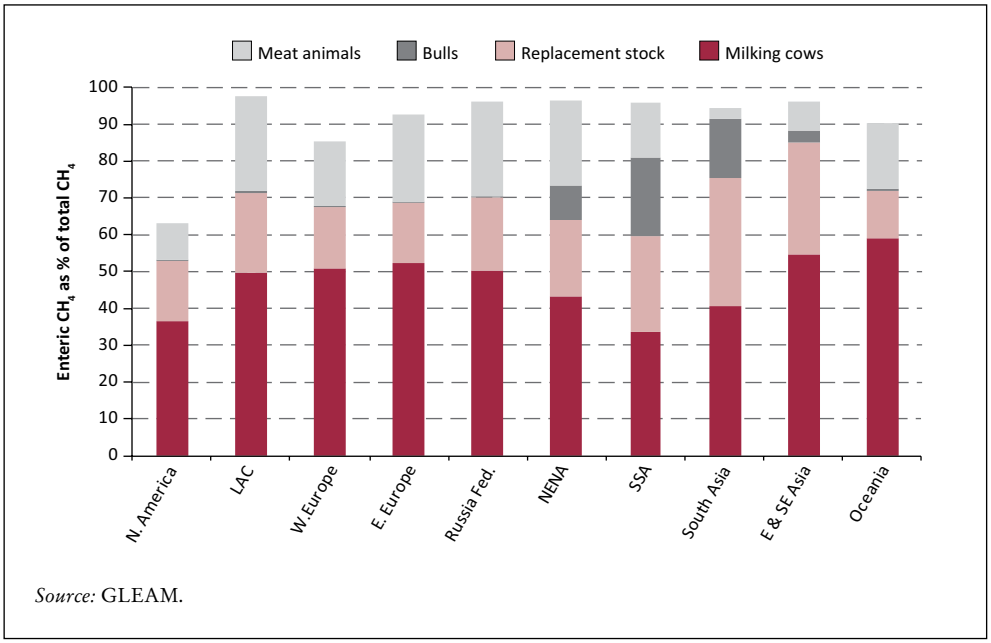
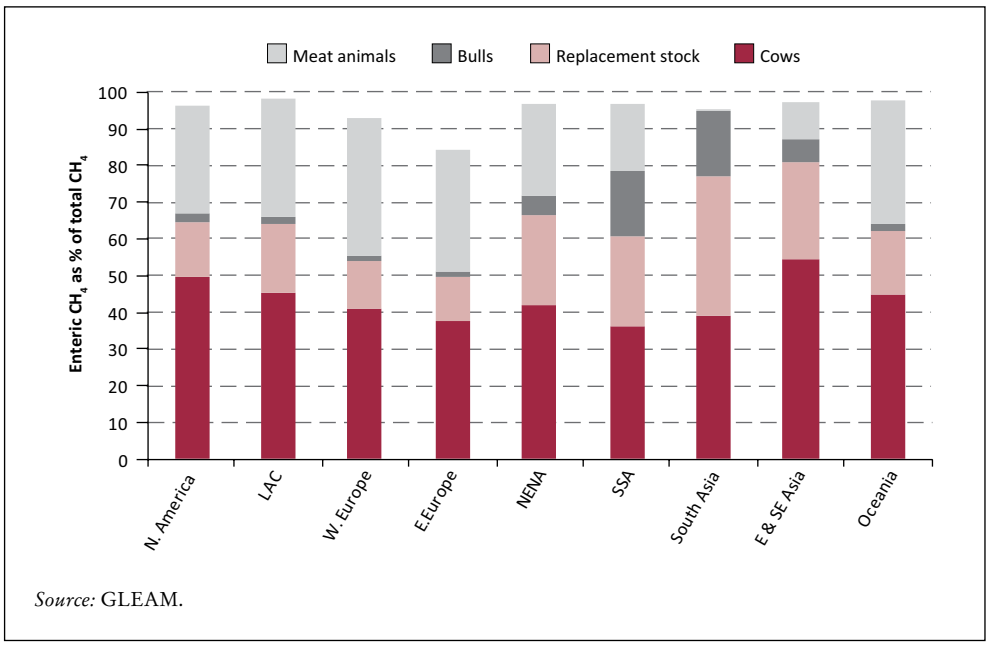
Regional variation in digestibility of the feed ration and CH_4 emissions from enteric fermentation for beef cattle



Source: GLEAM.

decreases the amount of CH_4 emitted per unit of product because emissions that arise from energy requirements for maintenance are spread over a larger output.

Feed digestibility. Enteric CH_4 emissions are also determined by feed properties, particularly the digestibility of the feed ration. The energy content of feed also affects the amount of CH_4 produced in enteric fermentation, with lower quality of feed causing greater CH_4 emissions (Figure 26). Regions with higher feed digestibility also often have higher proportion of high quality roughages, feed crops and concentrates in their diets, often an indication of higher quality ration (see Tables B7-B12 in Appendix B). As the digestibility of the feed ration increases, the amount of energy available to the animal also increases per kg of feed intake. With an increase in per kg of feed intake, more production can be realized and therefore CH_4 produced per kg of production decreases.



Herd structure. A key factor that explains the variations in emissions across regions is the structure of the herd. Breeding populations are required to maintain the herd and thus reproductive performance is important because the cost of maintaining and replacing breeding stock also affects feed efficiency. In regions where the composition of the herd is skewed towards higher number of animals in the breeding herd, overall CH_4 emissions and emission intensities are most likely high because demand is placed on feed (with a large share of feed energy used for maintenance requirements rather than production). Figures 27a and 27b present the percentage contribution of enteric fermentation to total CH_4 from beef and dairy cattle by cohort groups. A breakdown of enteric CH_4 emissions by source not only illus-

Figure 27a.

Source: GLEAM.

Figure 27b.
Regional variation in the relative contribution of animal cohorts to enteric CH_4 – beef herds

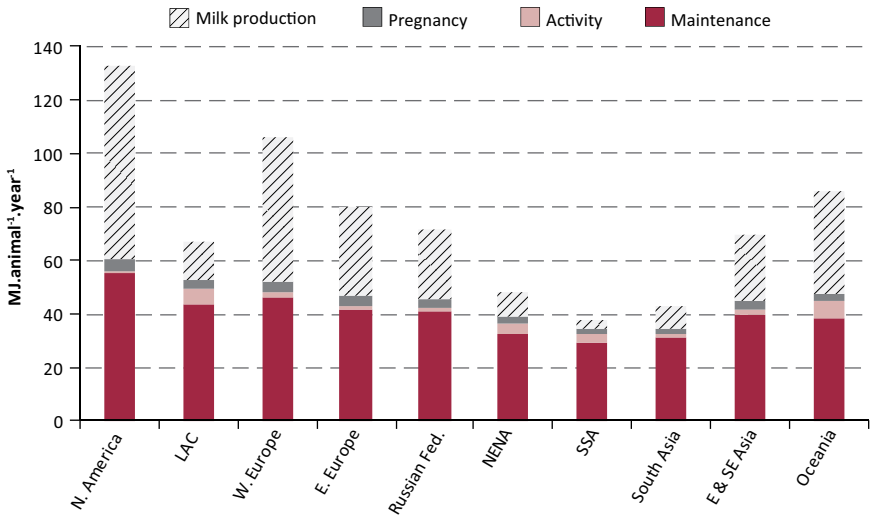
Source: GLEAM.

trates the key hotspots of CH_4 emissions but also explains the variation in emission intensity among regions.

Figure 27a illustrates regional differences in dairy herd structure. Non-milk producing animals in dairy herds typically include replacement animals and adult bulls; these categories of animals are significant contributors to the CH_4 costs of producing milk at the herd level. While CH_4 from enteric fermentation is the main contributor to GHG emissions in all regions, there are major differences in the sources of emissions. Generally, in regions such as sub-Saharan Africa and South Asia, a large proportion of enteric CH_4 (approximately 50 percent) originates from the breeding herd and replacement stock, in combination with a low milk production per cow; hence a large proportion of the resources are used for other purposes such as maintenance and draught power. In these regions, non-milk productive functions contribute substantially to the maintenance energy requirement of the herd because they represent a significant use of energy and resources with no production of usable edible product produced.

In contrast, in Western and Eastern Europe, Oceania, Russian Federation, and East & Southeast Asia, more than 50 percent of the enteric CH_4 is from milking cows, pointing to increased use of feed for productivity purposes and thus explaining the lower emission intensity in these regions.

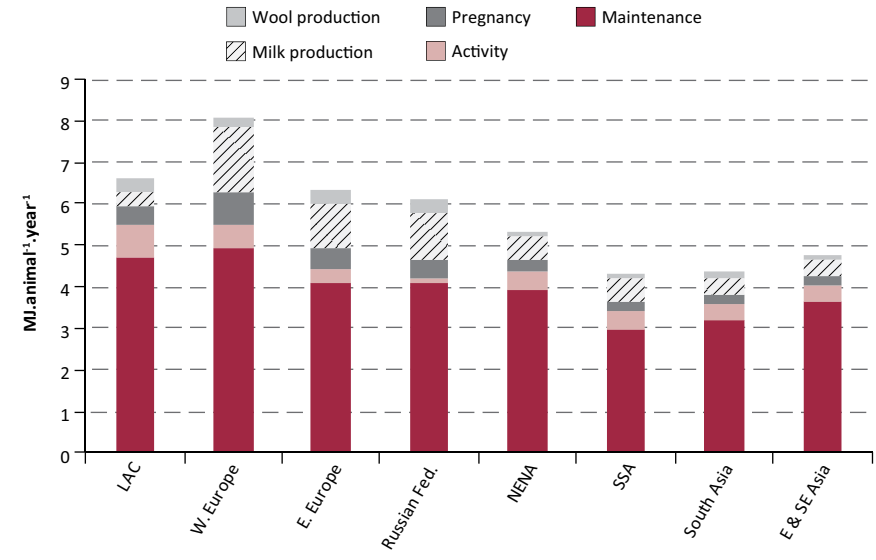
In typical beef systems, mature cows are kept for only calf production and have to be maintained along with bulls and replacement stock, which increases emissions per unit of carcass produced. The breeding stock in beef production systems (cows, replacement stock and bulls) accounts for 55-99 percent of the total feed requirements of the beef herd, and 52-97 percent of total CH_4 emissions. A higher slaughter generation (meat animals for fattening) is an indication of higher reproductive performance of the breeding herd and specialization of production such as in Oceania, Europe, North America and Latin America.



For small ruminants, there is no systematic difference in herd structure among regions, largely attributable to the greater fecundity in small ruminants and faster growth rates compared with cattle. The absence of draught power also reduces the gap among regions.

Energy partitioning and utilization. Methane is produced in the process of feed energy utilization within the animal. Changes in the efficiency of feed energy utilization therefore influence CH_4 emissions of animals. The efficiency of feed energy utilization depends on the type of animal, the type or quality and quantity of feed, environmental conditions, etc.

The way energy is partitioned between the different body functions (maintenance and production) also helps explain the variation in emission intensity. All animals have a necessary maintenance requirement that must be met and results in no production, yet are still associated with CH_4 losses. Ruminants partition feed energy over the following functions: maintenance, growth, lactation and reproduction; and in all cases, maintenance has priority. In situations where feed quality is low, relatively less energy is left for (re)productive functions.



The proportion of feed energy expended on animal maintenance as opposed to productive purposes is higher in those regions with low production rates at both animal (Figures 28a, 28b and 28c) and herd (Figures 29a and 29b) level. Figures 28a, 28b and 28c present the partitioning of energy requirements across the world regions for

milk production from cattle and small ruminants. For example, in dairy cattle in sub-Saharan Africa, NENA, South Asia and Latin America & Caribbean, energy intake is low and, as a consequence, a large proportion of energy is used for maintenance (78 percent, 67 percent, 72 percent and 67 percent, respectively) while in industrialized regions a greater share is used for lactation as illustrated in Figure 28a.

Key assumptions and uncertainties. Given that enteric CH_4 is the single largest contributor to GHG emissions in ruminant production, the method and EFs used for calculating CH_4 from enteric fermentation are fundamental for assessing the carbon footprint of ruminant species. Enteric CH_4 emissions were calculated on the basis of the IPCC Tier 2 approach (IPCC, 2006 Volume 4, Chapter 10), where CH_4 emissions are estimated for different animal categories in the herd as a direct function of gross energy requirements and the CH_4 conversion rate (see Appendix A).

Uncertainties in Tier 2 estimates may be associated with population data, production practices and performance data, including feeding strategy. The use of Tier 2 methodology requires a detailed characterization of the livestock population. Uncertainty in livestock population depends on the extent and reliability of livestock population data. In addition, different accounting conventions for animals, particularly for those that do not live for a whole year such as small ruminants, also add to the uncertainty. Furthermore, total animal numbers are often reported as single values and composition of the different cohorts in herds is not reported separately, making it difficult to characterize these populations.

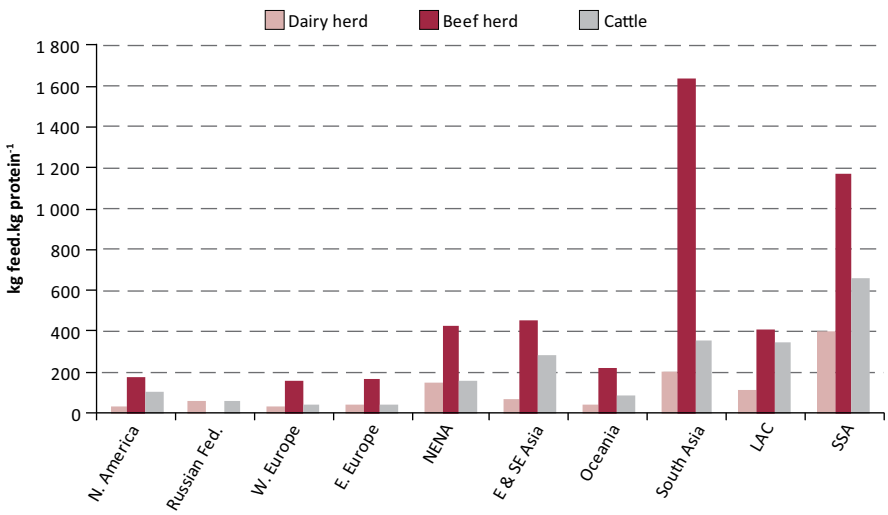
To overcome this problem in this study, the population was modelled on the basis of a number of herd parameters (see Tables B2-B6 in Appendix B) obtained through

data collection and literature reviews. In addition, there is a scarcity of published data on production practices, dietary information, dry matter intake (DMI) and animal performance, which may contribute to the uncertainty of model prediction. While the feed rations used in this assessment represent the general diet characteristics within each region/country, there may be some uncertainty associated with local variation in feed as well as management practices which may also affect the ultimate energy requirements of the animal and consequently CH_4 emissions.

5.2 EMISSIONS FROM FEED PRODUCTION

Feed production constitutes 36 percent, 36 percent and 28 percent of the total emissions for cattle, small ruminants and buffalo, respectively. Emissions related to feed are a function of several factors:

- *Feed ration* (i.e. specific feed materials in the ration). Feed materials have different emission intensities because they are produced in different modes. Generally, rations with higher proportions of by-products and concentrates tend to have higher emission intensities. The regional average feed composition for ruminant species is presented in Appendix B.
- *Mode of feed production:* whether feed production utilizes additional production inputs such as fertilizers, pesticides, etc.
- *Source of feed materials:* reliance on off-farm produced feed or imported feed also has an impact on the emission intensity of the feed-crop.
- *Feed associated with LUC adds additional emissions* (see Appendix C on land use and LUC).



Feed conversion is a measure of the efficiency with which animals convert feed into a gain in body weight or usable product. There are large differences in feed conversions among the various species. The feed conversion of ruminants is usually much lower than that of non-ruminants. High feed consumption per kilogram of protein is partly due to the biological time-lag that it takes for an animal to reach slaughter weight or to calve, and partly due to the amount of feed required by the breeding stock. For example, a suckler cow gives birth to one calf per year. This calf needs between one to four years to reach slaughter weight, depending on production conditions.

Feed conversion also varies among regions for the following reasons:

- animals need a certain amount of feed as their maintenance energy requirement;
- the proportion of breeding stock in the herd – these animals also need to be fed even though they are unproductive;
- regions that rely on dairy herds for their meat supply have a higher feed conversion ratio (FCR) because they produce two products; and
- the characteristics of the production system are also important; aspects such as mortality rates (when animals die or are culled before they reach slaughter weight or first lactation represents significant loss of feed resources), growth rates, age at first calving (lower age at first calving reduces feed requirements during the growth period), etc. influence feed requirements.

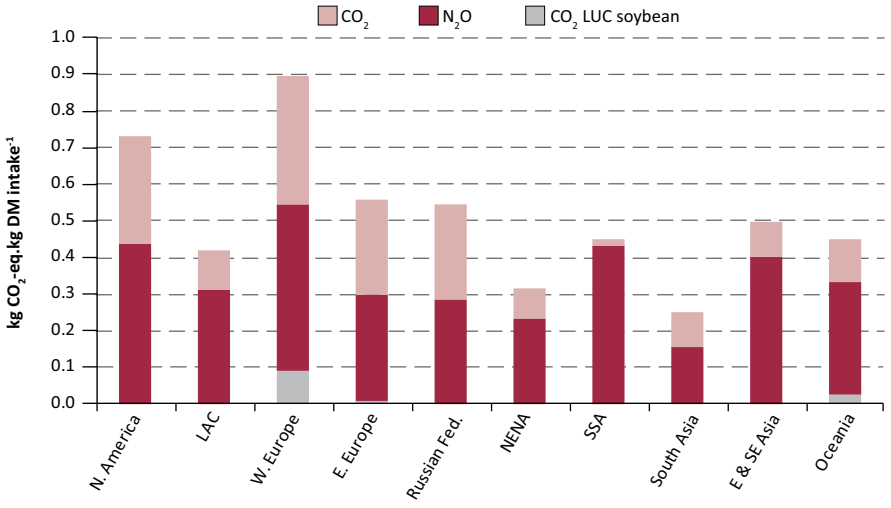
Figure 30 compares feed utilization efficiency for dairy and beef herds by region expressed as DMI per unit of protein produced. Increased animal performance due to improved genetics, nutrition and management results in improved feed use efficiency. This improvement is largely a function of dilution of the growing animal's

Figure 30.
Regional variation in feed conversion ratio for the cattle sector

Source: GLEAM.

maintenance requirements in respect to their total feed requirements. A higher proportion of feed is used for growth and production while a lower proportion for maintenance.

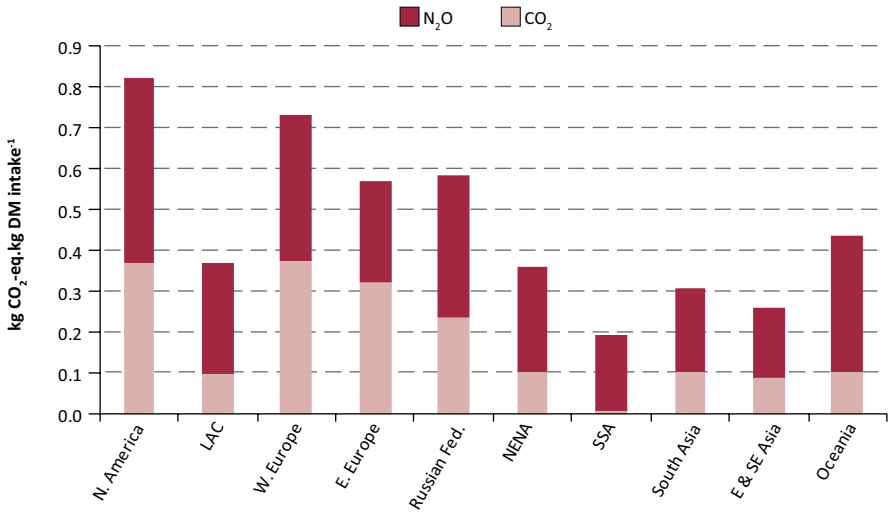
In cattle production, emissions of N_2O are the predominant emissions in feed production in all regions (Figure 31a). This trend is similar for small ruminants, with the exception of North America and Western Europe where both N_2O and CO_2 emissions contribute equal shares of emissions, while in Eastern Europe CO_2 emissions per kg of feed intake are higher (Figure 31b). In cattle production, South Asia has the lowest emission intensity per kg of DMI, a consequence of the large proportion of crop residues used as feed material which make up more than 60 percent of the feed ration (see Tables B7 and B8, Appendix B).



5.2.1 Nitrous oxide from feed production

Nitrous oxide emissions associated with feed production are related to the use of N fertilizer in feed production, N_2O arising from the deposition of manure on grazing land, N from crop residues returned to soils, and N_2O emissions from the application of manure to land.

Manure is an important source of N_2O emissions, and in ruminant production systems manure N_2O emissions from feed production result from manure deposited directly by animals on pasture as well as the manure applied to crops. In the latter case, manure applied to land comprises of all manure that is handled in MMS and includes manure from other species.



N_2O emissions may arise directly as a result of application of the N sources mentioned above. In addition to the direct emissions, N inputs may also lead to indirect formation of N_2O after leaching or following gaseous losses and deposition of ammonia and nitric oxides. In ruminant production, the main source of N_2O

Figure 31a.

Source: GLEAM.

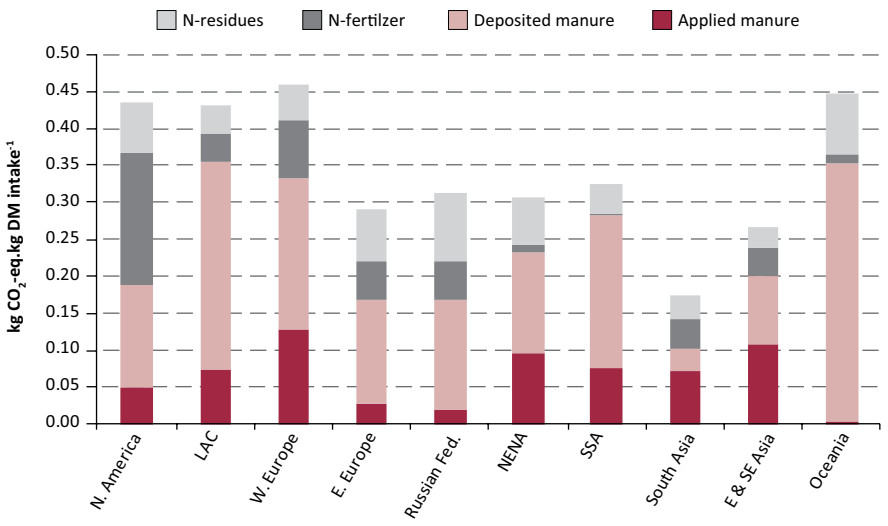
Figure 31b.
Regional difference in N_2O and CO_2 emission intensity of feed – small ruminants

Source: GLEAM.

emissions is manure, with most of the N_2O losses originating from manure that has been deposited or applied.

Figures 32a and 32b present emission intensities for feed for cattle and small ruminants illustrated by region and source of N. In all developing regions, as well as in Oceania and Western Europe, the predominant source of N_2O emissions associated with both cattle and small ruminant species is manure deposited during grazing and applied manure. On the contrary, N_2O emissions from fertilizer application (N fertilizer) are important in North America and to a lesser extent in Europe.

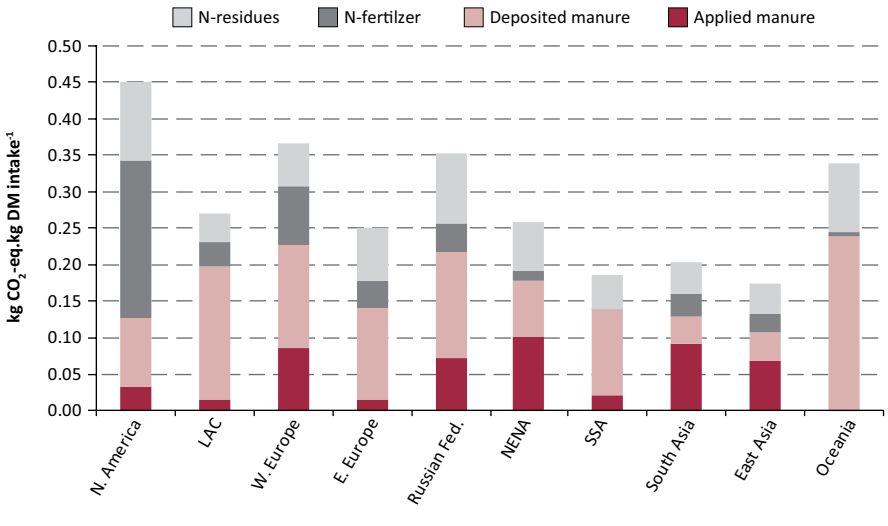
The composition of the feed ration is a key factor in explaining the variation in N_2O emissions because of the vast differences in feed production (see Tables B7-B12, Appendix B, for detailed feed basket composition). For example, in regions where fresh grass is the dominant source of feed, N inputs within the system are more likely to come from manure. However, in intensive grazing systems, N_2O emissions are also likely to be important due to the use of N chemical fertilizer to maintain the productivity of pastures. High N_2O emissions from grazing in regions such as Latin America and the Caribbean and sub-Saharan Africa are mainly a consequence of the importance of pasture as a source of feed. For small ruminants, N_2O emissions from grazing are concentrated in Oceania, sub-Saharan Africa and Latin America.



Regions with a high proportion of concentrates in the feed basket (and to a certain extent hay produced off-farm and silage), are likely to have a larger proportion of N_2O emissions from nitrogen fertilizer. N_2O emissions from fertilizer use in feed production for cattle are significant in North America, and Europe due to the high N application rates on feed in these regions. In the rest of the world's regions, use of fertilizer is negligible; in these regions, N nutrients for feed crop production are largely met from manure. It is also important to note that fertilizer input for other crops can be high in these regions as a consequence of large differences in crop yield and N fertilizer use. N_2O emissions from feed production can be very different for the same feed crop in grown in different locations.

Assumptions and uncertainties. Determining N_2O emissions is often difficult due to the high spatial and temporal variability of N_2O fluxes. N_2O emissions related to feed are based on the IPCC guidelines (2006) following the Tier 1 protocol, and in the modelling of N_2O emissions we adopted a simplified approach that took into account only N additions from fertilizer, manure and biomass on pasture and feed crops. However, other factors also drive N_2O emissions, such as local climatic conditions and soil properties (including water and N dynamics, soil type and structure), and management practices (tillage, irrigation, N application techniques, etc.), thus rendering the quantification of N_2O emissions challenging, which also implies that the results may contain substantial uncertainty.

There are additional uncertainties related to N_2O emissions, such as those related to N application rates coupled with limited information on manure application techniques and timing; the fate of manure and the lack of detailed estimates of the proportion of manure excreted at pasture; and how residues are managed (whether burned or incorporated). In addition, the N content in pasture and manure can vary during the year due to climatic conditions and stages of grass growth. All these aspects are difficult to capture given the scale of the analysis.



In this study, it is also assumed that all managed manure is applied to crops pro-

Figure 32a.

Source: GLEAM.

Figure 32b.
Regional difference in N_2O emission intensity of feed – small ruminants

Source: GLEAM.

duced in the same location that production takes place. This may result in high N_2O emissions from applied manure particularly in areas where crop yields are low.

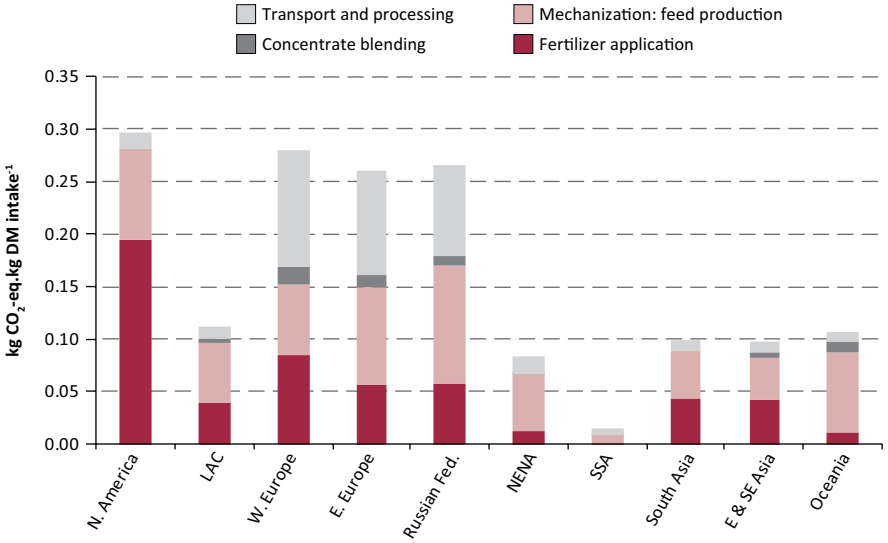
Another important aspect that influences the emissions from feed production is the choice of feed material; for example, in regions where the use of crop residues and by-products is important, there will be a tendency towards lower emission intensities per kg of DM because part of those emissions have been allocated to the main crop while regions that rely on concentrate feed, cultivated pasture, grains as a source of feed are likely have to have higher emissions intensities.

5.2.2 Carbon dioxide emissions from fossil fuel use in feed production

Carbon dioxide emissions from feed production are related to the use of fossil fuels, particularly diesel in tractors and harvesting machinery, oil in dryers, and natural gas in the manufacture and application of synthetic fertilizer and LUC. In the post-farm stages of feed production, CO_2 is emitted in conjunction with various feed processes (with drying being important) and transport.

In general, CO_2 emissions from energy use in feed production, processing and transport are strongly correlated to the feed ration. Other factors that also explain the variation in emission intensity among world regions include: the level of mechanization, the rate of fertilizer application, dependence on imported feed and source of feed (a key determinant of emissions related to transport of feed) and the extent to which the feed in question is associated with LUC.

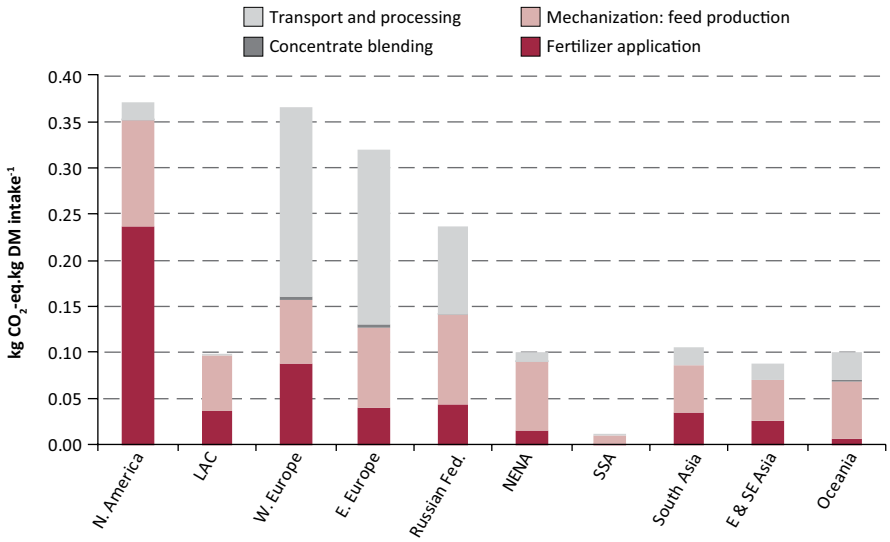
Figures illustrate the emission intensity of feed by different processes in feed production and by region for both cattle (Figure 33a) and small ruminants (Figure 33b). In both cases, CO_2 emissions from fossil fuel use in feed production are important in industrialized regions. In these regions, two key factors explain the high emission intensities: (i) high fertilizer application rates; and (ii) transport of feed due to the higher proportion of by-products, feed crops or imported hay in the feed ration.



In other world regions, emission intensity is low and dominated by CO_2 emissions from energy use in field work. In both cattle and small ruminant production, sub-Saharan Africa has the lowest CO_2 feed emissions and there are several reasons for this: (i) reliance on natural pasture as a source of feed and low concentrate feed use; (ii) low use/negligible use of inputs such as fertilizer in the production of feed; and (iii) the low level of mechanization in the region.

Assumptions and uncertainties. The estimation of CO_2 emissions in this study are influenced by a number of assumptions and factors such as energy source and related emission coefficients used (see Table B14, Appendix B); level of mechanization (Table A1, Appendix A); and where feed is sourced and composition of the feed ration – both of which are variable.

5.2.3 Carbon dioxide emissions from land-use change



Emissions from LUC attributable to the ruminant sector amount to 450 million tonnes CO_2-eq, the bulk of these emissions (93 percent) are related to pasture expansion into forest areas for beef production in Latin America. The use of soybean produced on previously forested land as feed especially for dairy production contributes another 30 million tonnes CO_2-eq. The approach used in this assessment for estimating emissions from C stock changes associated with livestock induced LUC is further elaborated in Appendix C.

Soybean expansion. In quantifying total emissions associated with the transformation of forest for soybean cultivation, LUC emissions are attributed to only those countries supplied by Brazil and Argentina with soybean and soybean cake. Tables 10 and 11 present the regional share of soybean and soybean cake sourced from Brazil and Argentina and main exporting countries, respectively.

This analysis shows that about 224 million tonnes CO_2-eq are emitted *per annum* from the expansion of soybean production in Brazil and Argentina to meet global demand for pigs, chickens and cattle feed. The bulk of these emissions arise in response to soybean demand in Europe, East Asia and LAC (Table 12) which source large quantities of their soybean feed from Argentina and Brazil. The emissions estimated for the livestock sector in Western Europe are particularly high, which not only indicates a high reliance on imported soybean and soybean cake for feed, but also use of soybean with a high emission intensity, particularly because a large share is sourced from Brazil (see Table 10).

On a species level, the largest share of these emissions is attributed to the non-ruminant sector, equivalent to 195 million tonnes CO_2-eq (87 percent). This is not

Table 12. Regional comparison of land-use change emissions associated with soybean production

Source: GLEAM.

surprising because of the high share of soybean in diets of non-ruminants. Regarding the cattle sector, LUC emissions from soybean are important in Europe where it is utilized in dairy production. The results suggest that emissions are largely influenced by: (i) the quantity of soybeans and soybean cake imported from the two countries; and (ii) the share of soybean in the ration of the diet.

Pasture expansion. According to our estimations, about 13 million hectares of forest land in Latin America were converted to pasture land between 1990 and 2006. Deforestation for pasture establishment in the region emitted about 420 million tonnes CO_2-eq per year, releasing on average 32 tonnes CO_2-eq ha^{-1} yr^{-1}. At country level, changes in C stocks range between 30 and 35 tonnes CO_2-eq ha^{-1} yr^{-1} (Table 13). The estimates of GHG emissions due to pasture-driven LUC presented here represent a first step towards an estimation of LUC emissions. The analysis is consistent with the Tier 1 methodology outlined in the IPCC guidelines (IPCC, 2006). In order to progress towards better methodologies, certain gaps in data, methods, and in scientific understanding need to be addressed.

These preliminary estimates indicate that the inclusion of CO_2 emissions from land-use change have a significant influence on the carbon footprint of livestock products. However, changes in soil carbon sequestration due to land use are important are important and need to be considered.

Assumptions and uncertainties. Due to the uncertainty in the methods and data for calculating the impacts of LUC, we recognize the high level of uncertainty associated with this estimation. There is much uncertainty regarding the magnitude of LUC emissions due to (a) uncertainty in the estimates of deforestation rates; (b) uncertainty in the carbon storage capacity of different forests, (c) the modes of C release, and (d) uncertainties in the dynamics of land use, thus limiting the accuracy of the estimated carbon loss (Houghton and Goodale, 2004; Ramankutty *et al.*, 2006).

Table 13. Annual carbon stock changes and emissions from pasture expansion in Latin America

Countries	Average emissions		Total carbon losses
	tonnes CO_2/ha	*tonnes CO_2/ha/yr*	*million tonnes CO_2-eq*

Chile	- 510.7	- 31.9	-36.7
Paraguay	- 488.1	- 30.5	-31.7
Nicaragua	- 485.3	- 30.3	-13.8

Source: Authors' calculations.

This analysis also relies on a Tier 1 approach and use of IPCC default values and is therefore subject to high levels of uncertainty. We test other existing methods and assumptions in Appendix C to illustrate the range of uncertainty that exists.

The way in which the LUC emissions should be allocated over beef production is a question for further research. Within this analysis, we allocate emissions to total beef produced within the country; however, not all beef production is carried out on deforested land. A related methodological issue is the debate on the allocation of emission related to LUC because of the complexity in ascertaining the key driver of land-use change. In addition, the calculated emission intensity is highly sensitive to the time period selected over which emissions from the initial deforestation are annualized. Appendix C explores alternative approaches to estimating emissions related to LUC, incorporating some of the issues discussed here.

5.3 EMISSIONS FROM MANURE MANAGEMENT

5.3.1 Methane from manure management

Animal manure emits CH_4 depending on the way it is produced and managed. Ruminants (cattle, buffalo and small ruminants) contribute 109 million tonnes of CH_4 from manure (2 percent of total emissions from ruminants), of which 86 percent is from cattle. Three primary factors affect the quantity of CH_4 emitted from manure management operations: type of treatment or storage facility, climate and composition of the manure.

Storage and treatment of manure in liquid systems such as lagoons or ponds leads to the development of anaerobic conditions which result in high CH_4 emissions. In addition, higher ambient temperature and moisture content also favour CH_4 production. The composition of manure is directly related to animal types and diets.

Manure CH_4 emissions are lower in regions where manure is handled in dry systems. In dairy and beef cattle production, where liquid MMS (lagoons, liquid/slurry systems) are common, the proportion of manure CH_4 emissions in total CH_4 emissions is considerable, and particularly in regions where animals are confined for a part of the year, such as Europe and North America. For dairy, this ranges from 5 percent in Eastern Europe to 35 percent in North America; on the other hand, in beef production the use of liquid systems is confined to Western Europe and Eastern Europe where 6 percent and 14 percent of CH_4 emissions originate from manure, respectively. The anaerobic nature of liquid manure systems increases the potential for CH_4 production and reduces N_2O production.

In the other world regions, a large fraction of the manure from cattle is handled in dry systems, while in small ruminant production manure is managed in dry systems, including drylots and solid systems, or deposited on pastures and ranges.

Maps 9 and 10 in Appendix G present the CH_4 conversion factor that defines the portion of CH_4 producing potential achieved by each manure management system. Methane conversion factor is higher in North America and Europe, which explains the higher CH_4 emissions. The high CH_4 conversion factor in North America and Europe is due to the use of liquid MMS.

Assumptions and uncertainties. In this study, CH_4 emissions from manure management are calculated using the IPCC Tier 2 approach. This approach uses country-specific inputs of volatile solids estimated from DMI, feed digestibility and ash content of manure, a CH_4 conversion factor based on climate and type of manure management and storage system, and the maximum CH_4 potential (Bo) of manure based on species and diet.

Uncertainties related to estimation of CH_4 from manure management derive from: limited activity data on manure management; differences in manure management practices; and the effect of time-related aspects such as storage periods, as well as seasonal temperature variations in emission rates which are not explicitly accounted for in the calculations.

5.3.2 Nitrous oxide from manure management

Nitrous oxide is produced directly and indirectly during storage and treatment of manure before it is applied to land. Indirect N_2O emissions result from volatile N losses that occur mainly from ammonia (NH_3) and NO_X and leaching of nitrate. Key important variables that influence N_2O emissions from manure management include the amount of N excreted and the way in which manure is managed. A considerable amount of N entering the livestock food chain through feed is wasted; ruminants excrete between 75 percent and 95 percent of the N they ingest (Castillo *et al*., 2000; Eckard *et al*., 2007). Maps 11 and 12 in Appendix G compare the proportion of feed nitrogen retained by dairy and beef herds.

Animal productivity is important for N excretion; as more milk or meat is produced per animal, the maintenance requirement of protein per unit of production is reduced. Thus, the animal product can be produced with less N consumed and excreted. Figure 34 illustrates the relationship between animal performance and N excretion per kg of milk protein; a comparison among regions reveals that, on average, high-producing animals excrete less N per unit of protein produced because more nutrients are directed towards production.

Manure handling and storage also influence N_2O emissions from manure. A large proportion of N_2O from manure management is released as direct N_2O, the bulk of which originates from dry systems (with approximately 60 percent and 65 percent from drylot systems in beef and dairy cattle production). All manure from small ruminants and buffalo is managed in dry systems (drylot and solid systems). Nitrous oxide emissions are most likely to occur in dry manure handling systems that have aerobic conditions (in the presence of oxygen), but that also contain pockets of anaerobic (in the absence of oxygen) conditions.

For dairy and beef cattle, most N_2O emissions from manure management are found in developing regions. Oceania is the only region without N_2O emissions

Figure 34.
Nitrogen excretion per kg milk protein versus average regional milk yield – dairy cattle

Source: GLEAM.

associated with manure management because all manure from beef and small ruminants in Oceania is assumed to be deposited on pasture. The proportion of N_2O from leaching is insignificant and has a limited impact on total N_2O from manure management because only a small proportion of leached N is converted to N_2O.

Assumptions and uncertainties. The basis for the estimation of N emissions is the total mass of N excreted. Excretion is determined as the difference between crude protein intake and retention within the animal. N_2O emissions associated with manure deposited on pasture, ranges and paddocks are not included in these estimates but considered as part of the feed production component (cf. Appendix A), because they are considered as a source of N fertilizer in feed production.

5.4 COMPARISON WITH OTHER STUDIES

A direct comparison with literature values from other LCAs is often complicated by the use of differing boundaries, functional units, disparate assumptions and algorithms in calculating emissions. Nevertheless, comparisons can be useful to provide an indication of the validity of results and contribute to drawing conclusions. Tables 14 and 15 compare existing studies for beef cattle and small ruminants with the current study. While several studies have focused on the cattle sector and to a limited extent small ruminants, many of these estimates are at a much smaller scale and are often specific to regions or production systems within countries (e.g. Verge *et al.*, 2008; Peters *et al.*, 2009; Biswas *et al.*, 2010; Beauchemin *et al.*, 2010; Pelletier *et al.*, 2010; Nguyen *et al.*, 2010; Kanyarushoki *et al.*, 2010; Zhou *et al.*, 2007, Zervas and Tsiplakou, 2012; Edwards-Jones *et al.*, 2009). For purposes of this comparison, only those studies with a national or regional scope were selected.

Table 14. Comparison of emission intensities for beef cattle

Y: emission category included; N: emission category excluded.

The following factors have been identified as potential reasons for the deviation in results.

Scope. Studies can: (a) have different system boundaries; (b) include different emissions categories within the same system boundaries; (c) have different functional units; or (d) include different emission sources within an emission category.

Input data/assumptions. Quantifying emissions requires input data on key parameters such as livestock population numbers and distributions, herd structures and crop yields. Ideally, validated empirical data sets should be used, but there are often gaps in the data on key parameters, which necessitate assumptions. In many cases, key input data have been found to vary; for example a comparison of small ruminant population numbers in the 27 Member States of the European Union (EU27) revealed that the small ruminant population for these countries used in this current study are 30 percent higher than those used by Leip *et al*. (2010). The authors also noted that there was an observed difference between the small ruminant inventory that they utilized and national inventory reports. The animal inventory utilized in this study was, however, found to be consistent with those reported by the countries.

Calculation methods. A review of the studies revealed the major differences in methodology across all studies particularly in the use of different approaches such as use of Tier 1 vs. Tier 2 approaches, and differences in allocation technique applied. Generally, due to the importance of enteric fermentation, most recent studies apply a Tier 2 approach, particularly for cattle. While the approach may be similar, studies may obtain different results which may largely depend on data inputs such as animal weights, feed digestibility and feed composition, all of which are important in assessing emissions from enteric fermentation. On the other hand, the assessment of enteric fermentation in small ruminants in the few studies conducted (Leip *et al.,* 2010; Yamaiji *et al.*, 2003; Edward-Jones *et al.*, 2009) has largely been based on the Tier 1 approach using the IPCC default value of 8 kg CH_4 per head.

The allocation technique applied may also explain variations in emission intensity. Significant differences were found between this study and the EU27 study (Leip *et al*., 2010) for small ruminant milk production (cf. Table 14), which is also explained by the differences in allocation techniques. The authors allocate emissions between three outputs: milk, meat and lamb/kids based on the nitrogen content of the products, and emissions related to the raising of young animals during pregnancy are allocated to meat. In contrast, this study allocates emissions between milk, meat and wool based on economic value of the products and subsequently utilizes protein content of products to allocate emissions among the edible products (see allocation technique in Appendix A). A key explanation of the deviation between the current study and EU27 study is related to the fact that a large part of the total dairy herd emissions (i.e. emissions associated with the adult females and male animals and replacement animals) in our study are allocated to milk, while only emissions of the dairy activity (time from the first lactation to the slaughtering of the animal) are allocated to milk in the EU27 study (Weiss and Leip, 2012).

The overlying issues with comparison lie in the lack transparency of information and a standardized methodology or protocol for conducting LCAs and reporting results. The variability among studies in methods used places emphasis on the need to clearly define and agree on methodologies for estimating GHG emissions from the ruminant sector.

5.5 ANALYSIS OF UNCERTAINTY

Estimates of GHG emissions are subject to large uncertainties. Fundamentally, uncertainties are associated with the variables used in the calculation of EFs, in estimates of activity data (e.g. animal populations and herd parameters) and assumptions made. This section presents a partial analysis of uncertainty, based on the Monte Carlo (MC) Simulation approach.

In order to focus the analysis of uncertainty, parameters that had the greatest influence on emission intensity were identified. Key contributors to emissions were defined as those emissions categories contributing more than 10 percent of the emissions and with a high degree of uncertainty arising from either the lack of data or inherent

Table 16. Summary of parameters and uncertainty distributions used in the Monte Carlo simulation runs for dairy and beef in France

Parameters and emission factors	Distribution	CV[1]	Min	Max	Reference and basis for uncertainty estimates
Parameters					
Feed digestibility	Normal	0.10			Assuming IPCC uncertainty range of ±20% (IPCC, 2006 – Volume 4, Chapter 10, Section 10.2.3)
Dairy: Milk yield	Normal	0.2			Institut de l'Élevage, 2011
Dairy: Age at first calving	Normal	0.19			Institut de l'Élevage, 2011
Beef: Age at slaughter	Normal	0.23			Institut de l'Élevage, 2011
Beef: Age at first calving	Normal	0.17			Institut de l'Élevage, 2011
Emission factors					
Enteric CH_4 emission factor	Normal	0.10			Assuming IPCC (2006, Volume 4, Chapter 10, Section 10.3.4) uncertainty range of ±20%
EF1: N_2O emission factor, synthetic and organic N	Beta Pert		0.003	0.03	IPCC (2006, Table 11.1)

[1] CV – Coefficient of Variation is the ratio of the standard deviation to the mean. The 95 percent confidence interval is approximately equal to the standard deviation or coefficient multiplied by two.

variability or assumptions made. For the ruminant sector, emission categories that contribute more than 10 percent include CH_4 from enteric fermentation, CO_2 from land-use change, and N_2O from feed production (see Section 4). Section 5.4 highlighted some of the important factors that are likely to influence emissions. The MC simulation was applied to two countries, France and Paraguay. In France, uncertainties in both mixed dairy and beef production systems were assessed, while in Paraguay the focus was on grazing systems. The choice of countries was based on criteria such as the availability of statistics for inventory data [standard deviation (SD), confidence interval or ranges], and relative importance of production in these countries.

5.5.1 The approach

Choice of probabilistic distributions of input variables. Monte Carlo simulations enable an investigation into how input uncertainty propagates through the life-cycle emissions model. However, there is little data on probability distributions of the input data required to perform a MC simulation.

In this assessment, the probability distributions were defined using the SD from a number of sources and applying the coefficient of variation indicated in Tables 16 and 17, and normal distributions were assigned to technical parameters for which no choice of mode could be justified given available information.

Table 17. Summary of parameters and uncertainty distributions used in the Monte Carlo simulation runs for beef in Paraguay

Parameters and emission factors	Distribution	CV[1]	Min	Max	Reference and basis for uncertainty estimates
Parameters					
Feed digestibility	Normal	0.10			Assuming IPCC uncertainty range of ±20% (IPCC, 2006 – Volume 4, Chapter 10, Section 10.2.3)
Beef: Age at slaughter	Normal	0.24			Ferreira *et al.* (2007); Fréchou (2002)

[1] Two standard deviation CI 95%.
[2] No uncertainty analysis is needed for Tier 1 since the default assumption is that all biomass is cleared and therefore the default biomass after conversion is zero.
[3] No uncertainty analysis is needed for Tier 1 since the default assumption is unchanging carbon stocks in DOM.
Source: Authors' calculations.

For the IPCC parameters, these are mainly provided with a potential range, often estimated by expert opinion or drawn from studies. The ranges for EF1, EF3, EF4, EF5 were taken from IPCC (2006) and beta-pert distributions were used to model parameters from IPCC based on the maximum and minimum value. These distributions and underlying data sources are also summarized in Tables 16 and 17.

We also employed MC simulation analysis to understand the uncertainty associated with LUC. The approaches described in Appendix C were used to generate parameter ranges used in the MC simulation. The three alternative soybean approaches were only applied to the French case study where imported soybean cake is used as feed. The soybean emission intensity calculated for the GLEAM and the three additional scenarios for soybean imported by France from Brazil and Argentina are presented in Table 18.

The approach for assessing the uncertainty related to changes in C stocks resulting from pasture expansion into forest areas takes into account the *uncertainty associated with carbon fluxes from carbon pools considered* and the *uncertainty as-*

sociated with the land area estimates. The two uncertainties were run separately and then combined. The IPCC guidelines (2006) indicate that, if using aggregate land use area statistics for activity data (e.g. FAO data on land area), as is the case in this study, a default level of uncertainty for the land area estimates of ±50 percent may be applied.

Estimates of the carbon loss on land conversion include uncertainties in several underlying quantities: the carbon in the above-ground biomass, the carbon in the below-ground biomass (generally estimated as a percentage of the above-ground biomass), the carbon in the soil, and the fraction of all carbon lost upon conversion. The uncertainty associated with carbon fluxes from three carbon pools considered in this study are taken from IPCC guidelines (2006, Volume 4) and the "Good Practices Guidelines" for national GHG inventories (IPCC, 2003) and are presented in Table 19.

Total uncertainty combining uncertainty in carbon stock changes per hectare with the uncertainty in land area converted was calculated using the *error propagation approach* outlined in Chapter 6, IPCC Good Practice Guidance (2000, Chapter 6 equations 6.3 and 6.4) that combines different uncertainties to provide an uncertainty estimate for an inventory. The result of the combined uncertainty used as input in the Monte Carlo simulation is presented in Table 17.

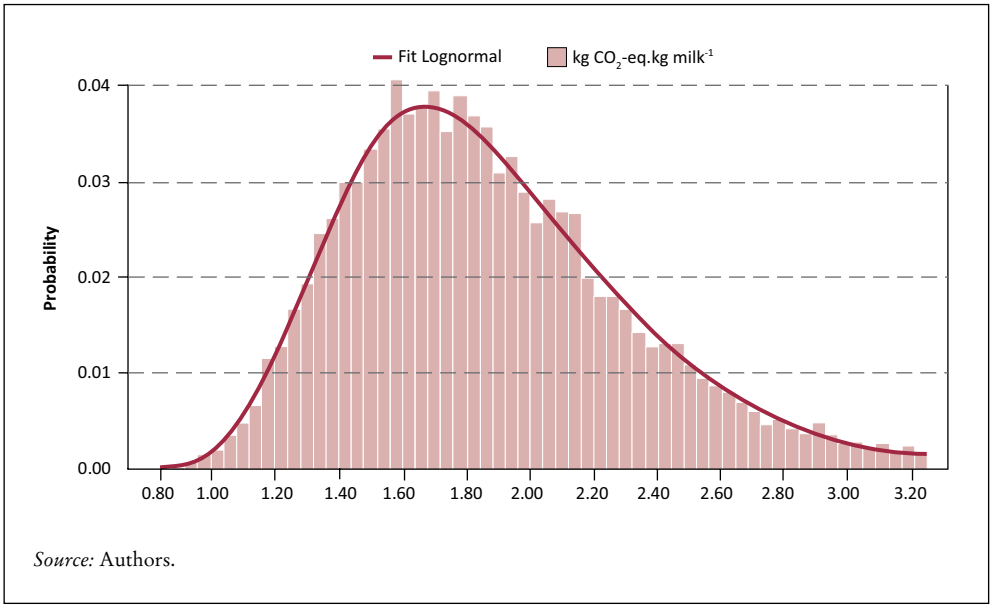
Uncertainty estimates and sensitivity analysis. In this assessment, the number of simulations run was 10 000. For any analysis of this type, it is important to determine the sources of uncertainty and the impact that parameters and their embedded assumptions have on the results. A sensitivity analysis was therefore used to identify parameters that have a significant effect on the uncertainty estimates. Sensitivity analysis also identifies the most influential parameters indicating emissions sources that offer the opportunity to decrease the overall uncertainty associated with life-cycle of milk and beef production emissions. The relative sensitivity of input variables was assessed by Monte Carlo using the *Rank Correlation Coefficient (RCC)*[8] calculated between all inputs variables and the emission intensity as their contribution to the overall uncertainty.[9]

5.5.2 Results from the uncertainty analysis

France

The mean emission intensity for milk production in mixed farming system in kg CO_2-eq calculated on the basis of kg milk was estimated to be 1.9 kg CO_2-eq/kg milk (±0.95 kg CO_2-eq/kg milk at the $CI_{95\%}$). The range of values around the mean obtained with the uncertainty analysis was 0.9-2.8 kg CO_2-eq/kg milk (Figure 35 and Table 20). The average emission intensity for beef is 15.6 kg CO_2-eq/kg CW (±8.0 kg CO_2-eq/kg CW) (Figure 36 and Table 20) The range of values was 7.5-23.6

[8] RCC is a measure of the strength and direction of association between input variables and output estimates. If an input parameter and an output estimate have a high correlation coefficient, it means that the input has a significant impact on the output; positive correlation coefficients indicate that an increase in the input is associated with an increase in the output estimate while negative coefficients indicate an inverse relationship. The larger the absolute value of the correlation coefficient, the stronger the relationship.



[9] Crystal ball computes the rank correlation between inputs and each output parameter then normalizes these to sum to 100 percent. This provides a measure of sensitivity, i.e. the contribution of each parameter to the overall uncertainty of emission intensity.

Table 20. Summary of results from Monte Carlo analysis for mixed dairy and beef production in France

	Mixed dairy production	Mixed beef production
Mean emission intensity	1.89 kg CO_2-eq/kg milk	15.6 kg CO_2-eq/kg CW
EI standard deviation	0.49	4.10
Coefficient of Variation	26%	26%

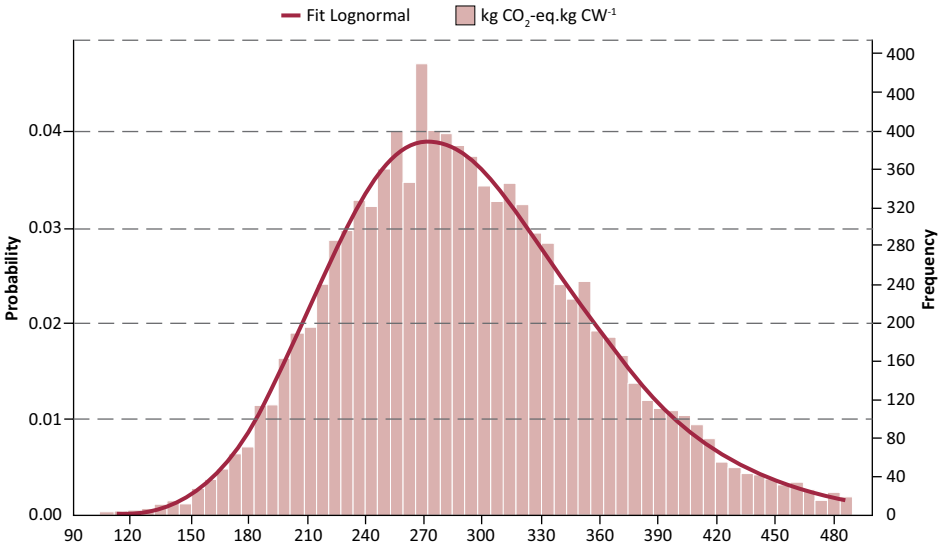
kg CO_2-eq/kg CW. Both probability distribution frequencies (PDFs) for France are positively skewed indicating that the distribution has a longer right tail (Figures 35 and 36).

The coefficient of variation defines the standard deviation as a percentage of the mean and can be used to compare SDs with different means. Despite the markedly different means and SD for milk and beef, the coefficient of variation for both milk and beef in France is 26 percent of the mean.

Impact of alternative soybean approaches on emission intensity. Different scenarios to assess the impact of soybean-related LUC were tested for both dairy and beef production systems in France and the results are presented in Table 21. Soybean cake accounts for a small proportion of the feed ration (between 2-6 percent of the feed ration for both dairy and beef) and hence has a negligible impact on emission intensity.



Paraguay

Figure 37 presents the results from the Monte Carlo simulation for Paraguay. The mean value for the emission intensity of beef produced in grazing systems in Paraguay (including carbon losses from deforestation for pasture) is 294.2 kg CO_2-eq/kg CW (±136.3 kg CO_2-eq/kg CW), with the 95 percent certainty interval around the mean ranging from 157.8-430.6 kg CO_2-eq/kg CW. The coefficient of variation (CV) is estimated at 24 percent of the mean.

Impact of LUC uncertainty on emission intensity of beef in Paraguay. Table 22 presents the results from the propagation of uncertainty associated with land area estimates, carbon stock losses per hectare as well as the combined scenario of the two uncertainties.

The assumptions and uncertainties in total land area converted and carbon stocks and their impact on the mean were about the same magnitude. The sensitivity analysis showed that uncertainty in the total land area converted is the single largest contributor to variance, accounting for 27 percent of the variance, while uncertainty in estimates of the carbon in soil and biomass accounts for nearly 9 percent of the variance.

Analysis of sensitivity. Tables 23 and 24 illustrate the *contribution to variance* (CoV)[10] and the *RCC* for the uncertain input parameters (above a 1 percent threshold) and presents the most important factors affecting the total uncertainty measured by the absolute value of *RCC* between the parameters and the emission intensity. For milk production in mixed systems in France, three parameters contribute about 90 percent of the total variance in the emission intensity; feed digestibility is the largest contributor to variance, accounting for almost half of the total, and the uncertainty in N_2O EF3 and milk yield contributing another 22 and 20 percent of the variance, respectively. In beef production, the N_2O EF3 and feed digestibility parameters contribute 93 percent of the variance (Table 23).

[10] The contribution to variance (CoV) provides information on how much each variable contributed to the uncertainty of emission intensity relative to the contribution of other variables.

Table 23. Percent Contribution to Variance (CoV) and Rank Correlation Coefficient (RCC) in mixed dairy and beef systems in France

Parameter	Dairy		Beef	
	CoV	**RCC**	**CoV**	**RCC**
Feed digestibility	47%	-0.66	42.2%	-0.63
N_2O EF3 Pasture, ranging and paddock	22.2%	0.45	51.5%	0.69
Milk yield	20.4%	-0.43	NA	NA
Age at first calving	5.4%	0.22	NS	NS
EF for enteric fermentation	1.7%	0.12	NS	NS
EF 1 for synthetic and organic N	1.0%	0.09	2.5%	0.15
EF 4 for N volatilization	NS	NS	1.5%	0.12
EF 5 for N leaching	NS	NS	1.2%	0.1

NA: Not Applicable; NS: Not Significant.

Table 24. Percent Contribution to Variance (CoV) and Rank Correlation Coefficient (RCC) for grazing beef systems in Paraguay

Parameter	Beef	
	CoV	**RCC**
N_2O EF3 Pasture, ranging and paddock	44%	0.64
Land-use change pasture: combined scenario	34%	0.52
Feed digestibility	17%	-0.40
Age at slaughter	5%	0.21

Source: Authors' calculations.

The sensitivity analysis shows that the key parameters contributing to uncertainty for both the dairy and beef scenarios are:

- the feed digestibility variable plays a significant role in total emissions; 47 percent and 42 percent of the uncertainty in emission intensity of milk and beef is caused by the uncertainty in feed digestibility variable, respectively. Digestibility is a dominant factor in the calculations of a number of emission sources and hence its role in influencing the uncertainty in emission intensity.
- N_2O EF3 for manure deposited on pasture due to the high degree of uncertainty i.e., wide distribution (large natural variability) of possible values.
- In dairy production, milk yield has an impact on the uncertainty of milk emission intensity due to the high variability in milk production.

For Paraguay, the sensitivity analysis shows that 4 parameters: N_2O EF3 Pasture, ranging and paddock, feed digestibility and land-use change, and age at slaughter contribute 99 percent of the variance to the emission intesity of beef in Paraguay (Table 24).

The uncertainty in N_2O EF3 is the largest contributor to variance (44 percent); the rate of emissions of N_2O (per unit N applied/deposited) is perhaps the most uncertain effect in GHG emission profile. In addition to the wide distribution N_2O EF3 (the N_2O emissions factor for N deposited on pasture, range or paddock), it is assumed that 95 percent of the manure in this case is deposited directly on pasture

hence the high N_2O emissions. The uncertainty in the estimates of LUC combined scenario (carbon stock losses per hectare and in the land area estimates) account for 34 percent of the variance.

In conclusion, the uncertainty performed for the two case studies show that relatively few parameters (N_2O EF3 Pasture, ranging and paddock, feed digestibility and LUC) are responsible for most of the variance. Although the present analysis captures several important parameter uncertainties, significant model uncertainties still remain.

Point estimates from LCAs describe only an average situation and many scenarios may be equally plausible. Uncertainty analysis such as these offer the opportunity to understand and estimate the imprecision of the average result resulting from uncertainties in input data as well as deliver more meaningful results.

6. Conclusion

Globally, ruminant supply chains are estimated to produce 5.7 gigatonnes CO_2-eq *per annum* of which 81 percent, 11 percent and 8 percent is associated with cattle, buffalo and small ruminant production.

This report provides the first comprehensive and disaggregated global assessment of emissions from the ruminant sector, which enables the understanding of emission pathways and hotspots. This is a fundamental, initial step towards identification of mitigation strategies.

Average emission intensity for products from ruminants were estimated at 2.8, 3.4 and 6.5 kg CO_2-eq/kg FPCM for cow milk, buffalo and small ruminant milk, respectively, and 46.2, 53.4, and 23.8 kg CO_2-eq/kg CW for beef, buffalo and small ruminant meat, respectively. Although there is great heterogeneity among production systems, some commodities are associated with particularly high emission intensities. These emission profiles and the on-going growth in output call for the adoption of mitigation practices.

The ranges of emission intensity within supply chains suggest that there is room for improvement (Tables 7 to 9). This mitigation potential is further explored in an overview report published in parallel to this one (FAO, 2013a). It is estimated to reach 30% of the sector's global emissions. The overview report also explores regional mitigation potentials through case study analysis. When drawing any conclusions about scope for improvement, one must distinguish those production parameters that can be managed from those that are related to agro-ecological conditions and cannot be managed. This is particularly true for extensive production systems, where the environment cannot be controlled, or at prohibitive costs.

Regarding these systems, and those facing particularly harsh environments, mitigation practices should not be proposed at the cost of diminished resilience and food security. Bearing these caveats in mind, the results of this study indicate six areas of possible interventions to reduce the emission intensity from ruminant supply chains:

- Reducing LUCs arising from pasture expansion and feed crop cultivation;
- Improving feeding practices and digestibility of diets;
- Improving grazing and pasture management to increase soil organic carbon (SOC) stocks;
- Increasing yields, e.g. through genetics, feeding and animal health;
- Improving manure management – reducing the use of uncovered liquid MMS, particularly in dairy systems; and
- Increasing energy use efficiency, especially in postfarm part of the supply chain.

Comparison of this study with others shows that methods matter. Discrepancies in results are well explained by different system boundaries, allocation methods and computation of emissions, especially with regard to LUC, enteric CH_4 and feed N_2O. The many different methods that are being used to measure and assess the emissions of animal rearing make it difficult to compare results and set priori-

ties for the continuous improvement of environmental performance along supply chains. This calls for an effort to harmonize approaches and data used in this kind of analysis.

This report presents an update and refinement of the previous assessment in *Livestock's long shadow* (FAO, 2006). It should be understood as one step in a series of assessments, to measure and guide progress in the sector's environmental performance.

Numerous hypothesis and methodological choices were made, introducing a degree of uncertainty in the results. Furthermore, data gaps forced the research team to rely on generalizations and projections. A partial sensitivity analysis was conducted in order to illustrate the effect of these approximations. Results were tested for methodological choices regarding land-use change emissions and input data uncertainty. This partial analysis showed that the emission intensity at 95% confidence interval is ±50%

Priorities for refinement of GLEAM include:

- Information about the feed rations, particularly the amount of roughage, by-products and concentrates in the ration;
- Information on manure management;
- Methods for allocation of emissions, especially for slaughter by-products;
- Quantification of the emissions associated with land use and LUC;
- Quantification of feed N_2O that better reflect where and how manure N is applied to crops.

Methodological developments are been carried out by private and public sector organizations to improve the accuracy and comparability of results over time. LEAP – the Partnership on Livestock Environmental Assessment and Performance[11] will be instrumental to these developments; this multi-stakeholder initiative is facilitated by FAO and involves government representatives, private sector organizations and civil society in an effort to harmonize indicators and methods for the assessment of environmental performance in the livestock sector.

Although estimating GHG emissions from the sector provides an important starting point for understanding the sector's potential for mitigating emissions, identifying approaches to reduce emissions requires complementary analysis.

First, the private and public costs of mitigation, as well as the social dimensions associated with technology changes and the impact of mitigation efforts on food consumption trends, should be understood in order to identify viable and acceptable options. Several groups are addressing these questions, including FAO. There is also a need to broaden the scope of environmental performance assessment beyond GHG emissions, in order to avoid undesired policy outcomes. GLEAM will progressively be adapted to compute a wider set of metrics that enable several environmental parameters to be quantified. The model provides a consistent and transparent analytical framework within which to explore proposed mitigation methods, thereby providing an empirical basis for policy-making.

APPENDIX A

The Global livestock environmental assessment model (GLEAM)

1. INTRODUCTION

The Global Livestock Environmental Assessment Model (GLEAM) is a process-based static model that simulates the functioning of livestock production systems. The current version of the model (V1.0) focuses primarily on the quantification of GHG emissions, but future versions will include other processes and flows for the assessment of other environmental impacts, such as those related to water, nutrient and land use.

The model differentiates the 11 main livestock commodities, which are: meat and milk from cattle, sheep, goats and buffalo; meat from pigs; and meat and eggs from chickens. It calculates the GHG emissions and production for a given production system within a defined spatial area, thereby enabling the calculation of the emission intensity for combinations of commodities, farming systems and locations.

The main purpose of this appendix is to explain the way in which GLEAM calculates the emission intensity of livestock products. The input data used in GLEAM (and associated issues of data quality and management) are addressed in Appendix B. The focus of this appendix is on:

- providing an overview of the main stages of the calculations;
- outlining the formulae used; and
- explaining some of the key assumptions and methodological choices made.

2. MODEL OVERVIEW

The model is GIS-based and consists of:

- input data layers;
- routines written in Python (http://www.python.org/) that calculate intermediate and output parameters; and
- procedures for running the model, checking calculations and extracting output.

The basic spatial unit used in the GIS is a cell of 3 arc minutes. The emissions and production are calculated for each cell using input data of varying levels of spatial resolution (see Appendix B). The overall structure of GLEAM is shown in Figure A1, and the purpose of each module summarized below.

- The **herd module** starts with the total number of animals of a given species and system within a cell (see Appendix B for a brief description of the way in which the total animal numbers are determined). The module also determines the herd structure (i.e. the number of animals in each cohort group, and the rate at which animals move between cohort groups) and the characteristics of the average animal in each cohort (e.g. weight and growth rate).
- The **manure module** calculates the rate at which excreted N is applied to pasture and crops.

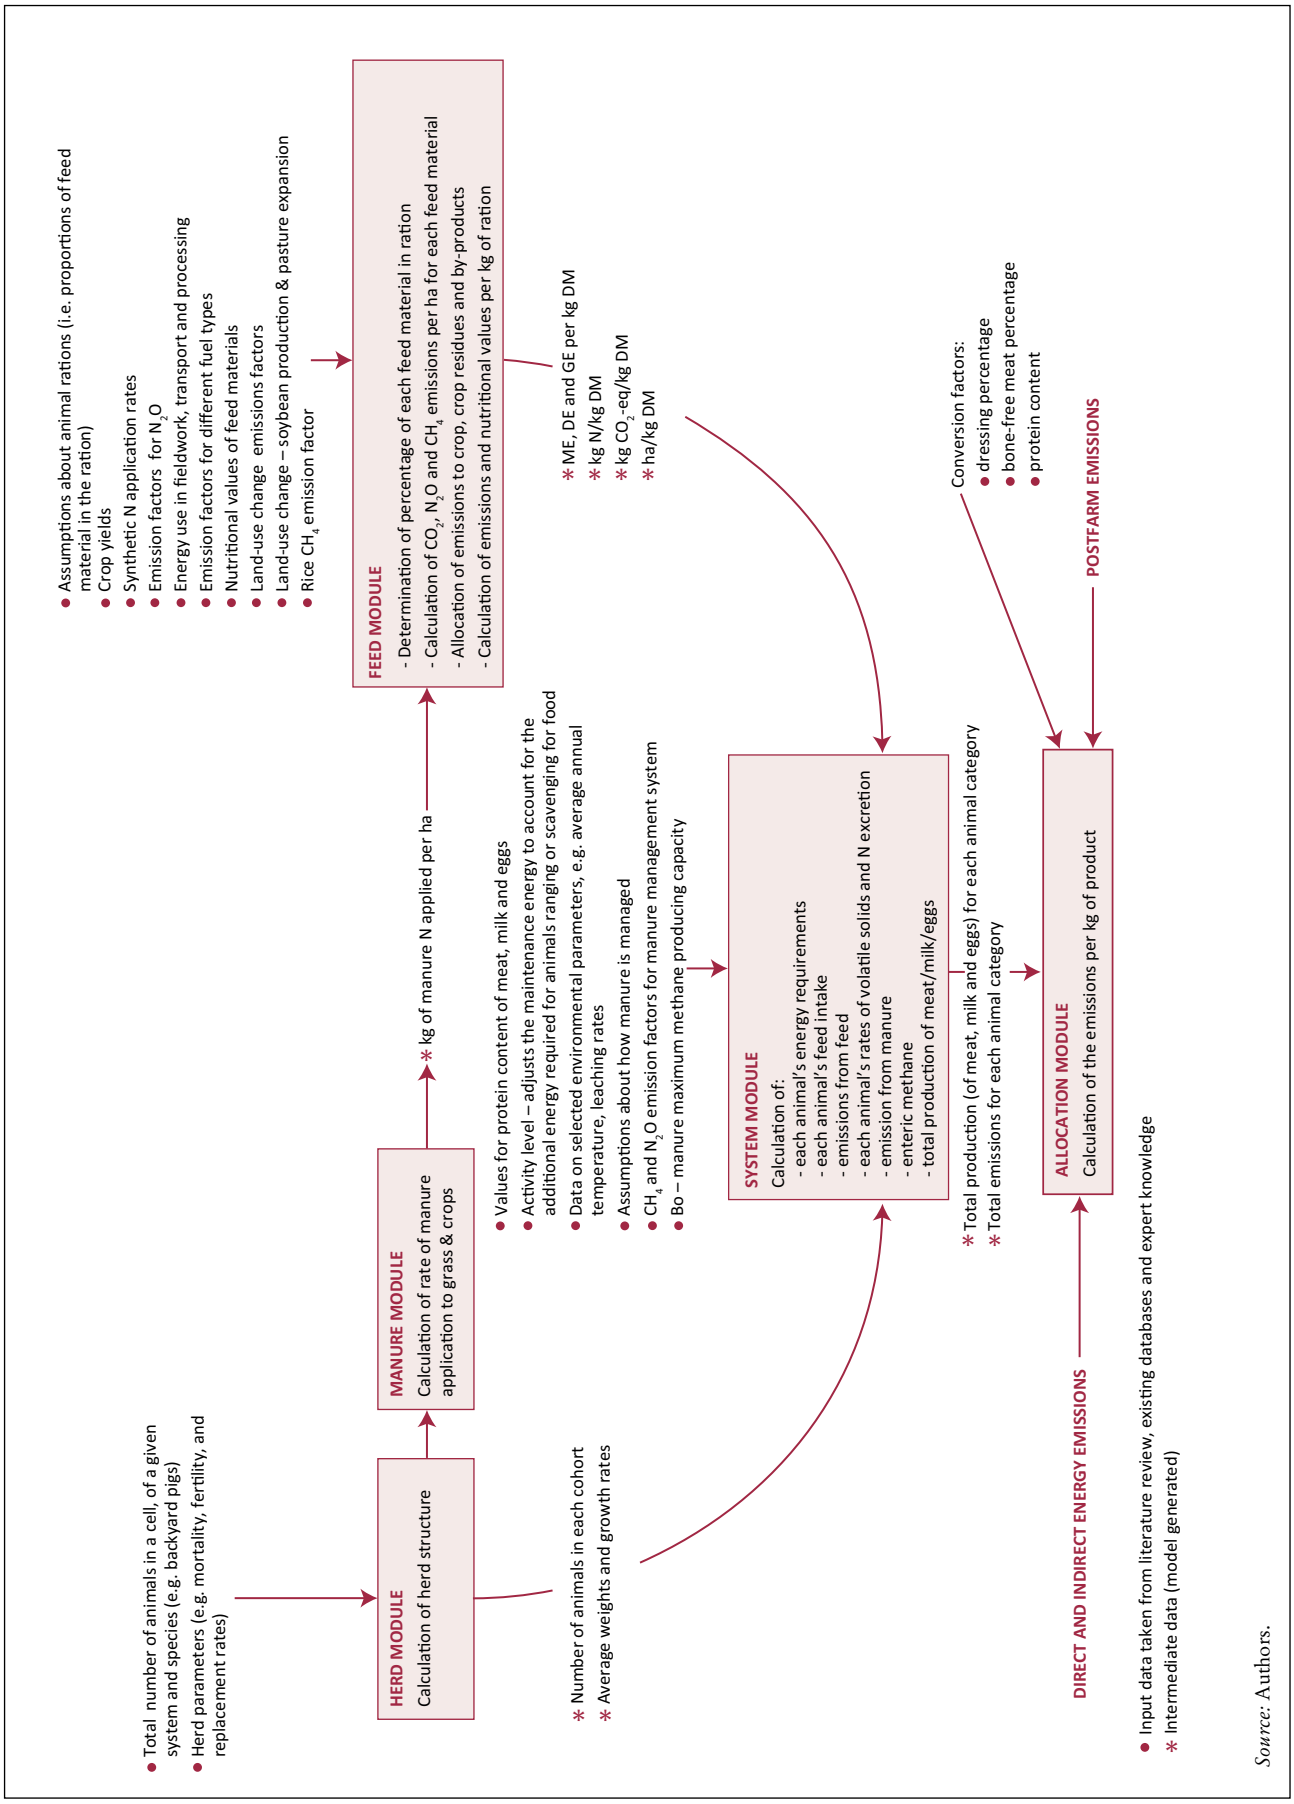
- The **feed module** calculates key feed parameters, i.e. the nutritional content and emissions per kg of the feed ration.
- The **system module** calculates each animal's energy requirement, and the total amount of animal product (milk, meat and fibre) produced in the cell each year. It also calculates the total annual emissions arising from manure management, enteric fermentation and feed production.
- The **allocation** module combines the emissions from the system module with the emissions calculated outside GLEAM, i.e. emissions arising from (a) direct on-farm energy use; (b) the construction of farm buildings and manufacture of equipment; and (c) post-farm transport and processing. The total emissions are then allocated to output in the form of products and services (milk, meat and eggs, fibre and draught power) and the emission intensity per unit of commodity calculated. Each of the stages in the model is described in more detail below.

3 HERD MODULE

The functions of the herd module are to:

- Determinate the herd structure, i.e. the proportion of animals in each cohort, and the rate at which animals move between cohorts; and
- Calculate the characteristics of the animals in each cohort, i.e. the average weight and growth rate of adult females and adult males.

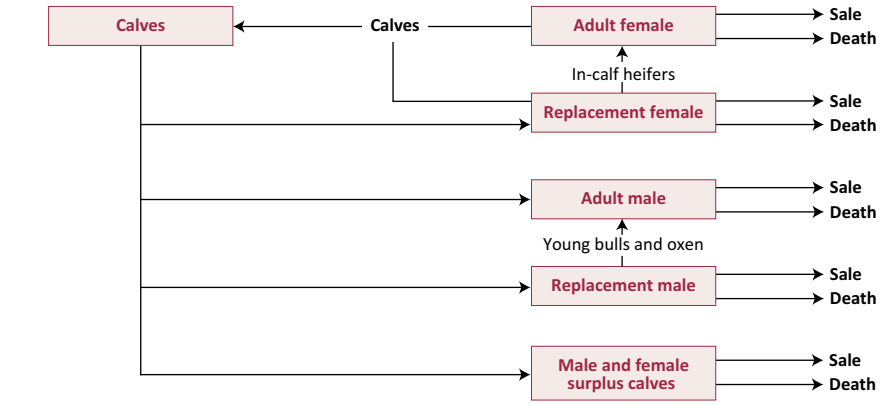
Emissions from livestock vary depending on animal type, weight, phase of production (e.g. whether lactating or pregnant) and feeding situation. Accounting for these variations in a population is important if emissions are to be accurately characterized. The use of the IPCC (2006) Tier 2 methodology requires the animal population to be categorized into distinct cohorts. Data on animal herd structure are generally not available at the national level. Consequently, a specific herd module was developed to decompose the herd into cohorts. The herd module characterizes the livestock population by cohort, defining the herd structure, dynamics and production.



Herd structure. The national herd is disaggregated into six cohorts of distinct animal classes: adult female and adult male, replacement female and replacement male, and male and female surplus or fattening animals which are not required for maintaining the herd. Figure A2 provides an example of a herd structure (in this case for cattle). In this assessment it is assumed that all surplus calves are fattened for meat.[12]

The key production parameters required for herd modeling include data on *mortality, fertility, growth and replacement rates,* also known as "rate parameters". In addition, other parameters are used to define the herd structure. They include:

- the age or weight at which animals transfer between categories e.g. the age at first parturition for replacement females or the weight at slaughter for fattening animals;
- duration of key periods i.e. gestation, lactation, time between servicing; and
- the ratio of breeding females to males.



[12] In some intensive dairy systems, surplus calves may be slaughtered within a few days after birth.

Figure A1.
Schematic representation of GLEAM

Source: Authors.

Figure A2.
Structure of herd dynamics for cattle

Source: Authors.

4. MANURE MODULE

The function of the manure module is to calculate the rate at which excreted N is applied to feed crops.

The manure module calculates the amount of manure N collected and applied to grass and cropland in each cell by:

- calculating the amount of N excreted in each cell by multiplying the number of each animal type in the cell by the average N excretion rates;
- calculating the proportion of the excreted N that is lost during manure management and subtracting it from the total N, to arrive at the net N available for application to land; and
- dividing the net N by the area of (arable and grass) land in the cell to determine the rate of N application per ha.

5. FEED MODULE

The functions of the feed module are to:

- Calculate the composition of the ration for each species, system and location;
- Calculate the nutritional values of the ration per kg of feed DM; and
- Calculate of GHG emissions and land use per kg of DM of ration.

The feed module determines the diet of the animal, i.e. the percentage of each feed material in the ration, and calculates the emissions (N_2O, CO_2 and CH_4) arising from the production, processing and transport of the feed. It allocates the emissions to crop co-products such as crop residues or meals) and calculates the emission intensity per kg of feed. It also calculates the nutritional value of the ration, in terms of its energy and N content.

5.1 Determination of the ration

Animal rations are generally a combination of different feed ingredients. For ruminants, three broad categories of feed are considered: roughages, by-products and concentrates. Typically, major feed ingredients include:

- Grass: ranges from natural pasture and roadsides to improved and cultivated grasslands and leys.
- Feed crops: crops specially grown to feed livestock, e.g. maize silage or grains.
- Tree leaves: browsed in forests or collected and carried to livestock.
- Crop residues: plant material left over from food or other crops, such as straw or stover, left over after harvesting.
- Agro-industrial by-products and wastes: by-products from the processing of non-feed crops such as oilseeds, cereals, sugarcane, and fruit. Examples include cottonseed cakes, rapeseed cakes and brans.
- Concentrates: high quality mixtures of by-products and feed that are processed at specialized feed mills into compound feed.

In all livestock production systems, the composition of the feed ration depends on the availability of pasture and fodder, the crops grown and their respective yields. The fraction of concentrates in the ration varies widely, according to the need to complement locally available feed, the purchasing power of farmers, and access to markets. While actual diets will vary depending on what crops are grown locally and the price of feed crops, the balance of forage, crops and by-products must be reasonable in order to match animal performance. The proportion of each feed component is determined differently for industrialized and developing country regions:

- for the industrialized regions, the composition (i.e. feed materials) and relative portions of the feed ration materials are taken from country national inventory reports, literature and targeted surveys.
- for developing countries, due to scanty information, a feed allocation scheme was devised based on literature and expert knowledge. This allocation scheme assumes that in developing regions there is a close relationship between land use and the feed ration.

Feed allocation scheme for developing countries. The feed allocation scheme is based on the availability of feed resources (crops and forage) and animal requirements. The determination of the feed ration is outlined stepwise below:

1. Define the proportion of by-products and concentrates in the ration (based on surveys, literature and expert knowledge) and the difference is considered roughages.
2. Calculate the total roughage availability in each pixel based on the dry matter yields per hectare of pasture, fodder and crop residues and the land area of the respective feeds. Data for this calculation was obtained from a number of sources: FAOSTAT for specific crops (e.g. fodder beet, soybean, rapeseed, cottonseed, sugar beet and palm fruit); You *et al.* (2010) from the Spatial Production Allocation Model (SPAM) for 20 crops; and Haberl *et al.* (2007) to estimate the above-ground net primary productivity for pasture.
3. Feed requirements for all ruminant species were then assessed. This was done by expressing the different ruminant species and categories of animals in cattle equivalent, to take into account the fact that these animals are competing for the same feed resource.
4. To assess the feed availability, a ratio between the total roughage availability (calculated in 2 above) and ruminant species biomass (in cow equivalent calculated in 3 above) was obtained.

5. Total ruminant annual feed requirements are then calculated for the total cow equivalent based on the assumption that an animal consumes about 2 to 3 percent of its bodyweight on a daily basis and hence, on an annual basis, DMI will range between 7.3 and 14 kg DM.
6. The total amount of roughage feed available is then compared with the animal feed requirements within each cell. Comparing the total feed availability with the animal requirements provides an indication of feed adequacy in terms of sufficiency, deficiency or surplus for any given location. An area can be classified based on the dry matter availability and generally a dry matter availability of less than 2 percent of the bodyweight can be considered as a deficit, dry matter availability between 2 and 3 percent can be considered as adequate, and above 3 percent can be considered as surplus. In situations where ample feed is not available to meet the requirements of the animals (i.e. less than 2 percent), the feed ration is supplemented with leaves and hay.
7. The proportion of each roughage material within the feed ration is then obtained by dividing the quantity available of each roughage material by the total available roughage.
8. The proportions of the roughage materials (calculated in 7 above) plus the by-products and concentrate proportions (defined in 1 above) form the total feed ration which sums to 100.

Tables B7 to B12 in Appendix B present the average feed rations and the proportions of the different feed materials within the feed ration for the world's main regions and species.

5.2 Determination of the ration's nutritional values

Nutritional values such as the digestibility and N-content of each individual feed material are used to calculate the nutritional value of animal feed rations. These nutritional values are multiplied by the percentage of each feed material in the ration to arrive at the average energy and N content per kg of DM for the ration as a whole. Table B13 in Appendix B compares regional variation in digestibility of feed rations for ruminant species.

5.3 Determination of the ration's GHG emissions and land use per kg of DM from feed

The categories of GHG emission included in the assessment of each feed material's emissions are:

- direct and indirect N_2O from grass and crop cultivation;
- CO_2 arising from loss of above and below ground carbon brought by land-use change;
- CO_2 from the on-farm energy use associated with field operations (tillage, manure application, etc.) and crop drying and storage;
- CO_2 arising from the manufacture of fertilizer;
- CO_2 arising from crop transport; and
- CO_2 arising from off-farm crop processing.

A brief outline of how the emissions were calculated is provided below.

Determination of feed emissions: N_2O from pasture and crop cultivation. Nitrous oxide emissions from cropping include direct N_2O, and indirect N_2O from leach-

ing and volatilization of ammonia. It was calculated using the IPCC (2006) Tier 1 methodology. Synthetic N application rates were defined for each crop at a national level, based on existing data sets (primarily FAO's fertilizer use statistics, http://www.fao.org/ag/agp/fertistat/index_en.htm) and adjusted down where yields were below certain thresholds. Manure N application rates were calculated in the manure module. Crop residue N was calculated using the crop yields and the IPCC (2006, Volume 4, Chapter 11, p. 11.17) crop residue formulae.

Determination of pasture and crop emissions: CO_2 from land-use change. The approach for estimating emissions from land-use change is presented in Appendix C.

Determination of feed emissions: CO_2 from fertilizer manufacture. The manufacture of synthetic fertilizer is an energy-intensive process, which can produce significant amounts of GHG emissions, primarily via the use of fossil fuels, or through electricity generated using fossil fuels. The emissions per kg of fertilizer N will vary depending on the factors such as the type of fertilizer, the efficiency of the production process, the way in which the electricity is generated, and the distance the fertilizer is transported. Due to the lack of reliable data on these parameters, and on fertilizer trade flow, the average European fertilizer emissions factor of 6.8 kg CO_2-eq per kg of ammonium nitrate N in all regions was used (Jenssen and Kongshaug, 2003), which includes N_2O emissions arising during manufacture.

Determination of feed emissions: CO_2 from field operations. Energy is used on-farm for a variety of field operations required for crop cultivation, such as tillage, preparation of the seed bed, sowing and application of synthetic and organic fertilizers, crop protection and harvesting. The type and amount of energy required per ha, or kg, of each feed material parent crop was estimated. In some countries, field operations are undertaken using non-mechanized power sources, i.e. human or animal labour. The energy consumption rates were adjusted to reflect the proportion of the field operations undertaken using non-mechanized power sources. Table A1 gives an indication of the average level of mechanization per region. From the level of mechanization, we also inferred reliance on animal draught power in the country, and therefore the bull to cow ratio in the herd. The emissions arising from fieldwork per ha of each crop were calculated by multiplying the amount of each energy type consumed per ha, by the emissions factor for that energy source.

Table A1. Estimated average level of mechanization by region

Continent	Estimated rate of mechanisation *(percentage)*
Africa	16
Asia	78
Central and South America	96
Europe	100
North America	100
Oceania	100

Source: FAOSTAT (2009).

Determination of feed emissions: CO_2 from transport and processing. Pasture and crop residues, by definition, are transported minimal distances and are allocated zero emissions for transport. Non-local feeds are assumed to be transported between 100 km and 700 km by road to their place of processing. In countries where more of the feed is consumed than is produced (i.e. net importers), feed that are known to be transported globally (e.g. soybean meal) also receive emissions that reflect typical sea transport distances. Emissions from processing arise from the energy consumed in activities such as milling, crushing and heating, which are used to process whole crop materials into specific products. Therefore, this category of emissions applies primarily to feeds in the by-product category.

Determination of feed emissions: CO_2 from blending and transport of compound feed. Energy is used in feed mills for blending non-local feed materials to produce compound feed and to transport it to its point of sale. It was assumed that 186 MJ of electricity and 188 MJ of gas were required to blend 1 000 kg of DM, and that the average transport distance was 200 km.

5.4 Allocation of emissions between crop and its by-products

In order to calculate the emission intensity of the feed materials, emissions need to be allocated between the crop and its by-products, i.e. the crop residue or by-products of crop processing used as feed. The general expression used is:

$$GHGkgDM = GHGha/(DMYGcrop \cdot FUEcrop + DMYGby \cdot FUEby) \cdot EFA/MFA$$

where:

GHGkgDM	=	emissions (of CO_2, N_2O, or CH_4) per kg of dry matter
GHGha	=	emissions per ha
DMYGcrop	=	gross crop yield (kgDM/ha)
DMYGby	=	gross crop residue or by-product yield (kgDM/ha)
FUEcrop	=	feed use efficiency, i.e. fraction of crop gross yield harvested
FUEby	=	feed use efficiency, i.e. fraction of crop residue or by-product gross yield harvested
EFA	=	economic fraction, crop or co-product value as a fraction of the total value (of the crop and co-product)
MFA	=	mass fraction, crop or co-product mass as a fraction of the total mass (of the crop and co-product)

Dry matter yields and estimated harvest fractions were used to determine the mass fractions. Where crop residues were not used for feed or bedding, they were assumed to have a value of zero, i.e. 100 percent of the emissions were allocated to the crop.

Allocation techniques of feed emissions is summarized in Table A2. Emissions from post-processing blending and transport are allocated entirely to feed. It should be highlighted that emissions that are not allocated to feed do not cease to exist. Rather, they are allocated to other commodities. Failure to follow this approach may lead to incorrect policy conclusions.

Table A2. Summary of the allocation techniques used in the calculation of plant-based feed emissions

Products	Source of emissions	Allocation technique
All feed crops and their by-products	N_2O from manure application N_2O from synthetic fertilizer CO_2 from fertilizer manufacture CO_2 from fieldwork	Allocation between the crop and co-product is based on the mass harvested, and the relative economic values (using digestibility as a proxy)
By-products only	CO_2 from processing CO_2 from LUC (for soybean)	Allocated to the processing by-products based on mass and economic value
Feed produced off-farm	CO_2 from transportation and blending	100 percent to feed material

Source: Authors.

6. SYSTEM MODULE

The functions of the system module are to:

- Calculate the average energy requirement (MJ) and feed intake (kg DM) of each animal cohort;
- Calculate the total feed emissions and land use arising from the production, processing and transport of the feed;
- Calculate the CH_4 and emissions arising during the management of manure;
- Calculate enteric CH_4 emissions.

6.1 Calculation of animal energy requirement

The system module calculates the energy requirements of each animal, which is then used to determine the feed intake (in kg of DM). The model uses the IPCC Tier 2 algorithms (IPCC, 2006 Volume 4, Chapter 10, Equations 10.3 to 10.13) to calculate energy requirements for each animal sub-category. The gross energy requirement is the sum of the requirements for maintenance, lactation and pregnancy, animal activity, weight gain and production.[13] The method estimates a maintenance requirement (as a function of live-weight and energy expended in feeding); a production energy requirement influenced by the level of productivity (e.g. milk yield, live-weight gain, wool production); physiological state (pregnancy and lactation); and the stage of maturity of the animal. Based on production and management practices, the net energy and feed requirements of all animals are first calculated, taking into account the following parameters:

- *Weight*. Larger animals need more energy for maintenance than smaller ones.
- *Production*. The output from animals can be milk and meat, but also non-edible products and services. Data on production of edible and non-edible products is taken from literature and statistical databases. In general terms, a higher production or more labour per day requires more energy and thus more feed per day.

[13] Total production is computed on the basis of herd parameters (reproduction, mortality, etc.) and productivity parameters (such as milk yield and weight gain) used in the analysis. Consequently, total production may not be consistent with total production in the FAOSTAT database.

- *Production/feeding environment (Grazing or stall feeding).* Animals in ranging systems that have to search for their feed (often over long distances) have higher energy requirements than those in grazing systems or stall-fed systems.

6.2 Calculating feed intake, total feed emissions and land use

The feed intake of each animal category (in kg DM/day) is calculated by dividing the animal's energy requirement by the average energy content of the ration from the feed module:

Feed intake (kgDM/animal/day) = total energy requirements (MJ/animal/day)/feed energy content (MJ/kgDM)

where: feed energy content = 18.45 (MJ/kgDM)

The feed intake of each cohort is multiplied by the number of animals in each group to obtain the total daily feed intake for the entire herd. The feed emissions and land use associated with the feed production are then calculated by multiplying the total feed intake for the herd by the emissions or land use per kg of DM taken from the feed module.

6.3 Calculation of CH_4 emissions arising enteric fermentation

Emissions from enteric fermentation (kg CH_4/head) are a function of feed digestibility (DE), i.e. the percentage of gross energy intake that is metabolized. An enteric methane conversion factor, Y_m (percentage of gross energy converted to methane) is used to calculate the methane emissions from enteric fermentation. A Tier 2 approach is applied for the calculation of enteric CH_4 emissions due to the sensitivity of emissions to diet composition and the relative importance of enteric CH_4 to the overall GHG emissions profile in ruminant production. The IPCC (2006) defines the CH_4 conversion factor (Y_m) as 6.5±1 percent, indicating that Y_m is at the high end of the range when digestibility of feed is low and vice versa. The Y_m value of 6.5 is realized at a digestibility of 65 percent. To better reflect the wide-ranging diet quality and feeding characteristics globally, this assessment developed specific Y_m values based on the following formula:

$$Y_{m\ Cattle} = 9.75 - 0.05 \cdot DE$$
$$Y_{m\ mature\ sheep} = 9.75 - 0.05 \cdot DE$$
$$Y_{m\ lamb<1\ year} = 9.75 - 0.05 \cdot DE$$

Y_m is subsequently used in the following formula to estimate the CH_4 emission factor

$$EFCH_4 = (365 \cdot GE \cdot (Y_m / 100) / 55.65)$$

where: $EFCH_4$ is the CH_4 emission factor (kg CH_4 head $^{-1}$ yr $^{-1}$); Y_m corresponds to CH_4 conversion factor; GE is the gross energy intake (MJ head^{-1} day^{-1}) and the factor 55.65 (MJ kg CH_4) represents the energy content of CH_4.

6.4 Calculation of CH_4 emissions arising during manure management

Calculating the CH_4 per head from manure using a Tier 2 approach requires (a) estimation of the rate of excretion of volatile solids per animal, and (b) estimation of the proportion of the volatile solids that are converted to CH_4. The volatile solids excretion rates are calculated using Equation 10.24 from IPCC (2006). Once the volatile solids excretion rate is known, the proportion of the volatile solids converted to CH_4 during manure management per animal per year can be calculated using Equation 10.23 from IPCC (2006).

The CH_4 conversion factor depends on how the manure is managed. In this study, the manure management categories and emission factors in IPCC (2006, Volume 4, Chapter 10, Table 10A-7) were used. The proportion of manure managed in each system is based on official statistics (such as the Annex I countries' National Inventory Reports to the UNFCCC), other literature sources and expert judgement.

6.5 Calculation of N_2O emissions arising during manure management

Calculating the N_2O per head from manure using a Tier 2 approach requires (a) estimation of the rate of N excretion per animal, and (b) estimation of the proportion of the excreted N that is converted to N_2O.

The N excretion rates are calculated using Equation 10.31 from IPCC (2006) as the difference between intake and retention. N-intake depends on the feed dry matter intake and the N content per kg of feed. The feed dry matter intake depends, in turn, on the animal's energy requirement (which is calculated in the system module, and varies depending on weight, growth rate, milk yield, pregnancy, weight gain and lactation rate and level of activity) and the feed energy content (calculated in the feed module). N retention is the amount of N retained in, either as growth, pregnancy live weight gain or milk.

The rate of conversion of excreted N to N_2O depends on the extent to which the conditions required for nitrification, denitrification, leaching and volatilization are present during manure management. The IPCC (2006) default emission factors for direct N_2O (IPCC, 2006 Volume 4, Chapter 10, Table 10.21) and indirect via volatilization (IPCC, 2006 Volume 4, Chapter 10, Table 10.22) are used in this study, along with variable leaching rates, depending on the AEZ.

7. ALLOCATION MODULE

The functions of allocation module are to:

- Sum up the total emissions for each animal cohort;
- Calculate the amount of each commodity (meat, milk, eggs, wool) produced;
- Allocate emissions to each commodity (meat and meat), non-edible outputs (fibre and manure used for fuel), draught and services; and
- Calculate total emissions and emission intensity of each commodity.

7.1 Calculation of the total emissions for each animal cohort

The system module calculates the total emissions arising from feed production, manure management and enteric fermentation. Post farmgate emissions (Appendix D) and direct and indirect on-farm energy use (Appendix E) are calculated separately and incorporated in the allocation module.

7.2 Calculation of the amount of each commodity (meat, milk, fibre) produced

Milk. Total milk production was calculated based on average milk production per animal and number of milking animals. Total milk is then converted to fat and protein milk. Using FPCM as the basis for comparison ensures a comparison between milk produced by different breeds and feeding regimes. All milk was converted to FPCM using the following equations:

Milk yield from cattle was corrected at 4.0 percent fat and 3.3 percent protein using the equation: FPCM (kg) = milk production, kg • [0.337+ 0.116 • fat, (percent) + 0.06 • protein, (percent)]

Milk yield from small ruminants was corrected at 6.5 percent fat and 5.8 percent protein according to Pulina, Macciotta and Nuda (2004) using the equation: FPCM (kg) = milk production, kg • [0.25+ 0.085 • fat, (percent) + 0.035 • protein, (percent)]

Buffalo milk production was expressed was corrected at 4 percent fat and 3.1 percent protein using the following equation (Di Palo, 1992): FPCM (kg) = milk production, kg • [1+ 0.011 • {(fat, (percent) • 10-40) + (10 • protein, (percent)-31)}]

Meat. Total meat production is calculated from the number of live animals (per cohort group) that leave the farm for slaughter and the live weight at which they are sold. Dressing percentages for the conversion of live weight to carcass weight are given in Appendix B, Tables B20 and B21. Conversion of carcass to bone-free meat is obtained by multiplying by 0.75 and 0.70 for large and small ruminants, respectively. The conversion of bone-free meat (BFM) to protein is based on the assumption that BFM is 18 percent protein by weight.

Natural fibre. Total fibre (wool, mohair and cashmere) is estimated by multiplying kg of fibre produced per animal by the number of fibre producing animals in the herd.

7.3 Allocation to co-products and calculation of emission intensity

For ruminant species, emissions are allocated between the edible commodities, i.e. meat and milk. In reality, there are usually significant amounts of other commodities produced during processing, such as skin, feathers and offal. However, the values of these can vary markedly between countries, depending on the market conditions, which, in turn, depend on factors such as food safety regulations and consumer preferences. Allocating no emissions to these can lead to an over-allocation to meat. The potential effect of this assumption is explored in Appendix F. Allocation techniques applied in this assessment are discussed below:

Meat and milk. Emissions related to goods and services other than meat and milk (e.g. fibre, manure used for fuel, draught power) were first calculated separately and deducted from the overall system emissions, before emissions were attributed to meat and milk.

Within the dairy herd, some animals only produce meat (fattened surplus calves), while others contribute to the combined production of meat and dairy products (milked cows, adult reproduction male animals and replacement stock). For the latter group, we chose to allocate GHG emissions on the basis of their protein con-

Table A3. Example of allocation between edible products from dairy production

	Part of herd producing milk and meat *(milking cows, adult male, replacement stock)*	**Part of herd producing meat only** *(surplus males and females)*
Total emissions *(kg CO_2-eq)*	1 700 000	350 000
Total protein *(kg)*	Milk: 18 000 Meat: 1 500	Meat: 2 500
Fraction of milk protein	0.92	NA
Fraction of meat protein	0.08	1
Emission intensity of milk	= (1 700 000 · 0.92)/18 000 **= 87 kg CO_2-eq/kg protein**	
Emission intensity of meat	= [(1 700 000 · 0.08) + 350 000]/(1 500+2 500) **122 kg CO_2-eq/kg protein**	

NA: Not Applicable.
Source: Authors' calculations.

tent. Table A3 provides an illustration of how the technique is applied. This method reflects the fact that a primary function of the livestock sector is to provide humans with edible protein. The advantages of using protein content are that it enables direct comparison with other food products and is also relatively stable in time (as opposed, for example, to the relative prices of meat and milk) and that it can be applied in situations where markets are absent or where they are highly localized and not comparable across regions. However, a disadvantage is that other nutritional properties, such as minerals, vitamins and energy, and essential fatty acids are not captured.

Emissions related to surplus calves fattened for meat production were entirely attributed to meat production. However, the emissions related to the production of calves, i.e. the pregnancy of the dairy cows and female replacement stocks, were allocated to milk because they are an essential input for milk production. No emissions were allocated to the other parts of the slaughtered animal (e.g. skin, horns), although these are utilized and represent an economic yield. This may result in a slight overestimation of the emissions per kg of carcass weight. In beef herds, all emissions were allocated to meat after the deduction of emissions related to draught power (in the case of cattle) and fibre (wool, cashmere and mohair) from small ruminants.

Manure. Manure is another by-product of livestock production. The emissions related to manure were allocated through the subdivision of the production processes:

- *Emissions related to manure storage* were fully allocated to the livestock system.
- *Emission from manure applied on the land used for feed, food and cash crop production* were allocated to livestock in situations where the crop as a whole or in part (e.g. silage, grain, oilseeds) was used for animal nutrition. In situations where manure was entirely deposited on grassland and feed crops, no allocation was required because the manure remained within the livestock system. On the other hand, where parts of the crop (e.g. crop residues) were used for feed, emissions were allocated according to the relative weight of harvested products used as feed, corrected for digestibility. Due to

the absence of an economic value for crop residues, digestibility was used as a proxy for economic value. In cases where the crop was not used for animal nutrition, emissions were not allocated to livestock.

- *Emissions from manure used for fuel at the household level* leave the livestock system and therefore emissions from burning were not allocated to the livestock system.
- *Emissions from manure discharged into the environment* were solely attributed to livestock activities.

Fibre (wool, cashmere and mohair). Fibre is a by-product of sheep and goat production; however in some countries these products can be considered as main products of production due to their price leverage and market value. In this study, the allocation of the carbon footprint to fibre was performed based on the market value of all system outputs – meat, milk, and fibre products. The fractions of the economic value of the co-product within the total economic value of all products produced by a given species were utilized as an allocation factor to partition GHG emissions between fibre and the edible products. This fraction was determined as:

$$F_w = (Wool_{kg} \cdot Price_{wool})/(Meat_{kg} \cdot Price_{meat} + Milk_{kg} \cdot Price_{milk} + Wool_{kg} \cdot Price_{wool})$$

where: F_w is the ratio of economic value of wool to the total economic value of all products produced. Similar calculations were performed for countries producing cashmere and mohair. Wool, meat and milk represent the mass of the product in kg. Table A4 provides an illustration of how the technique is applied. To implement the total economic value, producers prices averaged over five years were taken from the FAOSTAT price domain, reflecting prices that farmers receive at the farmgate. Subsequent to the deduction of emissions for fibre production from the overall emissions, protein content was then used to allocate emissions between meat and milk.

Table A4. Example of allocation between non-edible (wool) and edible products from sheep dairy production

	Part of herd producing milk, meat and wool			Part of herd producing meat and wool only
Total emissions *(kg CO_2-eq)*	80 000			20,000
Total protein *(kg)*	Milk: 500	Meat: 50		Meat: 200
Total economic value *($)*	Milk: 4 000		Meat: 9 000	Wool: 700
Fraction of milk protein	0.9			NA
Fraction of meat protein	0.1			1
Total emission allocated to wool	=80 000 · [700/(4 000+9 000+700)] **= 4 088 kg CO_2-eq**			=20 000 · [700/(4 000+9 000+700)] **= 1 022 kg CO_2-eq**
Total emissions allocated to milk and meat	= 80 000 – 4 088 **= 75 912 kg CO_2-eq**			= 20 000 – 1 022 **= 18 978 kg CO_2-eq**
Emission intensity of milk	= (75 912 · 0.9)/500 **= 138 kg CO_2-eq/kg protein**			
Emission intensity of meat	= [(75 912 · 0.1) + 18 978]/(50+200) **= 104 kg CO_2-eq/kg protein**			

NA: Not Applicable.

Animal draught power. Herd structure, and thus the emissions profile, is affected by the use of animals, usually oxen, for labour. The use of animals for draught power has an influence on the herd's sex and age structure which skews towards higher ratios of male and older animals. Oxen must grow to maturity before they can be used for traction, and this usually takes four years, and therefore they compete with other stock for feed and other resources. The animals are then generally used for a decade before they are slaughtered. The adult male to female ratio is substantially higher than normal when animals are used for draught power because males are slaughtered at a later age.

To allocate emissions to draught power services, we first calculated total emissions and meat output from draught animals alone. In a subsequent calculation step, emissions related to the meat produced from these animals were estimated as being identical to those of meat produced from non-draught animals, slaughtered at an earlier age. The difference (accruing from the extra lifetime and the energy requirements for the labour of draught animals) was then attributed to draught power services.

Capital functions of cattle. In any cattle production system, animals constitute a form of capital, and can be sold or bought according to investment and cash flow requirements. In many pastoral systems, the capital functions of cattle are a particularly important, because they enable the accrual of savings to manage cash needs, insure against risk, and manage crises in the absence of adequate financial institutions. Therefore, low replacement rates are often a feature in these systems, because cattle are often kept even after their productivity drops. While the provision of these capital functions affects the herd structure and emission profiles of these systems, no emissions were allocated to capital services, due to difficulties in obtaining relevant information.

Slaughter by-products. In addition to the production of carcasses, slaughtering processes also produce a whole package of by-products, organs, hide, blood, etc. that are utilized for other purposes, often outside the livestock food chain. Thus, the allocation of emissions to by-products produced at the slaughterhouse can have a major impact on the GHG emission intensity for meat products. This study did not explicitly take into account by-products from slaughter due to the lack of reliable information and data. However, we explored the impact of their inclusion on emission intensity of beef in a selected case study (see Appendix F).

In terms of edible product, ruminants produce both milk and meat. The emissions were allocated between these two commodities, using the following method:

- Quantify the total emissions from animals required for milk and meat production (adult female and adult male, replacement stock and surplus animals).
- Deduct emissions related to draft power (for large ruminants), and manure used for fuel based on the approaches outlines above.
- For the dairy sector, which produces both milk and meat, emissions are allocated on a protein basis (see Tables A3 and A4). For small ruminants, allocation is first performed between the edible and non-edible products based on economic value and subsequently protein content is used to allocate between milk and meat.

APPENDIX B

Data and data sources

This appendix presents the main data utilized in this assessment. The data can be classified into *basic input data* and *intermediate data*. Basic input data can be defined as primary data such as animal numbers, herd parameters, mineral fertilizer application rates, temperature, crop yields, etc. and are data taken from other sources such as literature, databases, and surveys. Intermediate data are an output of the modelling procedure required in further calculation in GLEAM and may include data on growth rates, animal cohort groups, feed rations, animal energy requirements, feed intake, etc.

1. DATA RESOLUTION AND DISAGGREGATION

Data availability, quality and resolution vary according to the parameter and the country in question. In OECD countries, where farming tends to be more regulated, there are often comprehensive national or regional data sets, and in some cases sub-national data (e.g. for manure management in U.S. dairy). Conversely, in many non-OECD countries, data are unavailable, necessitating the use of regional default values (e.g. herd parameters). Examples of the spatial resolution of some key parameters are given in Table B1.

2. HERD

Livestock distributions. Maps of the spatial distribution of each animal species and production systems are one of the key inputs into the GLEAM model. Total ruminant numbers at a national level are reported in FAOSTAT. The spatial distributions used in this study were based on maps developed in the context of FAO's Gridded Livestock of the World (FAO, 2007).

Herd parameters. The national herd is disaggregated into cohorts according to six animal classes: adult female and male, replacement female and male, and male and female surplus or fattening animals that are not required for maintaining the herd and are kept for meat production only. The key biological parameters required for herd modelling incorporate data on mortality, fertility and growth rate, also known as "rate parameters".

- *Fertility parameters:* data on fertility are usually incorporated in the form of parturition rates (e.g. calving, kidding, lambing rates), and are normally defined as the number of births occurring in a specified female population in a year. For cattle, the number of births per year is assumed to be one. However, in the case of small ruminants, litter size is taken into account. The model utilizes age-specific fertility rates for adult and young replacement females. The proportion of breeding females that fail to conceive is also included.
- *Mortality rates:* data on mortality are incorporated in the form of death rates. In the modelling process, age specific death rates are used; mortality rate in calves and mortality rate in other animal categories. The death rate of

calves reflects the percentage of pregnancies that end with a dead calf. This may occur by abortion, still birth or death in the first 30 days after birth.

- *Growth rates:* the growth rate of animals is based on the age at which they attain adult weight. For females, this depends on the age at first parturition, although some growth takes place after this. The age at which animals are sold for slaughter is based on the defined slaughter weight and the calculated growth rate.
- *Replacement rates:* these represent the number of adult animals replaced by younger adult animals per year. The replacement rate of female animals is taken from the literature. Literature reviews did not reveal any data on the replacement rate of male animals, so the replacement rate was defined as the reciprocal value of the age at first parturition, on the assumption that farmers will prevent in-breeding by applying this rule. For small ruminants, adult males are usually exchanged twice by farmers and therefore have three service periods.

Tables B2-B6 present input herd parameter data used in this analysis.

3. FEED

Animal rations are generally a combination of different feed ingredients. For ruminants, three broad categories of feed are considered: roughages, by-products and concentrates. Feed is defined by a feed ration which differs among animal categories as defined in the herd module. Three separate feed rations are formulated for the following categories: adult females; replacement males and females and adult males; and surplus (meat) animals for fattening. Tables B7 to B12 present the average feed rations and proportions of different feed materials within the feed basket by region and ruminant species.

In this assessment, all plant-based feed materials are identified by three key parameters: dry-matter yield per hectare; net energy content (or digestibility); and nitrogen content. These three parameters are data input in the calculation of the feed ration and its nutritive value. The dry matter yield determines the type of feed ingredients that make up the feed ration as well as the potentially available feed in a region. The digestibility and N-content of feed define the quality properties of feed and determine the efficiency with which feed is digested and eventual GHG emissions. Table B13 presents regional average feed ration digestibility values.

Emission factors for key data inputs into feed production. Emissions of fossil CO_2 from feed production, transport and processing are dependent on the amounts and types of fuels used. Table B14 presents emission factor data used in the calculation of the feed emission intensity.

Emissions of CO_2 and N_2O occurring during the production of nitrogenous fertilizers. The most commonly occurring mineral fertilizer, ammonium nitrate, which consists of equal parts of ammonium- and nitrate-nitrogen, currently releases ~6.8 kg CO_2-equivalents in production (Jenssen and Kongshaug , 2003). Due to the lack of reliable data on these parameters, and on fertilizer trade flow, the average European fertilizer emissions factor of 6.8 kg CO_2-eq per kg of ammonium nitrate N in all regions was used.

4. MANURE

There are considerable differences in emissions from MMS. Data requirements for the estimation of GHG emissions from MMS include: information on how manure is managed, the types of MMS, and the proportion of manure managed in these systems. Additionally, climatic information (e.g. temperature) is important because emission factors are climate dependent. It was thus necessary to consider the climate under which livestock is managed in each country.

On a global scale, there is limited data available on how manure is managed and the proportion of the manure managed in each system. Consequently, this study relied on various data sources such as national inventory reports, literature and expert knowledge to define the proportions of manure management systems. It uses the IPCC (2006) classification of MMSs (definition in Table 10.18, IPPC guidelines). Regional variations manure management practices are presented in Tables B15 to B19.

5. PRODUCTION AND ALLOCATION

Dressing percentage. Dressing percentage can be defined as the percent of the live animal that ends up in the carcass. The LW:CW ratio varies substantially depending on a range of factor including breed, gender, diet, age, diet, cold versus warm carcass weight, and distance trucked. Tables B20 and B21 present the dressing percentages used for large and small ruminants.

Emission allocation factors. Table B22 presents a comparison of dairy and beef herds in total cattle population across world regions, their contribution to total beef production and the allocation factors used in this assessment for the allocation of emissions between milk and meat from the dairy herd. Emission allocation factor for wool, yield and total economic value (for meat, milk and wool produced by sheep) are presented in Table B23. See Appendix A for more details on allocation techniques applied.

Table B22. Percentage of dairy and beef herds, ratio of beef production from cattle herds and emission allocation factor for milk and meat from the dairy herd

APPENDIX C

Changes in carbon stocks related to land use and land-use change

1. INTRODUCTION

This appendix discusses GHG emissions and changes in carbon stocks that result from land use and LUC. Land uses and LUCs are defined; the relevant carbon pools and emission sources are discussed in the context of these categories; the approaches to estimating emissions and changes in carbon stocks are outlined; and finally, justification for and an explanation of the selected estimation methods used in this study is also provided.

Land use, LUC and forestry (LULUCF) is defined by the United Climate Change Secretariat as: *a greenhouse gas inventory sector that covers emissions and removals of greenhouse gases resulting from direct human-induced land use, land-use change and forestry activities*. Six land use categories are defined in the 2006 IPCC Guidelines for National Greenhouse Gas Inventories: 1. Forest Land; 2. Cropland; 3. Grassland; 4. Wetlands; 5. Settlements; and 6. Other Land.

Land may remain in any of these categories or, in the case of LUC, its use may change to another category (e.g. from forest to grassland). Thus, each land use category can be further subdivided into land that is converted from one land use category to another, and land that remains in the same category. While this study focuses on the emissions from LUC, emissions from land use are also discussed.

1.1 GHG emissions from land-use change

Most LUCs alter the soil and vegetation of the land, thus changing the amount of carbon stored per unit area. These changes may be positive or negative, and may occur in each carbon pool: biomass (above- and below-ground); dead organic matter (dead wood and litter); and soil (soil organic matter).

LUC can significantly alter the carbon stored in biomass, by replacing the vegetation of the existing land use category with the vegetation of another land use category. Conversion of forest land to either grassland or cropland can lead to large and rapid losses of the typically large stores of carbon in forest vegetation, when this vegetation is replaced with herbaceous grasses or annual crops.

While most of the carbon stored in forest biomass is lost following conversion, some carbon will be transferred from one pool to another; e.g. when trees are felled, a portion of the above-ground biomass is transferred to the dead organic matter pool, and a portion of the below-ground biomass is transferred to the soil organic matter pool.

The drainage and cultivation or grazing of organic soils is also an important cause of the oxidation and loss of SOC for both croplands and grasslands (Armentano and Menges, 1986). While the most important GHG emission flux is CO_2, the oxidization of the various organic carbon pools as a consequence of LUC can also release N_2O.

Land conversion often results in an abrupt change where most biomass is lost, followed by a longer period where biomass is oxidized at a much slower pace. The IPCC (2006) assumes a default 20-year transition period following conversion over which all losses are accounted for.

The conversion of forest land to agricultural land may also lead to losses from the SOC pool. When forest land is converted to cropland, there is an average reduction in soil carbon of between 25 and 30 percent in the upper metre of soil (Houghton and Goodale, 2004).[14] These soil carbon losses are due, in part, to a lower fraction of non-soluble material in the more easily decomposed crop residues, and to the breaking up of aggregates and subsequent exposure of organo-mineral surfaces to decomposers following tillage (Post and Kwon, 2000). On the other hand, because grasslands, unlike crops, are not ploughed (temporary cultivated pastures are classified to be crops), little change in soil carbon is expected following the conversion of forests to grasslands (Houghton and Goodale, 2004).

When either cropland or grasslands are abandoned, there is a re-accumulation of carbon in vegetation as the land returns to its natural state, and the greater the biomass of the returning vegetation the larger is the long-term carbon sink due to the recovery. Post and Kwon (2000) note relatively low rates of accumulation in mineral soil following the abandonment of cropland. Considering all LUCs during the 1990s, Houghton & Goodale (2004) estimate that the average annual emissions from LUC were estimated to be 2.2 petagram C yr^{-1}, with almost all of this emanating from deforestation in the tropics.

1.2 Land use and its effects on emissions and carbon stocks

Agricultural lands hold substantial carbon stocks, mostly in soil organic matter. Carbon stock changes in agricultural lands are closely tied to management practices, which can either enhance or erode carbon stocks. Practices which raise (lower) the photosynthetic input of carbon and/or slow (accelerate) the release of stored carbon through respiration, erosion or fire will increase (decrease) carbon stocks (Smith *et al*., 2007). While it is possible for substantial biomass carbon to be stored through perennial plantings on agricultural lands (e.g. silvopastoral systems), carbon accumulation and losses occur mostly in the SOC pool. This below-ground carbon pool also has slower rates of turnover than above-ground pools, because most of the organic carbon in soils comes from the conversion of plant litter into more persistent organic compounds (Jones and Donnelly, 2004).

Smith *et al.* (2007) estimated that 89 percent of the agriculture sector's total mitigation potential is from SOC sequestration. For grasslands, practices such as the optimization of grazing intensities to maximize grass production, moderate intensification of nutrient-poor grasslands, and the restoration of degraded pastures are known to improve sequestration rates (Conant and Paustian, 2002; Sousanna *et al.*, 2010). Conversely, the overgrazing of grasslands reduces vegetation and the amount of litter returned to soils, and it leads to erosion and degradation contributing to CO_2 losses from the SOC pool. For croplands, significant changes in SOC stocks are associated with management practices including tillage, residue management, nutrient management and the use of organic amendments (Smith *et al.*, 2007).

[14] While there is some variation around this range, it has been documented in numerous studies, and has been found to be broadly robust across all ecosystems (Houghton and Goodale, 2004).

Historically, while agricultural management practices can result in either reductions or accumulations in the SOC pool, agricultural lands are estimated to have released more than 50 petagram C (Paustian *et al*., 1998; Lal, 1999, 2004), some of which can be restored via better management. Currently, however, the net flux of CO_2 between the atmosphere and agricultural lands is estimated to be approximately balanced (Smith *et al*., 2007). For the estimation of net livestock sector GHG emissions, which is the main purpose of this report, measures of net CO_2 current fluxes by region are of greater interest than the sequestration/mitigation potential.

The lack of a globally consistent and regionally detailed set of net CO_2 flux estimates make it difficult to quantify these potential emission sources and sinks by region in this study, although there are some relevant studies that provide useful estimates of these net fluxes for specific regions and agricultural land use categories. For example, based on literature observations for temperate grasslands mainly from Western Europe, Soussana *et al*. (2010) estimate that grasslands SOC sequestration rates averaged 5 ± 30 gC/m^2 per year. Nevertheless, Soussana *et al*. (2010) concede that the uncertainties associated with SOC stock changes following changes in management are very high. Further, stocks of SOC are very vulnerable to disturbances, including tillage, fire, erosion, and droughts that can lead to rapid reversals of accumulated stocks. Moreover, the authors recommend that further research is needed to separate the influence of management factors from other climate-related factors such as average temperature increase and CO_2 fertilization, in order to be able to attribute sequestration to direct anthropogenic causes.

There is also considerable potential to sequester carbon in croplands through a range of options available that include reduced and zero tillage, set-aside, perennial crops, deep rooting crops, more efficient use of organic amendments, improved rotations, irrigation, etc. In Brazil, for example, long-term field experiments (Costa de Campos *et al*., 2011; Dieckow *et al*., 2010; Vieira *et al*., 2009; Sisti *et al*., 2004) have evaluated the impact of conservation tillage and crop rotations on SOC. The results from these studies confirm that non-tillage and crop rotations can enhance the conservation of SOM and increase C accumulation. For example, Dieckow *et al*. (2010) who assessed the 17-year contribution of no-tillage crop rotations to C accumulation in subtropical Ferralsol of Brazil concluded that crop-forage systems and crop-based systems with legume represent viable strategies to increase soil organic C stocks. They found that the alfalfa system with maize at each three years showed the highest C accumulation (0.44 tonnes C/ha/yr). The bi-annual rotation of ryegrass (hay)-maize-ryegrass-soybean sequestered 0.32 tonnes C/ha/yr. However, an assessment of realistically achievable potentials for carbon sequestration in croplands needs to take into account economic, political and cultural constraints and other environmental impacts (such as non-CO_2 GHG emissions) also need to be accounted for.

2. QUANTIFICATION OF CARBON EMISSIONS AND SEQUESTRATION

2.1 Changes of carbon stocks related to land-use change

The most fundamental step in assessing emissions from LUC is the tracking of changes in areas of land use and conversions from one land use category to the next. This requires a time series of data, or at least two points in time, to capture changes in the area of land for each category.

Comprehensive guidance on methodological approaches for estimating LUCs as well as emissions and removals from LULUCF is provided in the 2006 IPCC Guidelines for National Greenhouse Gas Inventories (IPCC, 2006). Three different approaches are suggested with differing degrees of accuracy to best ensure the consistent representation of LUCs for given data quality and availability. The most accurate of these, Approach 3, requires the use of spatially-explicit data for land use categories and conversions, and includes the use of gridded map products derived from remote sensing imagery. At the other extreme is Approach 1, which relies on non-spatially explicit data from census and survey data, often reported at country or province level, and which only permits net changes in land use categories over time, and cannot specify inter-category conversions. Finally, Approach 2 enables the tracking of conversions between land use categories without the spatially-explicit location data. Naturally, the choice among the simple and more sophisticated approaches involve big trade-offs between the data and analytical resource requirements, and the accuracy with which LUCs and their attendant emissions and carbon removals are estimated.

For grassland remaining grassland, cropland remaining cropland, and conversion from forestland to either of these land use categories, the 2006 IPCC Guidelines require that changes in carbon stocks from each carbon pool (i.e. above-ground biomass, below-ground biomass, dead wood, litter and soil organic matter), as well as emissions of non-CO_2 gases, are estimated. The guidelines do, however, provide flexibility in the use of methods that range from very simple approaches that rely on default emission factors to more sophisticated approaches that use detailed location-specific data and process models that fully characterize the fluxes between carbon pools.

2.1.1 Biomass and dead organic matter (DOM) pools

As mentioned, land-use conversions are often associated with an initial abrupt change and subsequent transition period following conversion. The 2006 IPCC Guidelines provide separate equations for these two phases when using Tier 2 and 3 approaches. Where country-specific emission factors are available and comprehensive national data are available, country-defined Tier 3 methodologies based on either process models or detailed inventories, stratified by climate and management regime can be recommended. These methods can also use non-linear loss and accumulation response curves during the transition phase.

At the other extreme, Tier 1 methods assume that both biomass and DOM pools are lost immediately after conversion from forestland to agricultural land, and that agricultural land reaches its steady-state equilibrium in the first year following conversion. While the IPCC provides default values to quantify biomass levels prior to and after conversion, there is assumed to be no accumulation in the DOM pool in the transition phase on agricultural land following conversion from forestland.

The Tier 2 methods represent a compromise, better capturing the dynamics of land-use conversion, by specifying separate equations for the abrupt change and transition phases, accounting for biomass accumulation during the latter phase. They also rely on some country-specific estimates of initial and final biomass stocks, instead of relying solely on default values.

Further, both Tier 2 and Tier 3 methods account for transfers between carbon pools and can estimate carbon pool changes using either the gain-loss or stock-

difference methods**.** The former method includes all processes that cause changes in a carbon pool, including biomass growth and the transfer of carbon from one pool to another. Alternatively, the stock-difference method can be used where carbon stocks are measured at two points in time. Both methods are valid, providing they can represent disturbances and continuously varying trends, and can be verified with actual measurements (IPCC, 2006).

2.1.2 Soil organic carbon (SOC) stocks

Changes in the SOC pools in both mineral and organic soils should be taken into account when estimating emissions and carbon accumulation resulting from LUC (IPCC, 2006). This requires that the areas of converted land be stratified by climate region, management and major soil type. Simple Tier 1 methods, which rely on default reference SOC stock change factors, can be used, or more country- or region-specific reference C stocks and stock change factors can be combined with more disaggregated land use activity data to use either Tier 2 or Tier 3 methods. Some of the process models suited to Tier 3 methods are discussed in the following section.

In this study, LUC emissions are estimated for each major carbon pool, including the biomass, DOM and SOC pools are estimated using Tier 1 methods. While Tier 2 and Tier 3 methods are recommended, the Tier 1 approach was deemed to be appropriate given the global nature of the assessment combined with the absence of country-specific emission factors, inventory data and/or a suitable global process model.

2.2 Changes in carbon stocks for agricultural land remaining in the same land use category

As with LUCs, the estimation of emissions and carbon accumulation from management practices on land that remains in the same land use category requires that changes in carbon stocks from each major carbon pool (i.e., above-ground biomass, below-ground biomass, dead wood, litter and soil organic matter), as well as emissions of non-CO_2 gases, are estimated.

For agricultural lands, changes in these carbon pools and non-CO_2 emission fluxes depend on management practices such as grazing, burning, pasture management, tillage and residue management. Tier 2 and Tier 3 methods are able to estimate changes in each carbon pool and in emissions resulting from management practices, while Tier 1 methods can only be used to estimate these changes for the SOC pool (and non-CO_2 emissions from burning), but not for the other carbon pools. As with the measurement of emissions and carbon storage under LUC, the same gain-loss and/or stock-difference methods can be employed.

As discussed, Tier 3 methods can be used to more accurately assess changes in these carbon pools and non-CO_2 emission sources, using dynamic process models and/or detailed inventory measurements to estimate carbon stock changes. Process model-based approaches simultaneously solve multiple equations to estimate net changes in carbon stocks. These models can incorporate management effects such as grazing intensity, fire, fertilization, tillage and residue management, and they can be combined with regionally representative sampling-based estimates to validate and extrapolate to other agricultural lands. According to IPCC (2006), important criteria for selecting these models include: their ability to represent all relevant management practices and production systems, the compatibility of model's driving variables (inputs) with available country data, and validity gauged by the model's ability

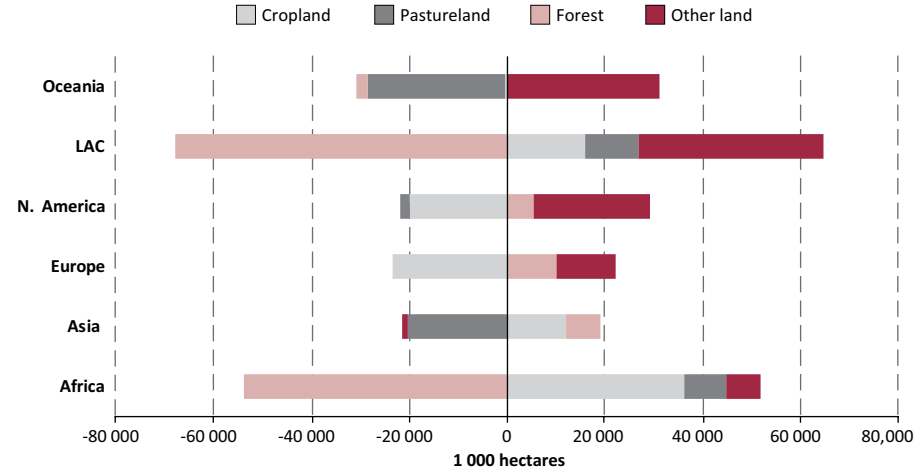
to represent stock change dynamics reported in empirical assessments. Well-known biogeochemical models that can satisfy these criteria include the Century model (and the daily time-step version, Daycent), DNDC and RothC.

The RothC (Hart, 1984; Jenkinson *et al.,* 1987; Coleman *et al*., 1997; Smith *et al.,* 2006) and Century (Parton *et al.*, 1987; Falloon and Smith, 2002; Kirschbaum and Paul, 2002) models can be used to simulate GHG gas exchange and carbon cycling dynamics of cropland, grassland and forestland land use categories, and both operate on monthly time-steps. Soil texture and weather data are the major input variables. While the Century model can simulate the dynamics of carbon in biomass, DOM and SOC pools, as well as nitrogen, phosphorous, and sulphur dynamics, RothC only estimates SOC stocks and CO_2 losses from decomposition of SOC.

The Daycent model is the daily time-step version of the Century model (Del Grosso *et al.*, 2001; Parton *et al.*, 1998), which is well suited to capturing N mineralization and N gas production in non-waterlogged soils, along with the same carbon pool dynamics modelled in Century. As with Daycent, the denitrification-decomposition (DNDC) model (Li, 1996; Li *et al.*, 1992 and 1994) simulates soil carbon and nitrogen fluxes using a daily time-step but, unlike Daycent, it is also able to represent N gas and CH_4 fluxes from waterlogged soils, such as found in rice paddies. Both Daycent and DNDC have higher data demands than either Century or RothC, due their short time-steps and wider range of biogeochemical dynamics. Since none of these models has been validated on a global scale, they have not been applied in this analysis.

3. QUANTIFICATION OF CARBON STOCK CHANGES FROM LAND USE AND LAND-USE CHANGE IN THIS REPORT

In this study, LUC emissions are estimated for three major carbon pools, including the biomass, DOM and SOC pools. It could be argued that Tier 2 and Tier 3 methods, including process-based modelling approaches, should have been used to capture variability and possibly to reduce uncertainty in the emission and carbon accumulation estimates. However, given the global nature of the assessment, and the absence of country-specific EFs, carbon stock/flux inventory data and/or a suitable global process model (cf. previous section), the Tier 1 approach was deemed a suitable option to develop preliminary estimates and shed light on the potential magnitude of the LUC emissions for the sector.



For the reasons outlined above, this assessment does not cover changes in C stocks occurring under constant land use management. This may be done in future updates once global datasets are available and/or models have been calibrated for global studies.

This section presents the approach applied in this study to quantify LUC emissions, discussing the rationale for the approach chosen, and the results from the analysis. It also explores the implications of alternative approaches to quantifying LUC emission.

3.1 Approach for feed crops

The analysis focuses on one specific feed product – soybean – in specific countries in Latin America. This assessment is based on observed land use trends, feed crop expansion trends and trade flow patterns as well as findings from previous studies such as Wassenaar *et al.* (2007) and Cederberg *et al.* (2011).

Figure C1.
Net land conversion between 1990 and 2006, by region

Source: FAOSTAT (2012).

This study uses IPCC guidelines as a basis for the quantification of LUC emissions. This choice is largely based on the fact that the IPCC approach meets the UNFCCC requirements for calculating and reporting of GHG emissions from LUC. The cropland part of this assessment also relies on other guidelines such as the PAS 2050 (also based on IPCC guidelines) for input data. According to IPCC guidelines, emissions arising from LUC are allocated over a 20-year period (the "amortization" period). Because of data availability (forestry inventories are only available from 1990),[15] in this assessment, the rates of LUC are taken as the average over the 16-year period (1990–2006). This practically discounts four years of emissions.

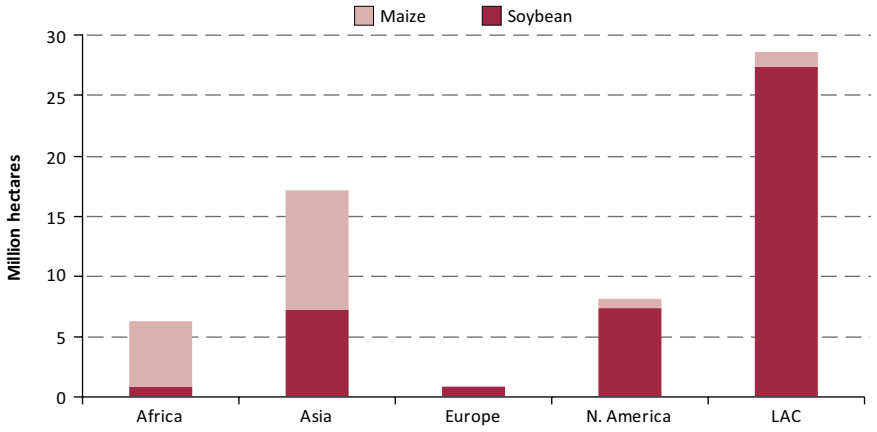
Agriculture has been a major driving force behind land transformation; globally, the area of land used for agriculture increased by 83 million ha over the period 1990–2006. In most regions, cropland has increased whereas pasture and forest land decreased (Figure C1). The most affected regions in terms of crop expansion are Latin America, Asia and Africa. Declining agricultural land (i.e. cropland and pastureland) is observable in Europe and North America where agricultural land abandonment has resulted in reforestation. During the period considered (1990-2006), deforestation occurred mainly in Africa and Latin America. More recent trends in deforestation, in particular in Asia, and their association with feed production are therefore not considered in this study.

Between 1990 and 2006, crop expansion was mainly driven by major oil crops (e.g. soybeans, rapeseed, sunflower and oil palm) the demand for which was fuelled by demand for vegetable oil, feed and, more recently, biofuel policies. The expansion of soybean production is argued to be one of the major drivers of LUC, par-

[15] The FAOSTAT forest area dataset (based on the Global Forest Resource Assessment) used in this study is only available from 1990 and in order to align the C stocks assessment with the livestock input data which is based on 2005 statistics, land use conversion trends were assessed for the period 1990 to 2006.

Table C1. Global area expansion for selected crops with highest area expansion (1990-2006)

Crop	Area expansion *(1 000 ha)*	Share of global gross crop expansion *(percentage)*
Soybeans	38 110	22.6
Maize	15 620	9.2
Rapeseed	9 815	5.8
Rice, paddy	8 650	5.1
Sunflower seed	7 237	4.3
Oil palm fruit	7 205	4.3



Source: FAOSTAT (2012).

ticularly deforestation (Pacheco, 2012; Nepstad *et al.*, 2006; Fearnside, 2005; Bickel and Dros, 2003; Carvalho *et al.*, 2002). The global area under cultivation of soybean has increased rapidly in recent decades; between 1990 and 2006, the global soybean area increased faster than any other crop (Table C1). Maize expansion is also important, representing 9.2 percent of global crop expansion. At the same time, crops such as wheat, barley and oats, have strongly declined, which explains the apparent discrepancies with the net land conversion trends in Figure C1.

A comparison of the two major crops driving agricultural expansion reveals key regional differences with regard to their importance (Figure C2). The expansion of soybean area has been significant in North and South America, while maize expansion is more important in Africa and Asia.

Deforestation for crop expansion has been an important LUC process in Africa, however crop expansion in the region has been mainly driven by sorghum and millet, with maize and soybeans only accounting for 5 percent and 0.5 percent of total gross cropland expansion respectively. In Africa, pasture expansion has also occurred largely at the expense of forest area. However, due to lack of reliable data and information it is difficult to draw conclusions on the land-use conversion trends in this region.

Figure C2.
Maize and soybean area expansion between 1990 and 2006, by region

Table C2. Average annual land-use change rates in Argentina and Brazil (1990-2006)

Land-use type	Argentina	Brazil
	(1 000 ha)	
Agricultural area	+351	+1 288
Grasslands	-7	+753
Arable land & permanent crops	+358	+535
Soybean area	+648	+534
Forest area	-149	-2 855
Other land	-201	+1 567

Source: FAOSTAT (2009).

In North America, soybean expansion is responsible for 37 percent of total crop expansion and maize 7 percent. However in this region the overall trend has been a decrease of total cropland (due to sharp decreases in wheat and barley areas) and pastures and an increase of forest area.

In Asia, soybean expansion is responsible for 7 percent of total crop expansion and maize 8 percent. At the same time, forest land has increased overall in Asia and pastureland has decreased. But the two trends occurred in different subregions within Asia. Pasture decrease mainly occurred in Mongolia and Iran, where maize and soybean expansion were null or limited. On the contrary, expansion of soybean and maize area has largely occurred in India and China (77 percent of gross maize expansion and 96 percent of gross soybean expansion), however, forest area increased in these two countries. Pastures decreased in India but to a limited extent of 1.2 million ha, compared to the 5.8 and 3.0 million ha of soybean and maize expansion in the country, respectively.

In Latin America, most of the decrease in forest area occurred in countries with soybean expansion. Trends in land conversion, particularly deforestation, are therefore closely linked to the expansion of soybean.

Based on these observations the scope of our assessment was narrowed to the soybean expansion in Latin America. Within Latin America, Brazil and Argentina account for 91 percent of the total soybean area. In the period 1990–2006, 90 percent of the soybean area expansion in Latin America took place there, further narrowing the scope to these two countries. An assessment of land use trends in these key producing countries shows that the expansion in soybean area has been largely gained at the expense of forest area (Table C2).

In Argentina, the annual increase of area dedicated to soybean is much larger than the increase of total arable land (Table C2), indicating that there has been a shift in land use from other crops to soybean. According to FAOSTAT statistics, 44 percent of the new soybean area was gained against other crops, while the rest was gained against forest (22 percent) and other land (31 percent). The latter category covers natural vegetation that does not include forest and grazed natural grasslands.

The reported annual increase of soybean area in Brazil is 534 000 ha (Table C2). We assumed a simplified pattern of deforestation in the Amazon, in which cleared land is first used as pasture and/or crop land, and then left as fallow land. The latter, classified as "other land" in FAOSTAT, is occupied by weeds, grasses, shrubs and,

Table C3. Net changes in area for main land-use categories (1990–2006)

Region	Arable land & permanent crops	Pasture	Forest area	Other land
		(1 000 ha)		
Africa	36 025	8 863	-53 700	7 001
Asia* (*South, East and SE Asia*)	12 149	-20 506	6 855	-1 068

partly, by secondary forest. Under this assumption, every year roughly 2.9 million ha are converted to arable land and grassland. At the same time, agricultural land is abandoned at a rate of 1.6 million ha per year. The annual net increase of arable land and grassland is 0.53 and 0.75 million ha, respectively. We thus assume that all incremental soybean area is gained at the expense of forest area.

Rates of C loss/gain arising from specific land-use transitions were taken from PAS 2050 guidelines (BSI, 2008), which are based on IPCC (2006). The PAS 2050 guidelines estimate deforestation (conversion of forest to annual cropland) releases in Brazil at an average 37 tonnes CO_2-eq/ha, and conversion of forest and shrub land to annual crop in Argentina at 17 and 2.2 tonnes CO_2-eq per ha, respectively. GHG emissions from soybean-driven LUC were calculated as the accumulated emissions for one year resulting from the total area deforested during the period 1990–2006 divided by the total soybean production in 2006. Based on this data, two LUC emission intensities were estimated for soybean cake produced in Brazil and Argentina, respectively: **7.69 and 0.93 kg CO_2-eq/kg soybean cake**. Soybeans and soybean cake produced elsewhere were assumed not to be associated with LUC.

3.2 Pasture expansion and land-use change

It has been argued that while forest conversion to soybean cultivation is occurring, the majority of deforested area is destined to pasture formation (Morton *et al*., 2006; Brown *et al.*, 2005). Wassenaar *et al.* (2007) developed a spatial and temporal model framework to analyse the expansion of pasture into forest in Latin America. The analysis predicted that, on average, 76 percent of deforested land would become pasture. Table C3 presents the net changes for different land use categories across regions; pasture expansion has been notable in Latin America and Africa while, at the same time, forest area in Latin America and Africa during the same period declined substantially.

3.2.1 Approach

The approach is based on the IPCC stock-based approach termed the *Stock-Difference Method*, which can be applied where carbon stocks are measured at two points in time to assess carbon stock changes (IPCC, 2006). The following emissions from deforestation were considered:

- CO_2 emissions from changes in biomass stocks (above-and below-ground biomass);
- CO_2 emissions from changes in dead organic matter (litter and deadwood);
- CO_2 emissions from changes in soil carbon stocks.

For each of the carbon pools mentioned above, several factors such as land use (forest, croplands, pasture), climatic zone, ecotype (tropical moist or tropical dry forest), soil type (mineral or organic soils), forest type, etc., were taken into consideration. Since data from forestry inventories are only available from 1990, the changes in carbon stocks due to deforestation could only be calculated for the period 1990-2006.

The calculations of land-use change were accomplished in two steps: first, the assessment of land use dynamics; and second, the carbon emissions based on land use dynamics and biophysical conditions. A complete assessment of carbon emissions from LUC involves the quantification of several key elements including deforestation rates, land use dynamics, and initial carbon stocks in biomass and soil. Two types of information are fundamental to enable emissions to be calculated: rates of deforestation and per hectare changes in carbon stocks in the different carbon pools. The following sections provide a detailed description of the applied methodology and assumptions made.

Determining total land area converted from forest to grassland. To accurately estimate carbon fluxes from LUC, it is critical to understand LUC dynamics following deforestation. With regard to land-use transition matrices, a simplified approach was adopted. Changes in land use area were estimated on the basis of the Tier 1 approach outlined in Chapter 3 of the IPCC guidelines, which estimates the total change in area for each individual land use category in each country.

FAOSTAT statistics on total land area (classified by land use category) were used to calculate the annual net change in the area of each land use category.

Table C4 presents the countries in which the increase in pasture area was largely facilitated by a decrease in forest area, and our estimates show that about 13 million hectares were deforested for pasture establishment.

Table C4. Pasture expansion against forestland in Latin America (1990-2006)

Countries	Pasture area change *(1 000 ha)*	Share of regional expansion *(percentage)*
Brazil	10 212.3	77.2
Chile	1 150.0	8.7
Paraguay	1 040.0	7.9
Nicaragua	454.3	3.4
Other*	365.0	2.8
Total	**13 221.6**	100

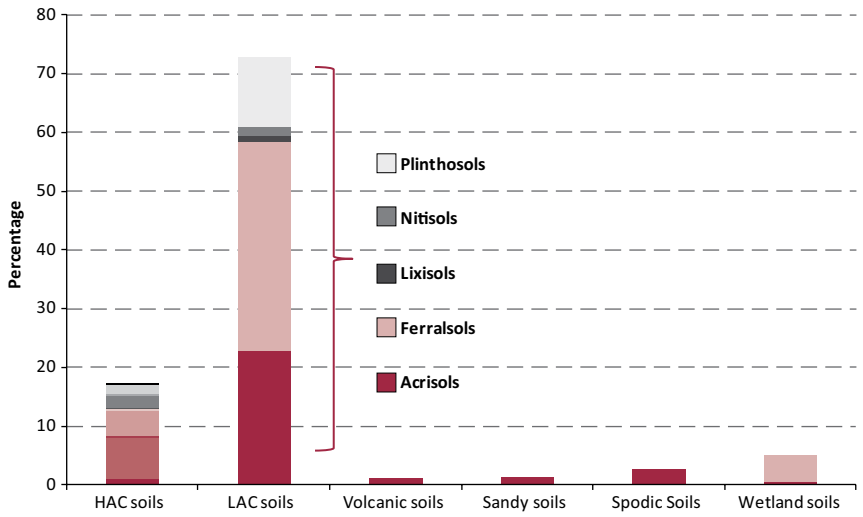
[2] Ratio of above-below ground factors are derived from IPCC guidelines, Table 4.7.

[3] Total biomass is the sum of above-and below-ground biomass.

* 'Other' category includes: Honduras, Ecuador, Panama, El Salvador and Belize.

Changes in carbon stocks from above- and below-ground biomass. The method applied here focuses on stock changes in biomass associated with woody vegetation which are capable of accumulating large quantities of carbon over a long period of time. The Tier 1 method necessitates the estimation of biomass before and after conversion using IPCC equation 2.16 (Volume 4, Chapter 2).



Biomass in forests is determined by ecological zone, type of native vegetation and geographical location of forests. Based on the IPCC Tier 1 approach, in the conversion of forest to grassland it is assumed that all biomass is cleared and therefore the default biomass after conversion is 0 tonnes DM ha^{-1}. The IPCC guidelines (Chapter 4, Volume 4, Table 4.7) provide average default values for above-ground biomass in forests. Due to the lack of data on below-ground biomass, the ratio of below-to-above ground biomass (root-to-shoot ratio) was used to estimate the below-ground component of biomass and the total biomass (tonnes DM/ha) given in Table C5. A default factor of 0.50 tonnes C per tonnes DM (carbon fraction for woody biomass was used to convert biomass into carbon stocks per hectare.

Changes in carbon stocks from dead organic matter (DOM) pools. The conceptual approach to estimating changes in C stocks in dead wood and litter pools is to estimate the C stocks in the old and new land use categories and apply this change in the year of conversion. Equation 2.23 (IPCC, 2006, Volume 4, Chapter 2) was used to estimate changes in C stocks from DOM.

According to the IPCC Tier 1 approach, DOM pools in non-forest land categories after the conversion are zero and this is based on the assumption that all DOM carbon losses occur entirely in the year of land-use conversion. Tier 1 also assumes that carbon contained in biomass killed during the conversion of land is emitted to the atmosphere and none is added to the dead wood and litter pools. Tier 1 default factors for dead wood and litter were taken from IPCC (2006, Volume 4, Chapter 2, Table 2.2).

Changes in soil carbon stocks. SOC stock changes do not occur instantaneously but over a period of years to decades. The current IPCC good practice guidance for GHG inventories assumes a period of 20 years for a new equilibrium to occur after conversion (IPCC, 2006). The change in the amount of SOC depends on factors such as climate region, native soil type, management system after conversion

Figure C3.
Main soil classes in Latin American forested areas based on the World Reference Base for Soil Resources classification

LAC: low activity clay; HAC: high activity clay.

and input use. The calculation of SOC losses per hectare of area transformed from forest to grassland is based on equation 2.25 in IPCC (2006, Volume 4, Chapter 2), which takes into account changes in soil carbon stocks associated with type of land use, management practices and input of organic matter (fertilization, irrigation, liming and grazing intensity) in the soil.

The approach makes a distinction between organic and mineral soil carbon pools, and the focus is on the impacts of LUC on the organic pool, because inorganic soil carbon is assumed to be insensitive to land-use change and management. Land converted to grassland was stratified according to climatic region, management and major soil types based on country specific classifications. The starting point was to derive a soil type classification of areas under forest in the selected countries in order to determine SOCs. This was accomplished with overlays of suitable climatic and soil maps coupled with spatial data on forest land area[16,17]. Figure C3 presents the mapping results of country-specific soil types on forested land and provides information on the dominant soil groups in forested areas in Latin America.

To establish SOC stocks, the soil divisions were further aggregated into dominant soil type classes (Figure C3) defined in IPCC guidelines based on the World Reference Base (WRB) for Soil Resources classification. Based on this aggregation, at a regional level, soils with low activity clay cover nearly 73 percent of the forested area in the nine countries. The remaining forested area is made up of the other five dominant soil types of which the high activity clay soil types cover 17 percent of the area (Figure C3).

The 2006 IPCC guidelines provide average default SOC stocks for the dominant soil classes clustered by eco-region reproduced in Table C6. The default reference soil organic C stocks are for the top 30 cm of the soil profile because different land use management methods mostly affect soil carbon in the surface layer.

For Tier 1, all stock change factors (F_{lu}, F_{mg}, F_I) were assumed to be equal to 1 for forest land, corresponding to the default values in IPCC guidelines. For grasslands, stock change factors used for land use and input (G_{lu}, *and* F_I) were assigned a value of 1.

The quality of management of tropical pastures after conversion is critical in understanding whether the soils under this land use represent a source or a sink of atmospheric carbon. Differences in management practices could significantly affect subsequent trends in soil carbon. Due to the limited data on management and input, default values were used.

It was assumed that pastures are moderately degraded and therefore a coefficient of 0.97 (IPCC, 2006 Volume 4 , Chapter 6, Table 6.2) for F_{mg} stock factor was applied, which represents overgrazed or moderately degraded grasslands with reduced productivity and receiving no management inputs. This assumption is based

on the findings of studies (Hernandez *et al*., 1995; Murty *et al*., 2002; De Oliveira *et al*., 2006; Cerri *et al*., 2005;) which inferred that most of the pastures in LAC are in some process of degradation caused by poor management methods, low input fertilization and no maintenance. The results (Table C7) show a net decrease in SOC with losses ranging between 1.1 to 2.3 tonnes C ha^{-1}.

3.3 Sensitivity analysis and the influence of LUC method

Modelling of land use and LUC emissions is subject to great uncertainties mainly because of the complexity of LULUCF processes, the challenges of obtaining reliable global data and the absence of validated approaches to estimate carbon stock changes. In particular, uncertainty regarding the magnitude of LUC emissions arises due to uncertainties in: (a) the rates of land use; (b) the carbon storage capacity of different forests, initial carbon stocks and the modes of C release; and (c) the dynamics of land use not normally tracked. In addition, a value judgment has to be made regarding what drives LUC and, consequently, how the emissions should be allocated. In order to explore the potential effect that different methodologies can have, the results obtained with the GLEAM approach are compared to three alternative approaches: (a) PAS 2050-1:2012; (b) One-Soy; and (c) reduced time-frame approach. These approaches are summarized in Table C8.

3.3.1 Alternative approaches

PAS 2050-1: 2012 approach. Several studies suggest that deforestation is related to the expanding soybean sector (Fearnside, 2005; Bickel and Dros 2003; Carvalho *et al.*, 2002), but others dispute this claim, and argue that soybean is expanding into land previously under pasture, and is not causing new deforestation (Mueller, 2003; Brandao *et al.*, 2005). Due to the lack of knowledge of the origin of the converted

Table C8. Alternative approaches for soybean LUC emissions calculations

Method	Spatial allocation	Temporal allocation of LUC emissions	Quantification of rates of LUC	Quantification of rates of C loss/gain
GLEAM approach (current study)	To all soybean produced within the country	20 years	FAOSTAT average LUC rates 1990-2006 Brazil: forest→crops (100%) Argentina: other crops (44%), forest (22%) and other land (31%)→soybean	IPCC (2006) Tier 1
PAS 2050-1:2012	To all soybean produced within the country	20 years	Average rates over 20 years. LUC rates based on (a) or (b) - whichever results in the highest emission factor. (a) from grassland forest and perennial arable in equal proportion (b) from grassland, forest and perennial arable in proportion to their rates of change	IPCC (2006) Tier 1
One-Soy	To traded soybean	20 years	FAOSTAT average LUC rates 1990-2006 Brazil: forest→crops (100%) Argentina: other crops (44%), forest (22%) and other land (31%)→soybean	IPCC (2006) Tier 1
Reduced time-frame	To all soybean produced within the country	20 years	FAOSTAT average LUC rates 2002-2007 Brazil: forest→crops Argentina: other crops (44%), forest (22%) and other land (31%)→soybean	IPCC (2006) Tier 1

Source: Authors.

land, the GLEAM results were compared with PAS 2050-1:2012 (BSI, 2012), which provides a way of quantifying LUC emissions when previous land use is not known and only the crop and country are known. The PAS 2050-1:2012 calculations of emissions related to land-use change are accomplished in two steps.

First, rates of land-use change need to be calculated based on the PAS 2050-1: 2012. To calculate these, four categories of land are considered: forest, pasture, annual cropland and perennial cropland. Time series data on land area for forest, pasture, annual and perennial crops taken from FAOSTAT were used to: (i) determine whether the crop in question was associated with LUC by quantifying the rate of expansion over a 20-year period; and (ii) determine the share of LUC associated with each land category. In a second step, carbon losses based on land dynamics and biophysical conditions (climate, soil type, forest type, crop management, etc.) were computed based on the IPCC (2006) Tier 1 approach. The two sources of carbon taken into account in this approach are vegetation and soil. Two LUC EFs were calculated, based on different assumptions regarding where land for soybean expansion is derived from: (i) assuming that land for soybean production is gained in equal proportions from grassland, forest and perennial cropland; (ii) assuming that land for soybean is gained from other land use categories in proportion to their relative rates of change. The highest of the two EF's was then selected, in accordance with the guidelines. BSI (2012) present a detailed account of methodology and data sources.

One-Soy approach. In this approach it is assumed that all soybeans, irrespective of where they have been produced, are associated with LUC. The central argument for this scenario is that the global demand for soybeans is largely interconnected and is a key driver of LUC. An average LUC emission factor associated with soybean was estimated by calculating the total LUC emissions attributable to globally-traded soybean and soybean cake and then dividing this by total global soybean cake exports. Because the emission intensity was applied to all traded soybean and soybean cake, the approach equally distributes the LUC emissions across all importing countries irrespective of where the soybean is produced.

Reduced time-frame approach. Annual deforestation rates are highly variable, so the period over which the rates of LUC are estimated can therefore have a significant influence on results. Since data from forestry inventories are only available from 1990, this assessment was based on the average rates of LUC over the period 1990-2006. This not only coincides with a period of high rates of deforestation but also high soybean area expansion. In the reduced time frame approach, the LUC emissions are calculated based on the average rates of LUC over the period from 2002-07, while maintaining the underlying assumptions in the study.

3.3.2 Results

Effect of LUC approach on soybean LUC emission factor. Table C9 reports the LUC factors for soybean cake (kg CO_2-eq per kg soybean cake) calculated using each of the approaches. The choice of method for estimating LUC EFs can strongly influence the emission intensity of livestock products and illustrates the complexity of analysing LUC processes.

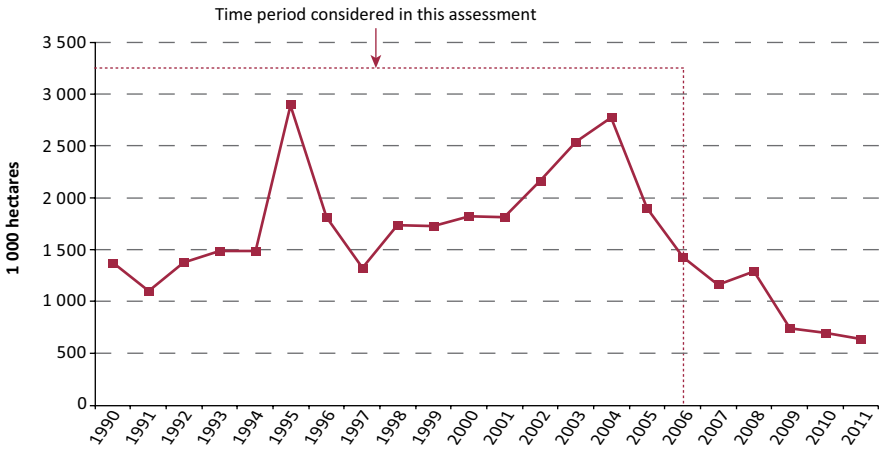
Table C9. Summary of soybean LUC emission intensity for the four approaches

Scenario	Argentina	Brazil
	(kg CO_2-eq per kg soybean cake)	
GLEAM approach (current study)	0.93	7.69
PAS 2050-1:2012	4.23	3.21
One-Soy	2.98	2.98
Reduced time-frame	0.34	3.70

Source: Authors' calculations.

The *PAS 2050-1: 2012* approach produces markedly different LUC emission factors due to the assumptions made regarding the land use category against which additional land for soybean production was gained and the relative share of this gain (Table C10). Unlike Brazil, Argentina has a higher EF using the default assumption (that expanded crop areas are derived from forest, grassland and perennial crops in equal proportion) than using the relative rates of change. The higher proportion of soybean cultivated on expanded areas in Argentina (76 percent) compared to Brazil (55 percent), combines with the default LUC assumptions, to give Argentina a higher soybean EF than Brazil under PAS 2050-1:2012.

The strength of the *One-Soy* approach is that it recognizes that global demand is a key driver of LUC. However, it penalizes those countries whose production is not directly associated with LUC and may not provide the right signals to producers and consumers of soybean.



In the *reduced time-frame approach*, the emission intensity of soybean cake from Argentina and Brazil reduces by more than half. Average annual deforestation rates appear to be close over the two periods 1990-2006 and 2002-2007 (1.76 and 1.98 million ha respectively, Figure C4), but the average annual rates of soybean expansion differ and they are higher for 2002-2007: between 1990 and 2006, the soybean area in Brazil increased by 534 000 ha/year whereas the increase for the period 2002-2007 was 840 000 ha/year. The lower emission intensity for 2002-2007 therefore results from the rate of deforestation relative to the rate of soybean expansion, not from the absolute change in deforestation rate.

Table C10. Proportion of expanded soybean area derived from each land-use category

Land-use category	GLEAM approach		PAS 2050-1:2012 approach	
	Brazil	Argentina	Brazil	Argentina
	percentage			
Forest	100	22	51 (33)	23 (33)
Grassland	0	0	0 (33)	0 (33)
Shrubland	0	31	0 (0)	0 (0)
Annual cropland	0	44	46 (0)	61 (0)
Perennial cropland	0	0	3 (33)	16 (33)

Note: Figures in brackets are the PAS 2050-1 default land use transformations.
Sources: Based on FAOSTAT (2012).

Figure C4.
Annual forest loss in Brazil

Source: INPE, 2012.

Table C11. Estimated changes in pasture area and annual carbon losses for the reduced time-frame approach

Country	Change in pasture area *(1 000 ha)*	Carbon losses *(tonnes CO_2/ha/year)*
Brazil	3 563.6	- 51.0
Chile	1 079.3	- 51.1
Paraguay	1 464.6	- 48.8
Nicaragua	311.6	- 48.5
Honduras	170.0	- 50.8
Ecuador	No gain in pasture	-
Panama	60.3	- 50.8
El Salvador	45.3	- 50.8
Belize	0.3	- 51.1
Total/average	**6 695.3**	**- 50.4**

Source: Authors' calculations.

For pasture expansion, emissions are highly sensitive to the time period chosen; using a ten-year time-frame scenario, annual carbon losses are 50.4 tonnes CO_2 ha^{-1} yr^{-1} (Table C11) while in the current study annual carbon losses were estimated at 32 tonnes CO_2 ha^{-1} yr^{-1}. Shorter periods, however, place emphasis on deforestation resulting in higher annual carbon losses per hectare placing higher relative weighting of near-term emissions.

4. COMPARISON WITH OTHER STUDIES

The emissions intensity for LUC per kg of soybean and soybean cake calculated in this study are compared with other studies in Table C12. The emissions intensity used in this study is higher than some other studies, but within the overall range.

The emissions intensity of soybean is highly dependent on the calculation method and assumptions (Flysjo *et al.*, 2012). Variation arises from differences in:

- Calculation of C losses in soil and vegetation (above- and below-ground).
- Quantification of land-use transitions – i.e. how much of the LUC can be attributed to cropping.
- Allocation of LUC arising from cropping to specific crops, e.g. emissions are usually allocated to one of the following: (a) soybean grown in country/region; (b) all expanding crops grown in country region; (c) all crops grown globally. This leads to huge variations in the emissions per kg of crop.
- The time period over which emission are allocated.

Table C12. Soybean LUC emissions per unit of output and hectare

Study	Area covered by study	Emissions	*Converted/all soybean /all crops
FAO (2010)	Argentina	1.04 kg CO_2-eq/kg soybean	All soybean

Table C13. Comparison of studies on LUC associated with pasture expansion in Brazil

Study and area	Approach	Scope	Carbon losses *(tonnes CO_2-eq /ha)*
Current study (Brazil)	IPCC stock-based approach (stock difference method) Period: 1990-2006	Biomass Soil carbon Dead organic matter	506.7
Cederberg *et al.*, 2011 (Brazil -Legal Amazon Area)	Net committed emissions approach Period: 1986-2006	Biomass Soil carbon CH_4 and N_2O	572
Leip *et al.*, 2010 (Beef imported into EU from Brazil)	Net committed emissions approach Period: 1986-2006	Biomass Soil carbon CH_4 and N_2O	568.7

For pasture expansion, with the exception of Brazil where impacts of deforestation have been analysed to a greater degree, there are relatively few estimates of the impact of carbon losses the due to deforestation. We therefore compared the results obtained for Brazil with estimates from other studies (Table C13).

Despite the difference in calculation approach, our estimates are very similar to those found in the literature. This may be partly coincidental because the approaches differed in many respects; for example, the period assessed, the calculation method and assumptions and well as emission factors. Cederberg *et al.* (2011) apply different carbon stock losses for the different pools and take into account the impacts on fire used in forest clearing on CO_2 emissions.

The estimates of LUC emissions presented in this report are still very preliminary and need to be interpreted with caution. This is an important area for improvement of GLEAM and it is planned that future developments of the model will include a more detailed and complete assessment of LUC emissions.

5. LAND USE

For the reasons explained above, this analysis could not incorporate C stock changes under constant land use. This section attempts to evaluate the effect of this simplification on results. Given the importance of grasslands as a potential as a C sink (Soussana *et al.*, 2010), we focus our case study on this land use rather than on feed-crops.

Furthermore, we selected the European Union for this evaluation in view of data availability in this region. National inventories in the European Union are indeed increasingly accurate because Member States are requested to maintain and monitor the area of permanent grassland by the Common Agricultural Policy. Member States are required to report annual estimates of their total area of permanent grassland.

Soussana *et al.* (2010) estimate an average grassland C sequestration rate of 5 ± 30 g C/m^2/year for temperate grasslands under baseline, constant land use. This estimate is derived from an exhaustive literature review, and inventories of SOC stocks at regional or local level, mainly from Western Europe.

Using this estimate, we computed that permanent grasslands in the European Union (estimated at 62.7 million ha) represent a sink of 3.1 ± 18.8 million tonnes C per year, equivalent to 11.5 ± 69.0 million tonnes CO_2-eq per year. This estimate

Table C14. Total GHG emissions from the ruminant sector in the European Union and changes in C stocks in permanent pasture

Systems	Total emissions based on a LCA approach and excluding land use[1]	C sequestration in permanent grassland under baseline constant management[2]
	(million tonnes CO_2-eq/year)	
Total ruminant sector	**390.5**	**11.5 ± 69.0**
Cattle, grazing	25.6	
Cattle, mixed	322.8	
Small ruminants, grazing	4.6	
Small ruminants, mixed	37.4	

[1] Based on GLEAM.

[2] Based on Soussana *et al.* (2010).

is compared with the 390.5 million tonnes CO_2-eq emitted yearly by the ruminant sector in the European Union (Table C14).

Taking into account C stock changes in permanent pastures, net emissions from the EU ruminant sector are therefore estimated between 310 and 448 million tonnes CO_2-eq/year.

Net sequestration/emission of C in permanent pasture under stable management practices may thus be significant in the European Union, and should be included in the assessment of GHG emissions of the sector. The estimate computed here is however one order of magnitude smaller than the sum of all other emissions along the supply chain. Furthermore, even in a region where data availability is comparatively high, the uncertainty about C fluxes is such that it cannot be ascertained if permanent grasslands are net sequesters or emitters of carbon.

The European Union only accounts for a limited share of total grassland area (about 2 percent according to FAOSTAT, 2013), so including land use sequestration/emissions could have even greater effects on net emissions of the sector in other regions. For example, Cerri *et al.* (2004) measured that brasilian pastures established in the early 90's could store up to 330 $g.m^{-2}$ of carbon in the 20 first centimeters of soil. This would however require a better understanding SOC dynamics in grasslands and the development of models and databases to monitoring and predicting changes in C stocks.

APPENDIX D

Postfarm emissions

GHG emissions accounted for in the post farmgate part of the supply chain include emissions related to fuel combustion and energy use in the transport, processing and refrigeration of products. The system boundary is from the farmgate up to the retail point. During this phase of the life cycle, three distinct emission streams were studied: emissions from the transport and distribution of live animals, milk and meat (domestic and international); GHG emissions from processing and refrigeration; and emissions related to the production of packaging material.

The system boundary for this part of the food chain included emissions from the farmgate to the retail distribution centre. Excluded from the analysis were estimates of GHG emissions from on-site waste-water treatment facilities, emissions from animal waste[18] at the slaughter site, the retail and consumption part of the food chain (household transport and preparation) and disposal of packaging and waste, which fall outside the scope of the system boundary studied but may warrant further research. Due to the lack of data, emissions related to by-products (rendering material, offal, etc.) are therefore currently excluded. However, we investigated the impact of allocating emissions to slaughter by-products (Appendix F).

1. APPROACH AND ASSUMPTIONS

1.1 Milk from ruminant species

The quantification of post farmgate emissions for milk produced by cattle, small ruminants and buffalo was based on a similar approach. The approach (and level of complexity) was largely influenced by two factors: the importance of the subsectors contribution to global milk production and the availability of data. Consequently, a more comprehensive approach was applied to the milk from the global cattle dairy sector, as outlined in FAO's report on GHG emissions in the dairy sector published in 2010.[19]

In the estimation of post farmgate emissions for small ruminant and buffalo milk, a similar but simplified approach was adopted; for small ruminants, it was assumed that all milk that left the farm was processed into cheese. FAOSTAT production statistics on goat and sheep cheese production were used to identify countries where cheese production is important. In producing countries with no cheese production, the sheep and goat milk was assumed to be consumed on farm and hence no post farmgate emissions were estimated for these countries. In addition, since not all milk is processed and traded, the proportion of small ruminant milk leaving the farm was estimated from the cheese production and total milk production within the country.

[18] In some countries, manure/slurry from the slaughterhouse is anaerobically digested and the biogas is used for heating and electricity. The challenge is that there insufficient information available on on-site energy generation from animal waste; thus, the resulting substituted energy and avoided GHG emissions are not considered in the calculations.

[19] FAO. 2010. http://www.fao.org/docrep/012/k7930e/k7930e00.pdf

The difference in calculation approach between cow's milk and buffalo milk is that for dairy cattle milk six products were considered (processed milk, cheese, whey, yoghurt, skimmed milk powder and whole milk powder), while post farmgate emissions for buffalo milk comprised emissions related to transport and processing of raw milk into processed milk. Emissions related to international trade of dairy products was only considered for the cattle dairy sector.

1.2 Meat from ruminant species

GHG emissions reported for this part of the food chain are based on the finished product leaving the facility and do not account for meat co-products and rendering products; however, in a life cycle assessment, when a system produces multiple products each of which have economic value, it is standard practice to assign some of the emissions from that process to each of the co-products.

In this analysis, all emissions were allocated to the carcass and therefore meat carries the whole burden. Post farmgate emissions for meat include: emissions associated with the transport of live animals to slaughterhouses, emissions related to slaughter and primary processing of carcasses, refrigeration of carcasses at processing plant and transport and refrigeration of product. Emissions related to international trade of meat products (carcasses and boneless meat) are taken into account. Due to the complexity of tracking trade flows of live animals the related emissions are excluded from this analysis.

2. ENERGY CONSUMPTION

Energy consumption is the most important source of GHG emissions from the post farmgate supply food chain. Table D1 presents average regional and country CO_2 emission coefficients applied in this analysis. The CO_2 intensities are determined by the composition of the energy sources employed and average GHG emissions from electricity consumption was modelled as a mix of existing electricity sources (e.g. coal, hydro, nuclear, oil, etc.) in different countries and regions taken from the International Energy Agency (IEA, 2009).

Table D1. Average regional specific CO_2 emissions per MJ from electricity and heat generation

Region/country	CO_2 emissions *(g CO_2/MJ)*
Europe 27	99
North America	142
Australia	254
New Zealand	84
Japan	120
Other Pacific	139
Russian Federation	90
Latin America	54
Asia (excluding China)	202
China	216
Africa	175

Source: IEA (2009).

The variation in CO_2 intensity is explained by the different energy sources and energy mixes utilized in different regions and countries. For example, regions such as Asia and Africa, and countries like Australia that rely on coal as their dominant source of energy for electricity production, have on average higher CO_2 emissions compared with Latin America and New Zealand with lower CO_2 emissions per MJ produced owing to the higher proportion of electricity that is based on renewable resources like hydroelectric power which are recognized to be carbon neutral.

3. EMISSIONS RELATED TO TRANSPORT

The food sector is transport-intensive – large quantities of food are transported in large volumes and over long distances. This can sometimes be of significance but, in terms of the overall contribution to the life cycle carbon footprint of a product, most LCA studies have found that the contribution of transport is relatively small. The carbon implications of food transport is not only a question of distance; a number of other variables, such as transport mode, efficiency of transport loads and the condition of infrastructure (road quality), fuel type, etc., are important determinants of the carbon intensity of products.

The efficiency of different transport modes varies considerably. Transport modes differ significantly in energy intensity and hence GHG emissions. Air transport has a very high climate change impact per tonne transported, whereas sea transport is relatively efficient. Long-distance transport by ship is very energy efficient, with estimates between 10 and 70 g CO_2 per tonnes-km, compared with estimates of 20-120 and 80-250 g CO_2 per tonnes-km for rail and road, respectively (Marintek, 2008). Poor road infrastructure has an impact on the emission per unit product transported because it increases fuel consumption. Cederberg *et al.* (2009) found that, in Brazil, due to generally poor road conditions, the consumption of diesel was estimated to be 25 percent higher than under normal road conditions. Different loads also affect the efficiency of utilization of transport per unit of product. Larger loads transported for longer distances are more efficient than lighter loads transported over shorter distances.

During transportation, food also often requires refrigeration which increases the use of energy and also introduces leakage of refrigerants into the GHG emissions equation (refrigerants are often high in climate impact).

Emissions related to transport were estimated for the different phases, that is, transportation of live animals from the farm to the slaughter plant and transportation of the processed product from plant to retail centre for distribution. In the case of international trade, emissions were calculated for transport from slaughter plant to the port of export to the retail point for distribution. In an effort to estimate the contribution of international freight transport to GHG emissions, we combined data on trade flows, transportation mode, transport EFs and distances.

The following sections provide a detailed description of the methodology and the assumptions used in the estimation of emissions associated with the transport of live animals and meat. For the approach on milk, a detailed description is provided in FAO's report on GHG emissions in the dairy sector published in 2010.[20]

[20] FAO. 2010. http://www.fao.org/docrep/012/k7930e/k7930e00.pdf

3.1 Transport of live animals from the farm to slaughter plant

Due to the complexity of live animal movements and data limitations, several simplifications and assumptions were made:

- *Share of animals transported to slaughter plants*: Not all animals produced are slaughtered in slaughter plants/abattoirs; slaughtering may also take place on-farm or may be carried out by local butchers within the vicinity of production and thus may not involve the transportation of live animals. For industrialized countries, it was assumed that about 98 percent of the animals are slaughtered in slaughterhouses. In developing countries, the share of animals transported to slaughter plants varied between 15 and 75 percent. A lower share was assumed for developing countries based on the assumption that slaughtering infrastructure is generally lacking and that animals are often slaughtered in closer proximity to where they are raised, with slaughter being carried out by local butchers or the household itself. Other factors taken into consideration include the importance of exports within the economy, where we assumed that key exporting developing countries such as Brazil, Argentina, Paraguay, Botswana and Namibia (due to phytosanitary requirements of importing countries) would have a higher share of animals slaughtered in slaughter plants.
- *Average distance between farm and slaughter plant*: Data on distances between the farm and slaughter plants was taken from literature for industrialized regions: an average distance of 80 km for Europe and 200 km for North America. In developing countries, due to poor infrastructure, slaughter is assumed to take place near the point of sale: an average distance of 50 km was assumed.
- *Mode of transport:* We assumed that a greater proportion of live animals was transported by road.
- *Emission intensity per kg of carcass transported*: Based on secondary data, two average coefficients were utilized in this study for two groupings of countries: 0.21 and 0.38 kg CO_2-eq per tonnes CW-km for industrialized and developing countries, respectively.

Transport emissions of livestock between the farm and the slaughter plant were calculated using the equation below:

$$GHG_{transport}^{farm\text{-}slaughterplant} = D_{farm\text{-}plant} \cdot ef_{transport} \cdot sh_{live\ animal}^{farm\text{-}plant}$$

where:

$GHG_{transport}^{farm\text{-}slaughterplant}$ = GHG emission intensity, kg CO_2-eq/kg CW-km

$D_{farm\text{-}plant}$ = average distance between farm and slaughter plant, km

$ef_{transport}$ = average EF for transport, kg CO_2-eq/kg CW-km

$sh_{live\ animal}^{farm\text{-}plant}$ = share of animals transported from farm to slaughter plant, percentage

Table D2. Emission intensity for road transport

	(kg CO_2-eq/tonnes CW-km)						
Articulated lorry, max load 32 tonne							0.11
Lorry, chilled, max load 20 tonne	0.085	0.102	0.18	0.16	0.14	0.08-0.25	
Lorry, frozen, max load 20 tonne	0.073	0.099	0.19	0.17	0.15	0.08-0.25	0.145

Note: Emission intensities also include emissions related to leakage of cooling agents.

* The EFs represent the percentage of the vehicle utilized and accounts for the fact that vehicles will not be fully utilized at all times.

Source: SIK (2010).

3.2 Transport and distribution of meat from processing plant to retail point

The calculation of GHG emissions associated with meat transport included the transport of meat from slaughter plant to a retail distribution point. Transport and distribution emissions sources comprise emissions from fuel combustion during transport, as well as emissions from energy consumption for refrigeration and refrigerant leakage from chilled vehicles or container ships. Two modes of transport were considered in this phase: refrigerated road transport and marine transport.

Road transport. Refrigerated road transport covered here refers to transport between the processing plant and the domestic market and, in the case of international trade, transport from plant to port and entry port to retail distribution centre in importing country. Table D2 presents emission intensities for different modes of road transport taken from peer-reviewed studies and databases such as Ecoinvent. Average emission intensities were found to vary depending on the transport load (tonnage), transport utilization and type of product transported (chilled or frozen).

In this study, the following average emission intensity values presented in Table D3 below were used. Regarding the transport of meat from processing plant directly to the domestic retail, we assumed that the product is transported as chilled carcass by a small vehicle with a maximum load of 20 tonnes within a minimum retail distance of 50 km.

Ocean transport. In 2005, about 6.5 and 0.97 million tonnes of beef and lamb were traded globally (FAOSTAT, 2012). Emissions from the international trade of meat were calculated on the basis of the amount and type of product traded, distances

Table D3. Average emissions intensities associated with road transport from plant to retail

	Chilled	Frozen
	(kg CO_2-eq/tonnes CW-km)	
Carcass	0.18	0.20
Boneless	0.117	0.130

Source: SIK (2010).

between the slaughterhouse and retail centre, and the average GHG emission per kg of product transported.

- *Trade:* A trade matrix was developed based on FAOSTAT trade flow data in order to determine key exporters (Table D4 as an example), destinations and quantities traded. This analysis covers almost 85 percent of the total amount of beef and lamb traded globally. A distinction is made between the type of meat traded (whether carcass or boneless) because it has implications for the amount of energy used for refrigeration during transportation and consequently CO_2 emissions.
- *Distance:* Distances were estimated between the major exporting and importing ports and it was assumed that the traded product was destined to major cities which are key population and consumption hubs. Emissions were calculated for the average distance for transport between the exporting country and importing country (port to port) and the transit distance inside the importing country to main retail centre. Distance matrices were estimated from http://sea-distances.com/index.htm and http://www.distances.com/.
- *Vessel size:* It was assumed that smaller ships are utilized for shorter distances (e.g. transport of products within regions) and larger ships for longer distances such as inter-continental trade. Table D5 presents emission intensities for ocean transport taken from secondary sources and demonstrates the variation in emission intensity for different vessel sizes.

Table D4. International trade in beef, 2005

Key exporters	tonnes
Brazil	1 285 805
Australia	991 945
USA	439 862
Ireland	363 372
Netherlands	351 757
New Zealand	344 289
Germany	335 044

Table D5. Emission intensity for ocean transport

Container ship	Winther *et al.* (2009)	AEA (2008)	Cederberg *et al.* (2009)	Ecoinvent
	(kg CO_2-eq/tonnes CW-km)			
Large, chilled/frozen	0.037	0.018	0.014	0.011
Small, chilled/frozen	0.056		0.061	0.043

Note: Emission intensities also include emissions include related to leakage of cooling agents.
Source: SIK (2010).

Based on secondary data, the average emission intensities applied were 0.025 and 0.05 kg CO_2-eq per tonne product (CW) transported per km for large and small container ships transporting carcasses, respectively and 0.014 and 0.029 kg CO_2-eq per tonne CW per km for large and small container ships transporting bone-free meat.

To manage the versatile nature and complexity of trade flows, we only accounted for trade from and to the most significant trading partners.

4. EMISSIONS RELATED TO SLAUGHTER AND PRIMARY PROCESSING OF MEAT

GHG emissions assessed here include emissions from the direct inputs of energy in the slaughter and primary processing of meat and milk, as well as the GHG emissions related to use and leakage of refrigerants. The meat sector also produces a range of co-products including by-products such as bones, blood, fat, offal, feather, etc. Due to the lack of data on the total amount of raw material rendered, this analysis does not take into account emissions associated with the co-products.

Average energy use per kg of carcass weight during slaughter was based on studies from Sweden (Anon, 2002), Denmark, Finland and Spain (Lafargue, 2007) and the European Union (Ramirez *et al*., 2006). Due to the limited data on energy use during this phase, in this study we assumed an average value of 1.4 MJ/kg CW and 4.5 MJ/kg CW for beef and lamb, respectively. Slaughterhouse emissions were calculated by combining this average value with the average regional specific CO_2 emissions per MJ of energy (taking into account regional/country electricity generating mixes) given in Table D1 to obtain the average GHG emissions per kg of carcass processed. Table D6 presents regional average emission factors for processed beef and lamb and mutton and illustrates the importance of energy source as well as the energy intensity associated with the processing of different meat. Compared with beef, processing of lamb and mutton on average has higher emission intensity per kg product processed because of the high energy intensity of the process (4.5 MJ/kg CW) and, when combined with high emitting energy sources such as coal, the emission intensity is high as is the case in Australia (Table D6).

Table D6. Regional emission factors for processing of beef and lamb

Region	Beef	Lamb and mutton
	(kg CO_2-eq/tonnes CW-km)	
EU27	0.14	0.45
North America	0.20	0.64

Africa	0.25	0.78

Source: Authors' calculations.

5. EMISSIONS RELATED TO PRODUCTION OF PACKAGING MATERIALS

Packaging is a fundamental element of almost every food product and a vital source of environmental burden and waste. The type of packaging used also influences transport efficiency because it has its own weight but also because it affects the weight/volume ratio of the product. Two types of packaging can be distinguished: primary packaging and secondary packaging. Primary packaging is packaging closest to the product and often follows the product all the way to the consumer. Secondary packaging is used to assemble together primary packaging to shelter the product during transport and make it possible to transport more of the product at a time. The climate impact of packaging is one of the least studied aspects within the food chain. Due to the lack of data on the global variations in packaging of meat, this study applied 0.05 kg CO_2-eq per kg CW for both primary and secondary packaging from slaughter-plant to retail.

APPENDIX E

Emissions related to energy use

This appendix presents the approach and coefficients applied in this study for estimating GHG emissions from direct on-farm energy use (non-feed related) and embedded energy in farm buildings and equipment. Direct and indirect emissions were estimated for all ruminant species; a general approach is used for all species with a few modifications taking into account differences between production typologies and species, but also between herd (dairy and beef).

1. INDIRECT (EMBEDDED ENERGY): EMISSIONS RELATED TO CAPITAL GOODS

Capital goods including machinery, tools and equipment, buildings such animal housing, forage and manure storage are a means of production. Though not often considered in LCAs, capital goods carry with them embodied emissions associated with manufacture and maintenance. These emissions are primarily caused by the energy used to extract and process typical materials that make up capital goods such as steel, concrete or wood. This assessment focuses on the quantification of embedded energy in capital goods including farm buildings (animal housing, feed and manure storage facilities) and farm equipment such as milking and cooling equipment, tractors and irrigation systems.

To determine the effective annual energy requirement, the total embodied energy of the capital energy inputs was discounted and we assumed a straight-line depreciation of 20 years for buildings, 10 years for machinery and equipment and 30 years for irrigation systems. A simplified approach was adopted in the calculations; emission coefficients were defined for the dairy cattle sector and these were then extrapolated to the beef cattle, buffalo and small ruminant sector.

1.1 Farm infrastructure

Emissions of a representative set of farm buildings were calculated from typical material of building components, including steel, concrete and wood used in the construction of animal housing, manure storage and feed storage facilities. Data related to the density of the building material was taken from various sources and literature.

- *Animal housing*: Five different levels of housing were defined with varying degrees of quality and emissions related to these were calculated (Table E1). These five housing types were then distributed across the different production systems (grassland and mixed), AEZs (arid, humid and temperate), and country grouping [OECD, least developed countries (LDCs) and other developing countries] based on the level of economic development. The percentage allocated for the different values of housing was based on two criteria: (i) livestock density in the two production systems and three AEZs based on number of adult females; and (ii) the average milk yield per cow per year. Tables E2 and E3 illustrate the allocation of embedded energy in small ruminant housing in arid zones in OECD countries and the average emission factor (accounting for depreciation).

Table E1. Typology of animal housing considered in this assessment

Level of investment and definition	Characteristics			Production system
	Floor, foundation, walls	**Roof, roof-frame**	**Supports**	
High: *high technology and use of high quality materials*	Material: concrete	Material: steel	- Stanchions - Columns - Rafters	- Industrial units - Peri-urban - Fattening units
Average: *intermediate level of technology and use of good quality materials*	Without walls; or ½ walls (concrete)		- Stanchions - Columns - Rafters	- Peri-urban - Fattening units - Mixed systems
Low	No walls, floor not paved	Material: steel	Material: Steel	Mixed systems
Very low	Cement floor or unpaved floor (dirt) No walls	Material: steel for roof	Local/hand-made material e.g. wood for columns/ rafters	- Mixed systems - Peri-urban
Nil: *situation with no housing or existing shelter such as kraals made from local materials (wood, manure) and no embedded energy involved.*

Table E3. Allocation of embedded energy in housing – an example for small ruminants in arid zones in OECD countries

Country grouping	Level of investment	Emission intensity *(kg CO_2-eq/25 kg LW AFSR[1])*	Allocation *(percentage)*	Emission factor *(kg CO_2-eq/25 kg LW AFSR[1])*
OECD	High	83.7	20	16.7
	Average	76.7	20	15.3
	Low	47.0	50	23.5
	Very low	10.5	-	0.0
	Nil	0.00	10	0.0
Total			100	**55.6**
Depreciation (20 years)				**2.8**

[1] AFSR: Adult Female Small Ruminant.

- *Manure storage:* The calculation for energy embodied in manure storage facilities was based on a similar methodology and allocation technique outlined above. As capital investment, only a platform of concrete was considered and calculated as a percentage of the floor-surface of the standard shelter (25 percent on 90 days and 50 percent on 180 days of manure storage). The period of manure storage considered includes 90 days in arid and humid areas and 180 days in temperate days in both grassland and mixed systems. Although liquid manure storage plays an important role in industrialized regions particularly for dairy, only solid manure storage was considered for this assessment.
- *Feed storage:* The calculation for energy embodied in feed storage facilities was based on a similar methodology and allocation technique outlined for housing and manure storage. The period of feed storage considered includes 90 days in arid and humid areas and 180 days in temperate days in both grassland and mixed systems. Due to their importance in a majority of countries, only hay and straw were used as the basis for feed density. The required volume of storage capacity was calculated on the basis of roughage requirements (based on 2 percent intake of DM) and the Bulk Specific Weight and Density[21] for hay and straw. The quality of the feed storage was assumed to be similar to the animal housing infrastructure.

1.2 Farm equipment

Emissions embodied in farm equipment were calculated on the basis of the five levels of farm infrastructure (ranging from nil to high), with allocation criteria similar to those outlined for farm infrastructure. For these calculations, farm equipment was divided into three categories: tractors, tractor implements and hand tools; milking and milk storage equipment; and irrigation facilities. Emissions related to steel were derived from the Ecoinvent database.

- *Tractors, implements and hand tools*: The calculation for energy used in the manufacture of tractors and tractor implements and tools is related to the number of tractors used per hectare; an average weight of steel per hectare based on Dyer and Desjardins (2005); and the stocking rate of adult females per hectare. It is assumed that in areas with over 1 000 ha per tractor, the use of hand tools is prevalent and for these situations we estimated 5kg of hand tools.
- *Milking and storage/cooling equipment*: Equipment taken into account includes bulk tanks and cans, post bars, vacuum pump, pipelines, plate cooler units. Table E4 presents the milking and storage/cooling equipment considered in this study.
- *Irrigation systems*: Two basic types of irrigation systems were considered: border strip and spray irrigation and were applicable only to the high and average level of investment farm. Due to the lack of more recent data, the calculation for energy embodied in irrigation systems is based on the approach used by Wells (1998).

[21] This is a measurement of a feed's mass (weight) per unit volume of space the feed occupies; the standard unit is kg/m^3.

Table E4. Milking, cooling and storage equipment considered in this assessment

Equipment	Description
Coolers	Medium-scale herd composed of 40 cows producing 20 l/day (milked twice a day); using a tank of 1600 litres Small-scale herd composed of 14 cows producing 20 l/day (milked twice a day); using 10 cans of 60 litres each
Post bars	Medium-scale herd – 4+4 posts steel made Medium-scale herd – 2 posts wood made
Pipeline	Medium-scale herd – double pipeline set suspended over the central corridor
Milking vacuum pump	Medium-scale herd – consider an average typology: 2 mobile and 1 fixed floor
Cooling system	Medium-scale herd – consider an average value among low, medium, high

Source: Authors.

Table E5 presents average emission factors for embedded energy for on-farm capital goods in dairy cattle production. For beef cattle and buffalo, we took a simplified approach by applying 50 percent of the EF coefficient calculated for dairy cattle. Emission factors used for small ruminant dairy are presented in Table E6 and a similar approach of applying 50 percent of the EFs to small ruminant meat herds was adopted.

2. DIRECT ENERGY: EMISSIONS RELATED TO ON-FARM ENERGY USE

On-farm energy in ruminant production relates to the use of energy for milking, milk pumping, on-farm cooling of milk, ventilation, heating and lighting, water heating, watering and feeding of animals.

Various studies have estimated the amount of direct energy used on farm (Barrington *et al*., 1999; Dalgaard *et al*., 2000; Cederberg and Mattsson, 2000; ADAS, 2000; Haas *et al*., 2001; Wells, 2001; Ludington and Johnston, 2003; Barber and Pellow, 2005; Casey and Holden, 2005; Dyer and Desjardins, 2006; Saunders and Barber, 2007; DEFRA, 2007a, 2007b; Schils *et al.*, 2007; FEC, 2008; Horndahl, 2008; DairyCo, 2009; Thomassen *et al*., 2008; CAFRE, 2009; Bestfootforward (personal communication, 2010); ATTRA, 2010; Williams *et al*., 2010; Rotz *et al.*, 2010). Based on these studies, it is estimated that the average energy use is 0.219 kWh/kg raw milk.

It is however difficult to make an accurate estimate of the average energy use for these individual farm processes as well as the type of energy used because of the lack of disaggregated data. However, four studies (Bestfootforward (personal communication, 2010); Ludington and Johnston, 2003; DEFRA, 2007b); and Thomassen *et al*., 2009) provide a breakdown by source, which indicates that 38 percent of total direct energy consumed on-farm is electricity and 62 percent non-electricity. Using the results above (i.e. total direct energy use is 0.219 kWh/kg raw milk, which is split 38:62 electricity: non-electricity) and assuming that the main non-electricity use is diesel, the emissions can be calculated, see Table E7. The two coefficients (0.083 and 0.135 kWh/kg milk) are used in the calculation of the EFs for on-farm direct energy use.

Countries were ranked by milk yield, then categorized into five groups (representing the five categories of dairy farm mechanisation: High, Average, Low, Very low, Nil). Energy use will vary between these five levels. It was assumed that the

rate of electricity use would be the same for high, average and low systems, where milking activities are largely mechanized. It was further assumed that no electricity is used in very low and nil level systems. For the allocation across the five categories, the median adult female (ADF) weight and milk yield were used and the milk yield per kg of ADF calculated for each category. Table E8 presents the emission intensity of milk from direct on-farm energy use for the different levels of mechanization.

On-farm energy use was then adjusted to reflect the variations across farming systems in terms of level of mechanisation and energy use efficiency. It was assumed that 50 percent of OECD emissions are from electricity. The EFs for OECD countries were adjusted to take into account variations in the amount of CO_2 emitted per kWh electricity. It was assumed that non-OECD countries do not use mains electricity, and standard emission factors are used for diesel/petrol (which means

that emissions in some countries, e.g. Brazil, will be overestimated). Table E9 presents the adjusted EFs for direct on-farm energy use for milk production in OECD countries and EFs for non-OECD countries.

Direct on-farm energy for non-dairy herd (beef cattle, buffalo, small ruminant meat herd/flock): Direct energy use is associated primarily with the handling of manure, bedding and feed, which are dependent on the system (i.e. grass or mixed) and the level of mechanization, rather than the climate. Therefore it was assumed that the energy use for a given mechanization level and system is independent of climate. We assumed that minimal direct energy use is associated with meat production was assumed –in developing regions - low levels housing and mechanized feed, bedding manure handling. Table E10 presents regional EFs for direct on-farm energy use for ruminant meat production used in this assessment.

APPENDIX F

Relative value of slaughter by-products and effect on allocation of emissions

The main edible product from slaughtered animals is meat, but slaughterhouses also produce a whole range of by-products (organs, hide, blood, etc.). Between 30 and 60 percent of animal weight, depending on the species, does not end up as meat for human consumption.

Little documented information is usually available on the marketing of by-products from abattoirs but it is generally considered that they constitute a crucial part of profitability, with a more than significant share of the margin. They are subdivided into edible and non-edible materials.

1. EDIBLE BY-PRODUCTS

The main edible by-products of a slaughtered animal are offal, also known as variety meat or organ meat. Offal is divided into red (heart, livers, kidneys, lungs, tongue, cheek meat and deboned head trimmings) and white (intestine, stomachs, sweetbread [thymus and pancreas] and brain). Edible by-products can also be blood and fats that are fit for human consumption, and used in further processed products such as sausages.

According to a survey in the French meat industry, all edible materials from the carcass, including meat and offal, account for 45 percent of the live weight of an adult cattle (see Table F1). By-products are therefore 55 percent of the animal live weight. This is consistent with the results of a study on yields of by-products in various breeds of cattle slaughtered in Texas in 1989 (Terry *et al.*, 1990). It is also

Table F1. Beef cattle products and by-products, by type of use

Use of animal products and by-products (ABP)	Beef *(percentage of LW)*
EDIBLE	
Meat, offal, blood and fats for human consumption	45
INEDIBLE	
ABP withdrawn for sanitary reasons, SRM*, wastes	10
Protein, blood and fats (pet food, animal feed, drug industry)	20
Bones (feed industry, glue, gelatine)	8
Skins & hides (leather)	6
Digestive tract content (compost/fertilizers)	10
Lost due to carcass chilling and drying	1

* Specified risk material with regard to BSE (brain, eye, medulla, etc.).

Source: FranceAgriMer. 2012. *Observatoire des coproduits* (based on a survey of 40 meat plants in France).

consistent with the results of a more recent USDA study (Marti *et al.*, 2011), that estimated total by-products at 44 percent of total live weight, but did not include the digestive tract content (approximately 10 percent).

Edible by-products, mainly offal, account for around 12 percent of adult cattle live weight (Ockerman and Hansen, 2000). Human consumption of offal varies by culture and region, but can be found almost everywhere, in developed as well as in developing countries. Following animal health crises, such as the outbreak of *bovine spongiform encephalopathy* (BSE) in 1996, and the ban on the use of these products by a number of countries, the global offal market accounts for 15 to 20 percent of production.

World trade of bovine offal is estimated at one million tonnes per year. Asia (in particular China and Japan) is the main outlet for bovine offal, and is far from being self-sufficient, with 40 percent of global imports. Russian Federation doubled its imports in the past ten years, importing more than 100 000 tonnes of beef offal today, despite the ban on U.S. beef in 2004 due to BSE. Other significant importers include Egypt and Central Africa.

Offal exporters are the main beef exporters: United States (27 percent), Australia (14 percent), Argentina (12 percent) and Brazil (9 percent). In other countries, offal is often sold locally.

2. NON-EDIBLE BY-PRODUCTS

For adult cattle, non-edible by-products represent on average 55 percent of the total live weight. Material to be eliminated, such as by-products withdrawn for sanitary reasons (e.g. liver with flukes), specified risks materials and wastes from the first water treatment, account for 10 percent of the animal weight and are a cost for the meat plant.

Hides and skin constitute the most profitable non-edible by-products of the meat industry, with about 6 percent of the animal weight and sometimes up to 75 percent of the by-products value (Marti *et al.*, 2011). They are also the most internationally traded by-products, with Italy and Turkey as major outlets for many exporters.

In terms of weight, the most important group of non-edible by-products (accounting for 20 percent of total live weight) is constituted by floor trimmings, blood and fats used mostly for pet food but also for animal feed (processed animal protein, like meat and bone meal), or in the drug or cosmetic industry. Bones (8 percent of the weight) often go through rendering with this category to produce processed animal protein. They can also be used to produce glue or gelatine that go back into the human consumption chain.

Digestive tract content is usually about 10 percent of the animal weight and is used as fertilizer or as biogas material on the meat plant to produce energy.

3. VALUE OF BY-PRODUCTS

Edible and non-edible by-products accounted for 11 percent of the total value of the carcass sold by slaughterhouses in 2011, according to a survey of 10 cattle slaughterhouses in France (Observatoire des prix et des marges, 2012). The share of by-products in the total value tends to increase over time (it was only 6 percent in 2005).

This result is consistent with a study by Terry *et al.* (1990) that estimates the value of edible and inedible by-products from cattle at 9 to 12 percent of the total live

Table F2. Total revenue from one adult cattle sold by the slaughterhouse and share of by-products

Year	Total revenue *(€/kg)*	All by-products value *(€/kg)*	All by-products *(percentage)*	Edible by-products value *(€/kg)*	Edible by-products *(percentage)*	Non-edible by-products *(percentage)*
2005	4.19	0.28	6	0.14	3	3
2006	4.39	0.29	6	0.15	3	3
2007	4.39	0.38	9	0.15	4	5
2008	4.5	0.26	6	0.16	4	2
2009	NA	NA	NA	0.17	NA	NA
2010	4.69	0.4	9	0.16	4	5
2011	4.96	0.53	11	0.16	3	8

NA: Not Applicable.

Table F3. Emissions intensity of beef with and without allocation to slaughter by-products in Western Europe

	kg CO_2-eq/kg LW
No allocation to by-products	18.8
With allocation to by-products	17.7

Source: Authors' calculations.

value. It is also consistent with Marti *et al.* (2011), who estimated that by-products added value to one steer at 10 percent in average over the period 2000 to 2011.

Nevertheless, because of consumption habits, value for edible by-products can be very different from one country to another. For example, offal like hearts or stomach has greater value on the Chinese market than on any other market.

According to data from the Rungis Wholesale Market in France, total value of offal for one adult cattle was € 52.2 in 2011, that is to say 0.16 cents per kg of total products for one animal. Offal market prices were lower in 2005, and the market is very sensitive to sanitary crises, but the contribution of edible by-products in the total revenue from slaughtered adult cattle is generally stable at about 3 to 4 percent. We estimate that the value of other edible by-products is not significant compared with edible offal.

Non-edible by-products therefore account for the rest of the revenue from by-products; about 8 percent of the total revenue in 2011, a share that has increased by 5 percent since 2005.

The global value of non-edible by-products is quite volatile and this is mainly driven by the value of hides and skins. The world skin markets drop of 2008 and 2009 is reflected in Table F2 with a decrease of non-edible by-products in 2008.

This case study in France is one of the few examples available. Results appear to be consistent with a similar study by USDA but they cannot be seen as representative on a global scale since the categories and actual uses of slaughter by-products varies greatly from region to region and in time. Furthermore, alternative types of allocation (e.g. dry mass) could be used however these require further developments.

Nevertheless, because of the similarities among Western European breeds and among European markets of animal products, we can extrapolate the results of the French case study to Western Europe. Table F3 presents the effect of allocation

emissions to by-products using 6 percent as the allocation value of emissions to slaughter by-products in Western Europe.

Due to the lack of a comprehensive global data on by-products in the meat sector, the allocation of emissions to slaughter by-products could not be performed in this assessment. This may be improved in a future assessment depending on information shared by the industry and the development of harmonized methods to allocate by-products at slaughterhouses.

B. California's Dairy Methane Targets 55
C. Key Takeaways: Climate Targets 57

I. Introduction

This white paper addresses several contested and commonly-raised issues related to the promotion of dairy digesters as the primary policy mechanism to reduce greenhouse gas (GHG) emissions from dairy operations in California. The purpose of this paper is to provide context for ongoing conversations regarding the role of dairy digesters in California's Low Carbon Fuel Standard (LCFS), as well as potential dairy methane regulations pursuant to SB 1383 (2016). The report analyzes and offers key takeaways for each of the following issues:

- The variety of manure management systems used on dairies and their respective prevalence and emissions;
- The appropriateness and applicability of the life cycle analysis used by the Air Resources Board (CARB) to evaluate the carbon intensity of fuels derived from dairy biogas in the LCFS program;
- The relationship between LCFS incentives for dairy biogas and dairy consolidation;
- The risk of emissions leakage were CARB to regulate dairy methane;
- The role of LCFS credits for fuels derived from dairy biogas in meeting California's climate targets.

II. Manure Management Systems and GHG Emissions

California's Low Carbon Fuel Standard (LCFS) assumes that liquid manure management systems are the standard practice for dairies and, as a result, that they are the appropriate baseline against which to compare a given climate intervention. By setting liquid manure management systems as the reference scenario, emissions reductions from digesters appear to be relatively higher because this method of manure management generates more emissions that can then be captured. While liquid manure management systems are the predominant approach in California, they are one of the more polluting manure management systems available. They are also less common in other dairying states. Dairies in all states, however, are eligible for LCFS credits and shaped by that program's incentives. This section describes how common liquid manure management systems are and what alternatives are available.

The major sources of GHG emissions in the dairying process are feed production, enteric fermentation, and manure management. These are present in all dairy operations to varying degrees. The relative contributions of feed, enteric fermentation, and manure management vary based on the practices employed. Emissions from feed production, for example, can be especially high in "high-yielding milk production systems."[2] Manure management emissions can vary significantly based on the scale of the operations and the specific practices employed, while enteric emissions tend to scale proportionally to herd size. While estimates of relative contributions vary, methane from enteric fermentation and feed production are generally thought to be the largest sources, followed by manure management.

A. Common Manure Management Systems

Livestock produce waste. Historically, when dairy farms were pasture-based and much smaller than the contemporary American dairy, cows deposited their waste in the pasture where it would degrade and incorporate into the soil over time. As dairy industrialized over the course of the 20th century, and particularly as the industry consolidated over the past 30 years, the amount of waste produced at the largest operations has become too great for the available land to absorb safely. When manure is

2 M. Henriksson, C. Cederberg, and C. Swensson, *Carbon Footprint and Land Requirement for Dairy Herds Rations: Impacts of Feed Production Practices and Regional Climate Variations*, 8 Animal 8, 1329 (2014), https://doi.org/10.1017/S1751731114000627.

land-applied above agronomic rates, or above the rate at which the crops and soil can absorb nutrients, it results in contamination to local waterways. As a result, larger-scale dairy (and other livestock) operations have had to develop new methods that allow them to collect the waste and store it until land is available and weather conditions allow for it to be safely disposed of.[3]

Manure management systems can be divided into three components: "1) manure handling, the method of manure removal or management in animal housing or grazing areas; 2) manure storage, the infrastructure and method for holding manure until its application; and 3) manure application and manner in which manure is land applied, typically for crop fertilization."[4] Different practices are available to dairies at each step in this process.

Different approaches are more suitable to different operations based on scale and location. The scale of the operation impacts the choice of manure management system for several reasons. On large-scale operations, there is generally inadequate pastureland available for grazing and inadequate cropland for manure application. As a result, feed must be purchased[5] and manure must be stored until the conditions are right and the land is available for spreading. The manure lagoon is the dominant form of manure storage for these large-scale operations. Anaerobic lagoons are designed minimize the amount of land required for spreading.[6] Concentrating manure production creates risks to air and water[7] so manure transport, storage, and spreading must all be carefully managed.

At the smaller-scale, dairies typically graze their cows and supplement with little to no purchased feed. Manure is produced at quantities and concentrations less likely to cause nutrient pollution and is typically land-applied on a regular basis (though some small and mid-sized farms may also use short-term storage for manure).

A key point of differentiation between dairy manure management systems is manure consistency: Some farms maintain their manure in solid form and others liquify the manure. Larger farms with manure lagoons tend to transport manure in liquid form, often using flush systems. Smaller farms more often maintain solid manure that can be land-applied daily.[8]

The specific practices adopted throughout the different parts of the manure management system affect one another as well, with the initial choice of manure consistency imposing decisive constraints.[9] One study found "clear patterns of related strategies, largely determined by the handling of manure as a liquid, slurry, or solid."[10] The diagram below was developed out of a survey of Wisconsin dairies to study how certain practices tend to lead to others. For example, larger operations tend to use freestall barns. The survey found that 68% of operations using freestall barns select a skid steer over various alternatives to collect

3 H.A. Aguirre-Villegas and R.A. Larson, *Evaluating Greenhouse Gas Emissions from Dairy Manure Management Practices Using Survey Data and Lifecycle Tools*, J. of Cleaner Production 143 (2017) 169e179, http://dx.doi.org/10.1016/j.jclepro.2016.12.133. This Wisconsin survey found that farms had more land per "animal unit" than larger farms, likely because "neither large farms nor permitted facilities have the sufficient land to agronomically recycle excreted P (Table C.4), suggesting that land is not increasing proportionally to the number of cows as farms grow."

FIGURE 1 Via H.A. Aguirre-Villegas and R.A. Larson, Evaluating Greenhouse Gas Emissions from Dairy Manure Management Practices Using SurveyData and Lifecycle Tools, Journal of Cleaner Production 143 (2017) 169e179, http://dx.doi.org/10.1016/j.jclepro.2016.12.133.

manure. Smaller operations tend to use tiestall barns and the survey found that 77% of tiestall barns select a barn cleaner over various alternatives to collect manure. The kinds of collection processes in turn impact the ways that manure can be efficiently stored, processed, and so on.

The fact that manure management processes are interrelated matters because it determines how flexible and open to change these systems are. The Wisconsin study came to the crucial conclusion that: "the inter-related nature of these systems demonstrates how MMS [Manure Management Systems] are often locked in across farm systems through structural and equipment investments... This suggests that changing MMS is complex and requires not only a shift in the potential handling method, but also potential shifts in storage and application equipment as well. Flush handling can't easily shift to scraper handling, without potentially shifting from liquid to a slurry and then investing in a surface application tank or truck system."[11]

The study also found that dairies using solid manure management systems were "highly heterogenous, where farmers may have a suite of alternative manure management strategies available to them, and substitution is viable."[12] The study found that dairies using liquid manure management systems, on the other hand, had "very few substitutes in their MMS, suggesting greater investment in certain infrastructures, which are not easily changed."[13]

This of particular concern in California, where liquid manure management systems dominate. It is not good news for advocates interested in relying on technological changes to reduce emissions from the dairy industry. It means that mitigation interventions can be constrained by decisions about manure consistency and ultimately by the scale of operation. This means that taking dairy decarbonization seriously requires reconsidering the federal and state policies that have consistently favored industrial-scale facilities.

1. Prevalence of Different Manure Management Systems

Confinement dairies with liquid manure management systems are more common in California than nationally. Manure lagoons are used on 58%

percent of dairies in California and 32% percent of dairies nationally.[14] In Tulare and Glenn Counties specifically, one survey found that 96% of dairies use storage or treatment ponds.[15] A 2011 survey of California dairies found that most had freestalls for housing and collect manure thorough flushing and/or daily scraping.[16]

Wisconsin is the number two state for dairy nationally after California, but the practices of Wisconsin dairies look different than those in California. Manure lagoons and liquid manure management systems are less common than in California. A survey of Wisconsin dairies found that they are prevalent on larger operations[17] but uncommon on smaller farms. Because Wisconsin had more smaller farms at the time of the survey, liquid systems were less common overall. 70% of permitted (larger) facilities used liquid manure management systems while 80% of smaller farms used solid manure management systems. Smaller Wisconsin operations tend to land-apply manure immediately, while the largest permitted operations rely heavily on long-term storage (lagoons). The major processing techniques used in the Wisconsin survey were: sand separation (50%), anaerobic digestion and solid-liquid separation (20%), solid-liquid separation and sand separation (10%).

Note that a key difference between dairies in California and colder climates like Wisconsin is that land application is rarely possible during the winter, because the ground is frozen. Instead, permitted facilities typically land apply in batches in the spring and the fall. Additionally, concerns around runoff due to rains when manure is land applied several times a week may be reduced due to California's drier climate.

California's model of dairying generally and manure management specifically has proliferated

in other states in recent years.[18] Some analyses distinguish between "traditional" dairying states like New York and Wisconsin, which still tend to have smaller farms on average, and "modern" dairying states, which tend to be in the West where the California-model has become more common.

2. *GHG Impacts of Different Manure Management Systems*

The variability in the climate, geography, scale, and practices of American dairies makes it challenging to make general comparisons regarding their emissions. Due in part to the many possible permutations of these practices and scales, there are limited comparative studies of emissions from small, pasture-based operations and large-scale dairy CAFOs. However, one of the few such studies "indicated that for the metric of milk production per farmland area, the environmental impact (in relation to potential resource utilization and pollutants) was lower for the pasture-based system than the confinement system. Furthermore, the pasture-based system had a lower total environmental impact compared with the confinement system."[19]

The same study acknowledged, however, that "some studies suggested that economies of scale and efficient management could put large farms in a better environmental position (Saam et al., 2005)."[20] The California dairy industry regularly makes this claim, touting its increasing efficiency as decreasing emissions intensity per cow. However, this perspective "misses the holistic economic and environmental impact of concentrating production on larger farms."[21]

Scale, of course, affects emissions and other environmental impacts on dairies. The volume of manure produced has direct implications for GHG emissions. Not only does more manure mean more emissions, but it typically means longer storage periods during which manure can emit GHGs.[22]

The manure form/consistency also has direct implications for GHG emissions. For example, "solid manures have less available water and are usually stored in stock piles that promote aeration, which reduces CH4 emissions. Liquid manures are stored on pits that promote anaerobic conditions, increasing CH4 emissions. Larger dilutions of manure imply larger manure volumes to be handled, which affects GHG emissions due to increased energy consumption"[23] Liquifying manure using flush systems can reduce ammonia emissions in the barn, but increases methane emissions.[24]

18 Rick Barrett and Lee Bergquist, *Industrial Dairy Farming is Taking Over in Wisconsin, Crowding Out Family Operations and Raising Environmental Concerns*, Milwaukee Journal Sentinel (Dec. 6, 2019), https://www.jsonline.com/in-depth/news/special-reports/dairy-crisis/2019/12/06/industrial-dairy-impacts-wisconsin-environment-family-farms/43186671002/ ("...massive milking operations, popularized in California, shatter the traditional model of Wisconsin farms. With so many cattle, they run the risk of contaminating groundwater and overwhelming lakes, rivers and streams with runoff pollution while making it harder for smaller farms to compete."); Lilli LeGardeur, *Milk It*, Louisiana Life (Jan. 4, 2008), https://www.louisianalife.com/milk-it/ ("90 percent of Louisiana dairy farms are "pasture-based," ... In confinement dairying – a relatively new style popular out West – cows are fenced inside dirt-floor lots and have all their food delivered ... Confinement dairying, by the way, is also called California-style dairying, after the state where it originated. So, to a Louisiana dairy farmer, those TV commercials depicting California cows gallivanting in fields of clover are doubly irritating. They know that most of those California critters never set foot in a grassy pasture. As one local farmer so adroitly observed, "Happy Cows – my ass.""); David Barboza, *America's Cheese State Fights to Stay that Way, Wisconsin Struggles to Keep Pace with West*, New York Times (June 28, 2001), https://www.nytimes.com/2001/06/28/business/america-s-cheese-state-fights-stay-that-way-wisconsin-struggles-keep-pace-with.html ("With the California-style operations, as they are called, about 2,000 megafarms, with an average herd size of 650 cows, produce more milk than 18,000 mostly smaller farms in Wisconsin, where the average herd is 80.")

Board, Short-Live Climate Pollutant Reduction Strategy (March 2017), https://ww2.arb.ca.gov/sites/default/files/2020-07/final_SLCP_strategy.pdf; Alice Rocha, *How Handling Manure Waste from Dairy Cattle Impacts Greenhouse Gas Emissions and Climate Impacts*, UC Davis CLEAR Center (May 14, 2021), https://clear.ucdavis.edu/explainers/how-handling-manure-waste-dairy-cattle-impacts-greenhouse-gas-emissions-and-climate ("Scraping and vacuuming, on the other hand, may leave thin layers of manure on the ground which can come in contact with cattle urine causing the emission of ammonia. The latter is generated by a reaction between urea in urine and the urease enzyme in manure.")

The Wisconsin survey modeled emissions from the dairy industry there, and found that:

- Long-term storage is common on larger farms handling liquid manure, which generally increases GHG emissions.
- A natural crust formation during storage creates aerobic conditions on the surface and reduces wind velocity, decreasing methane and ammonia emissions respectively, but increasing nitrous oxide emissions. Total GHG emissions are higher without this crust.
- Frequent manure application reduces both GHG and ammonia emissions from storage due to the shorter retention times and the reduced surface area. These emissions can increase, however, during application as more ammoniacal nitrogen and volatile solids are available to promote nitrous oxide, methane, and ammonia release. Daily or weekly application can also lead to runoff and leaching during precipitation events or snowmelt, resulting in potential eutrophication and loss of valuable nutrients.[25]

Regarding anaerobic digestion in particular, the Wisconsin survey found that:

- Out of the reported processing technologies, anaerobic digestion is the most effective to reduce GHG emissions from both energy and manure.
- Emission reductions from energy come from the displaced emissions that biogas-based electricity has when replacing grid electricity.
- Reductions from manure are mostly from the capture of methane during digestion which is then converted to carbon dioxide during combustion, as well as the reduction of carbon available to produce methane in storage.
- Solid-liquid separation further reduces GHG emissions as fewer volatile solids enter long term storage within the liquid fraction.
- After digestion, ammonia emissions are increased during digestate storage because: 1) mineralization in the digester increases ammoniacal nitrogen, and 2) the inexistence of a natural crust on the storage surface reduces the physical barrier that prevents aeration.[26]

B. Enteric and Other Non-Manure Management Emissions

Reducing emissions from manure management is critical. However, manure management contributes fewer emissions than enteric fermentation.[27] The reduction of enteric emissions has generally been sidelined as a more challenging technical problem because it is based on the natural feature of the ruminant digestive system. Considering the impact of various interventions on both enteric and manure management emissions, however, should be a component of any effort to meet climate targets for dairy.

While enteric fermentation and manure management primarily generate methane, the substantial emissions from feed production include nitrous oxide which is "emitted from cultivated soils and significantly influenced by cultivation practices, especially nitrogen (N) fertilization."[28] Emissions from feed vary based on the amount of feed imported and the composition of rations which themselves can vary based on geography and climate. Dairy feed can be homegrown—either on pasture or harvested corn or grass fermented as silage—or imported (including concentrates, silage, byproducts, and other grains).

Most dairy cows in California eat what's called

a "total mixed ration."[29] Total mixed ration "is essentially a nutritionally formulated feed mix, combining feeds formulated to a specific nutrient content. Such feeds may contain forage (grass silage, hay, or straw), grains (corn, oats, wheat, and barley), protein feeds (soybean, cottonseed, linseed, and groundnut), minerals, vitamins, feed additives, and by-products."[30]

The nutrition profile of grasses consumed through grazing, in contrast, is different, "with potential nutritional benefits, compared with conventional milk derived from total mixed ration."[31] The emissions intensity of each method is also different, depending on the particular composition of grazing forage and of a total mixed ration diet. For example, "Some studies have demonstrated benefits of inclusion of white clover in pasture, due to its ability to reduce nitrous oxide emissions, fix atmospheric nitrogen, and reduce carbon footprint (Ledgard et al., 2009; Yan et al., 2013)."[32] The UC Davis article also cites a Cornell study claiming that the emissions from using byproducts as dairy feed are 60% less than the alternative, which they define as sending the byproducts to a landfill for incineration.

32 *Id.*

C. California's Dairy Methane Reduction Strategy

According to California's Short-Lived Climate Pollutant Strategy, "California's dairy and livestock industries account for more than half of the State's total methane emissions and for about five percent of the State's GHG inventory."[33] On dairies, the strategy attributes 20% of emissions to enteric fermentation and 25% to manure management. California has more dairy cows and more dairy methane emissions than any other state.[34] Crucially, the strategy explains that California "also has higher per-milking cow methane emissions than most of the rest of the United States, due to the widespread use of flush water lagoon systems for collecting and storing manure."

The SLCP Strategy noted several potential mitigation measures, including switching away from flush water lagoon systems and switching to pasture-based dairy management.[35] CARB also convened a sub-working group in 2018, which put forth many recommendations on non-digester interventions. In practice, however, CARB has overwhelmingly focused mitigation efforts on the construction and operation of anaerobic digesters ("biogas control systems") on dairy operations and applies a high baseline emissions standard to California operations. Digesters capture the methane emitted from anaerobic lagoons, resulting in the perpetuation of flush water lagoon systems.

California's Alternative Manure Management Program (AMMP) has sought to support measures to mitigate manure emissions other than digesters. All measures other than digesters have been deemed "alternative manure management strategies," despite the fact that they remain commonplace practices is other parts of the country. From 2015-2021, the California Department of Food and Agriculture awarded $195 million to dairy digester projects through the DDRP program and $68.3 million to AMMP projects.

D. Key Takeaways: Manure Management Systems and GHG Emissions

Generalizing about GHG emissions from manure management can be challenging because emissions vary based on factors including soil type, climate, and the specific GHG, but the following are generally true:

- **The more cows an operation has, the more manure is produced, and the more methane is generated**, all else being equal. Decreasing per-cow emissions will not necessarily lead to overall methane reductions if the industry grows.

- **Anaerobic lagoons generate more methane emissions than shorter-term manure storage or more frequent land application.** This is because the manure is stored for a longer period of time and generates more emissions in liquid form.

- **Liquifying manure using flush systems can decrease ammonia emissions but will increase methane emissions**. Flushing also requires large quantities of water. See CARB's Short-Lived Climate Strategy for a discussion of emissions from California dairy practices.

- **Manure lagoons and liquid manure management systems are standard on industrialized dairies because they operate at a scale that makes regular land application of manure unsafe, requiring long-term manure storage.** The industrialized model of dairying generates too much manure to spread regularly on the land without causing nutrient pollution. As a result, industrial-scale dairies must store

33 Cal. Air Res. Board, Short-Live Climate Pollutant Reduction Strategy (March 2017), https://ww2.arb.ca.gov/sites/default/files/2020-07/final_SLCP_strategy.pdf.
34 *Id*. at 63.
35 *Id*. at 65.

manure for long periods of time, land applying only when cropland is available and the climactic conditions are appropriate. This requires operations to transport manure from barns to manure lagoons where it can be stored.

- **Manure lagoons and liquid manure management systems are far less common on small and mid-sized dairies, which can apply manure to land more frequently.** Smaller operations often have adequate land to spread manure safely at more regular intervals. As a result, they don't have to store manure for long periods of time—one of the major sources of methane emissions. This also gives smaller operations more flexibility and a greater range of options for how they manage manure. Not only do smaller operations generate fewer emissions, but their systems are less rigid than those of industrial operations. They can adapt to new mitigation measures more easily.

- **The industrialized model of dairying was pioneered in California and exported nationally. Industrialized dairies are more common in California than anywhere else in the country.[36] California's incentives for digesters are again promoting an industrialized model of dairying nationwide.** Dairy digesters, and the lucrative LCFS credits that manure biogas can generate, are only feasible on the largest dairies operations. While industrial-scale facilities are the norm in California, this isn't the case in many other dairying states where smaller operations are still more common. Smaller scale dairies aren't suited to digesters precisely because they do not have highly emitting lagoons; however, lucrative LCFS incentives for digesters are available nationwide. At the same time, additional revenue from LCFS credits further bolsters the competitive edge of the largest operations. Creating incentives for dairies to adopt liquid manure management practices with anaerobic lagoons could increase emissions in other states where these polluting systems are less common.

- **California is also promoting alternative manure management practices, but these have been funded at a fraction of the rate of digesters.** What CARB calls "alternative manure management strategies" are not radical departures from dairying practice. The Alternative Manure Management Program (AMMP) defines these practices as essentially anything that's not a digester (those practices "that don't include use of an anaerobic digester, and support management of manure in a dry form.")[37] The broad range of practices that fit within this definition—like solid separation, conversion from flush to scrape in conjunction with some form of drying or composting of collected manure, and pasture-based management—are common nationwide.[38]

- **Even with CARB's aggressive digester push, California is significantly behind on its methane targets** and, according to CARB's analysis, relying on digesters alone to reach the target would cost an additional $3.9 billion. See CARB's 2022 Dairy and Livestock Methane Progress Report here.

38 *Id.*

Around the country, in California, and in the Central Valley itself, farmers and community members are reimagining our food systems. California policymakers have a crucial role to play leading the nation in this conversation. California policymakers should be thinking creatively and holistically about what a just transition would look like for California dairies and the policy mechanisms that would be required to support a more sustainable industry.

III. Life Cycle Analysis Assumptions and Applications

The Low Carbon Fuel Standard (LCFS) allows dairies to generate credits for the production of manure biogas-derived transportation fuels. These credits are intended to incentivize the construction and operation of anaerobic digesters on dairy operations.

The LCFS calculates the carbon intensity (CI) of different transportation fuels by analyzing the life-cycle greenhouse gas emissions associated with a given fuel. To conduct these life cycle analyses, the LCFS uses "fuel pathways," which delineate which processes are included in a given fuel's life cycle. The program employs a version of the "GREET" model, which stands for the "The Greenhouse Gases, Regulated Emissions, and Energy Use in Transportation" model.[39] The GREET model was developed by Argonne National Laboratory.

There are several different kinds of pathways in the LCFS program. Lookup table pathways are applied to conventional fuels where the basic values are well-established. Fuel producers can simply look up the CI values for these fuels because they are set by CARB. Tier 1 pathways allow producers of alternative fuels to input operational data into a simplified version of the CA-GREET model to calculate the CI of their fuel. Tier 2 pathways allow alternative fuel producers to use the full CA-GREET model to conduct a custom CI analysis.

Evaluating the completeness and accuracy of LCFS manure biogas life cycle analyses is challenging because almost all participating swine and dairy operations have opted to use the customizable Tier 2 pathway. This means there is not one single life cycle analysis for biogas; instead, most of the several hundred producers that generate credits for the capture of manure methane have conducted their own customized analysis using the CA-GREET model. However, there are several issues apparent in CARB's Tier 1 pathway and considerations regarding the GREET model overall.

Life cycle analyses generally could be critiqued on a number of bases, including the emissions they opt to include, the reference scenario they assume, how emissions are quantified, and whether the model's assumptions are borne out in on-the-ground monitoring. Based on forthcoming research, it is our understanding is that, *when all is working as intended*, CARB's life cycle analysis for manure-derived biofuels generally reflects the actual emissions and reductions from biogas control systems. That is, if we accept the assumptions built into the model, the emissions and reductions counted by the model are generally accurate in practice when biogas systems are functioning as intended. The primary issues with the life cycle analyses for manure-derived biofuels, therefore, are high-level disagreements about the appropriate reference scenario and the life cycle analysis' focus on transportation emissions at the expense of agricultural emissions, as well as more specific monitoring to groundtruth those assumptions and to monitor for fugitive emis-

39 Argonne National Laboratory, *GREET: The Greenhouse Gases, Regulated Emissions, and Energy Use in Technologies Model: The Gold Standard for Life Cycle Analysis of Technologies and Energy Systems* (May 2020), https://www.anl.gov/sites/www/files/2020-10/GREET_Impact_Sheet.pdf.

40 Our research on this topic was informed by a background interview with an environmental scientist who shared their evaluation of monitoring concerns as well information about forthcoming research.

sions, which are a "substantial" concern.[40]

A. Groundtruthing Life Cycle Analysis Estimates and Reported Reductions with Data

One article describes the downside to "bottom-up" emissions analyses like CARB's:

> *Bottom-up inventories, including those used by the US Environmental Protection Agency (US EPA, 2017) and the California Air Resources Board (Charrier, 2016), estimate dairy emission rates at the state level based on the total number of cows and herd demographics and on the average statewide manure management approach, CH_4 emissions factor, and climate. However, livestock emissions, especially from dairies, remain one of the largest uncertainties in these inventories (Maasakkers et al., 2016), as there is no comprehensive information source for the number of cows or manure management strategies*.[41]

California has a lot riding on the reported (on-paper) emissions reductions from dairy digesters. These estimates should be groundtruthed with actual monitoring. On its own terms—that is, if concerns about the assumptions made in CARB's life cycle analysis models are temporarily set aside—forthcoming research based on a single facility suggests that CARB's manure biogas life cycle analyses are accurate when biogas control systems are working as intended. However, biogas control systems may not always work as intended. One environmental scientist our team spoke with cited "substantial" concern about fugitive emissions from digester systems. Fugitive emissions are essentially leaks where the captured methane can escape and be vented to the atmosphere.

CARB itself came to this conclusion in the wake of a methane survey, acknowledging:

> "As expected with any new technology, during the initial operational deployment of [anaerobic digesters (AD)] situations may arise including leaks or higher-than-predicted venting that can impact the desired methane control efficiency. Characterizing potential AD fugitive emissions through the use of tools like the NASA JPL flyovers can help achieve and maintain the expected methane reductions by helping digester operators optimize their systems and reduce revenue loss."[42]

CARB requires an engineering review for biogas pathway applications, but no ongoing monitoring at the facility level, and does not conduct ongoing monitoring at the regional level itself. Monitoring for methane from dairies overall is challenging because the emissions are so dispersed, intermittent, and can depend on variables like soil type and weather. Unfortunately, unlike other air pollutants like ammonia, methane monitoring is not well-suited to community monitoring efforts. Fortunately, California is home to environmental scientists with this expertise. One environmental scientist suggested that a cost-effective approach to monitoring that prioritized measurable and preventable emissions would be third-party monitoring of fugitive emissions from biogas control systems. At a bare minimum, CARB should be collaborating with these scientists to ensure the methane emissions it reports as captured are not leaking out through biogas control system.

B. High-Level Life Cycle Analysis Concerns: Reference Scenario Assumptions

The purpose of the CA-GREET model is to estimate the CI of transportation fuels. In evaluating the emissions impact of the displacement of conventional fuels by new, alternative fuels, the structure of the analysis is to assume a static baseline or reference scenario. The analysis can then evaluate a specific alternative fuel intervention against that reference scenario, where the new fuel is the only change. In the manure biogas life cycle analyses, therefore, the model assumes a dairying reference scenario upon which the transportation fuel intervention operates. CARB's reference scenario is based on the dominant approach to dairying in California. That is, CARB's life cycle analysis assumes the ongoing presence of industrial-scale confinement dairies with liquid manure management systems. There are two important critiques of this assumption:

- Rather than seek to change the dairying model to one that generates fewer GHG emissions, CARB takes this system as a given and builds on top of it.
- Because LCFS credits are available nationally, but the reference scenario is based on the (more-polluting) California model of dairying, the program could incentivize a harmful shift in practices from out-of-state dairies at the same time it entrenches those practices at home.

The reference scenario is illustrated concretely by the life cycle analysis' assumption that, if not for the addition of an anaerobic digester, manure would be stored in anaerobic lagoons and, if not for the digester, manure methane would be vented directly to the atmosphere. This is not the case on many of the thousands of farms otherwise eligible for LCFS credits nationwide.[43] Rather than devise a mitigation intervention applicable to these farms, CARB simply excludes them from the program if their practices do not match those in the reference scenario. This is unfortunate, because it limits eligibility for the lucrative LCFS credits to operations with the most polluting practices (those that match the reference scenario).[44]

Manure lagoons are used on 58% percent of dairies in California but only 32% percent of dairies nationally.[45] One early GREET study acknowledged that not all dairies use anaerobic lagoons, explaining: "EPA also estimates MCFs of wet (e.g. anaerobic lagoon, liquid slurry and deep pit) and dry (e.g. daily spread and pasture) manure management systems for cool, temperate and warm climate zones... Note that in Wisconsin, solid storage is used for a larger share and anaerobic lagoons for a smaller share of manure than in the United States as a whole, while in California more than 50% of manure is treated by anaerobic lagoon."[46] But given the concentration of this model of dairying in California's Central Valley, CARB has settled on this reference scenario.

In addition to ensuring that LCFS credits are only available to the largest polluters, this reference scenario allows these operations to claim massive emissions reductions since reductions are equivalent to their "captured" or "avoided" emissions.[47]

43 LCFS credits are not limited to California dairies. Operators need only to inject the resulting natural gas into a common carrier pipeline in North America and link the energetic attributes of that biogas with a pipeline withdrawal for natural gas sold in California. The same principle is applied for electricity generated in the combustion of biogas on-site. (Note, however, that the 2023 SRIA for the new LCFS regulation did propose altering the book-and-claim accounting system.)

44 Traditional pasture-based dairies leave manure in pasture where it is deposited by cows. This is possible because manure is produced in quantities below agronomic rates—the available land can adequately and safely absorb the nutrients from the manure. Industrial scale operations collect and store manure for two reasons. First, they generally hold livestock in confinement, so the manure isn't deposited in pasture as a matter of course and needs to be cleaned out of barns. Second, too much manure is produced on industrial-scale facilities for the available land to absorb nutrients without creating serious environmental harms. As a result, manure is collected and stored in "lagoons." To transport manure into lagoons, manure is typically flushed out of barns, liquifying it and creating new emissions in the process. Manure from the lagoons can periodically be spread on land ("land-applied") at or below agronomic rates.

45 Jeongwoo Han, Marianne Mintz, and Michael Wang, *Waste-to-Wheel Analysis of Anaerobic-Digestion-Based Renewable Natural Gas Pathways with the GREET Model ANL/ESD/11-6*.

46 *Id.*

This means that the more emissions they generate, the more they can capture, the more reductions they can claim publicly, and the more revenue they obtain through LCFS credits. Finally, by calculating credits that are issued nationally based on a California-specific reference scenario, the program risks shifting practices in other states towards California's more polluting model of dairying.

C. High-Level Life Cycle Analysis Concerns: Focus on Transportation, Not Agriculture

The goal of the GREET model used by CARB is to estimate life cycle emissions of transportation fuels, not to estimate emissions from agriculture. Transportation fuel life cycle analyses differ markedly from agriculture life cycle analyses.[48] Biofuels like manure biogas straddle agriculture and transportation fuel life cycle analyses, requiring value judgements about where to set system boundaries. Life cycle analyses for biofuels are well-characterized by the paper cited above as follows:

> *Particularly with biofuels, policy-related requirements, modeling assumptions, analysis limitations, and software can have a significant effect on results (Agostini, Giuntoli, Marelli, & Amaducci, 2020; Hoekman & Broch, 2018; Obnamia, Dias, MacLean, & Saville, 2019). As a result, users need to carefully consider the context, usefulness, and applicability of these complex analyses. Many biofuel life cycle accounting policies and studies try to evaluate the changes that biofuel production has on food production systems. To evaluate impacts to production systems, most analyses use some metric to first assess the status quo such as a reference system (Hoekman & Broch, 2018), business-as-usual (BAU) scenario, or baseline, and then quantify changes that biofuel production creates. As a result, most biofuel-related system boundaries (Figure 8) also include quantifications which involve product substitution or displacement (Vadenbo, Hellweg, & Astrup, 2017).*[49]

A paper by Argonne National Laboratory scientists reiterates that, in the case of biofuels, "GHG emissions for RNG pathways are highly dependent on the specifics of the reference case, as well as on the process energy emissions and methane conversion factors assumed for the RNG pathways."[50] The goal of the LCFS biogas life cycle analysis is to compare the status quo with an alternative where anaerobic digesters are used to capture methane and the resulting transportation fuel displaces conventional fuel use.

Concretely:[51] the GREET model's life cycle anal-

47 Cal. Air Res. Board, *Tier 1 Simplified CI Calculator Instruction Manual: Biomethane from Anaerobic Digestion of Dairy and Swine Manure*, https://ww2.arb.ca.gov/sites/default/files/classic/fuels/lcfs/ca-greet/tier1-dsm-im.pdf?_ga=2.140068787.1623257348.1702923028-1380165209.1657241991.

48 Writing on fuel life cycle analyses, scientists from Argonne National Library explained: "A fuel cycle typically includes feedstock recovery and transportation, fuel production, transportation and distribution, and combustion as an end use." Jeongwoo Han, Marianne Mintz, and Michael Wang, *Waste-to-Wheel Analysis of Anaerobic-Digestion-Based Renewable Natural Gas Pathways with the GREET Model ANL/ESD/11-6*. A different paper by Argonne National Laboratory scientists characterized the system boundaries for animal agriculture systems, on the other hand, as follows: "The process considered for animal systems in cradle-to-farm-gate system boundaries normally include feed production, animal husbandry, manure storage and farm management. Farm-gate-to-grave systems include processes such as transportation of product from farm to processing plants, manufacturing of packing materials such as bottles for milk and cartons for eggs, and distribution to retailers and consumers." Heidi Sieverding et al., *A Life Cycle Analysis (LCA) Primer for the Agricultural Community*, 112 Agronomy J. 5, 3788 (May 6, 2020), https://acsess.onlinelibrary.wiley.com/doi/pdfdirect/10.1002/agj2.20279.

49 *Id.*

50 *Id.*

51 The LCFS calculator for Tier 1 pathway for biogas from swine and dairy manure requires applicants to "add facility information and verifiable monthly feedstock, operational energy use, fuel production and co-product data, and transport distances used in calculating the CI of biomethane from dairy and swine manure digesters." Cal. Air Res. Board, *Tier 1 Simplified CI Calculator Instruction Manual Biomethane from Anaerobic Digestion of Dairy and Swine Manure* (June 20, 2023), https://ww2.arb.ca.gov/sites/default/files/classic/fuels/lcfs/ca-greet/t1_biomethane_DSM_instruction_manual_v0620023.pdf. The Tier 1 calculator quantifies baseline emissions (of anaerobic lagoons and non-anaerobic storage) as well as emissions associated with the biogas control systems themselves (like emissions from venting events and emissions from effluent ponds), and other emissions not related to the biogas control system itself. The calculator then quantifies avoided methane by comparing baseline methane emissions to project methane emissions. Note that new models for the life cycle analysis are expected to be published for public comment on Tuesday, December 19, 2023. The Tier 2 pathway for manure biogas is simply a customized version of the full CA-GREET 3.0 model. As such, it requires far more input from the producer than the simplified Tier 1 pathway. Additionally, users can choose either a United States or IPCC reference scenario. If they choose a United States reference scenario, they can further specify a reference scenario by state.

ysis for manure biogas begins at manure storage in the lagoon. Beginning the life cycle analysis with manure storage leaves out all emissions that occur before storage: emissions from feed production, general dairy operations, enteric fermentation, and the collection and transportation of manure to lagoons. The justification for starting the life cycle analysis with manure storage in the lagoon is that the manure will be stored in lagoons regardless of the addition of an anaerobic digester incentivized by LCFS credits.[52] That is, CARB assumes a reference scenario based on liquid manure management systems with anaerobic lagoons, as discussed *supra*. Upstream emissions should be considered if CARB seeks to understand the impact of the LCFS on agricultural emissions. Excluding these emissions is justifiable to the extent that CARB limits use of the life cycle analysis to claims about transportation fuel reductions.

At the other end, the life cycle analysis model is bounded by the end-use of the energy generated, either the combustion of RNG as transportation fuel or as electricity. The life cycle analysis also excludes emissions from the storage and disposal of digestate,[53] the by-product of anaerobic digestion. The exclusion of digestate is justifiable if CARB also excludes emissions from manure land application in the reference scenario. An environmental scientist consulted for this research explained that forthcoming research at a single dairy found that emissions from land application and from digestate application are likely comparable. The scientist also stressed that a generalized comparative analysis of manure application versus digestate application would be extremely challenging to implement because emissions are dispersed and vary based on soil conditions, climate, and the specific pollutant studies.[54]

Focusing life cycle analyses on transportation fuels is an intentional and understandable choice by CARB given the intended function of the LCFS. CARB is required to "[c]onsider the significance of the contribution of each source or category of sources to statewide emissions of greenhouse gases."[55] Transportation is the largest source of greenhouse gas emissions in California at 38%.[56] Agriculture is responsible for 9% of emissions in California.[57] Because CARB focuses on transportation fuel life cycle emissions (and, by extension, assumes the existing system of dairying), the Board's decision not to include upstream emissions from dairy operations is justifiable. No life cycle analysis can include all processes and all systems. The exclusion of upstream emissions, however, remains justifiable *only so long as* CARB's focus remains fixed on transportation emissions. CARB should not claim reductions from dairying overall without having analyzed emissions upstream of manure storage.

However, CARB makes a great deal of the avoided methane from agriculture, in addition to the displacement of conventional transportation fuels. This is a key reason that LCFS credit values are so high. CARB also frequently touts emissions reductions from the dairy sector on the basis of

52 Jeongwoo Han, Marianne Mintz, and Michael Wang, *Waste-to-Wheel Analysis of Anaerobic-Digestion-Based Renewable Natural Gas Pathways with the GREET Model ANL/ESD/11-6* (waste is collected in both the reference case (current manure management) and the "new" AD cases.").

53 Anaerobic digester residue is eventually land-applied and still generates emissions, as one GREET study acknowledged. *Id.* That study explained that "62% of the C in the residue is assumed to become CO 2 , and the rest (38%) is assumed to remain stored in the soil." *Id.* That study further asserted that the impacts of anaerobic digester residue land application, "that is, synthetic fertilizer displacement and N2 O and NOx emissions—should be included in LCAs of AD pathways." *Id.* The solid digestate "may be recycled for animal bedding or as a soil amendment, but this is not considered in our analysis." Heidi Sieverding et al., *A Life Cycle Analysis (LCA) Primer for the Agricultural Community*, *supra* note 48.

54 Indeed, existing literature shows variation in emissions based on a number of factors including different methods of digestate storage and processing. Holly et al., for example, found that storage of digestate with limited oxygen increased nitrous oxide emissions. Holly et al., *Greenhouse Gas and Ammonia Emissions from Digested and Separated Dairy Manure During Storage and After Land Application*, 239 Ag., Ecosystems, and Env't 410 (Feb. 15, 2017), https://www.sciencedirect.com/science/article/pii/S0167880917300701. That study also concluded that "[nitrous oxide] from digester separated solids was much higher than the separated solids without digestion." *Id.*

56 Cal. Air Res. Board, Current California GHG Emission Inventory Data, https://ww2.arb.ca.gov/ghg-inventory-data.

57 *Id.*

the LCFS analysis. While the LCFS can estimate a total quantity of emissions captured by anaerobic digesters, the narrow transportation focus of the LCFS has allowed the agency to ignore the fact that this invention locks in the most highly emitting form of dairying, precluding broader reductions.

The dairy sector is responsible for more than half of California's methane emissions.[58] Making claims about reductions from the dairy sector requires a full analysis of dairy emissions. Yet in CARB's *Analysis of Progress Towards Achieving the 2030 Dairy and Livestock Sector Methane Emissions Targets*, the agency begins with primacy of digesters, rather than with a holistic analysis of dairy emissions.[59] CARB's narrative of its process reflects this, stating: "To understand what level of resources are needed to achieve the target, CARB staff looked at existing dairy methane emissions reduction efforts, including both grant programs that fund the initial capital costs and market-based programs that incentivize GHG emissions reductions or low carbon fuel production."[60] But existing emissions reduction efforts have been defined through the transportation lens of the LCFS, which assumes the perpetuation of California's most highly-emitting dairying model. This assumption should not be the starting point for CARB's dairy mitigation strategy.

There is a second broader critique of the limitations of a baseline scenario based on the status quo at a time when we need to decarbonize all sectors simultaneously. The choice is less between the status quo and anaerobic digesters but between anaerobic digesters and a host of other policy choices. Because the dairy digester intervention only evaluates how transportation emissions will change as a result, it risks locking in or increasing dairying emissions at a time when they, too, need to decline.

While relying on a static reference scenario is necessary in any single analysis to draw a meaningful comparison between two alternatives, we are in a time of major transition: We need to decarbonize all sectors—including agriculture—simultaneously, using multiple different tactics. This presents conceptual difficulties for a binary life cycle analysis comparing a static baseline and one potential intervention. The LCFS relies on a static reference scenario of "Current Manure Management" to find that this intervention is better, but it's an intervention that increases the value of manure while other interventions could decrease the value of the manure. The manure biogas life cycle analysis' reliance on a static baseline freezes the reference scenario, both in theory and practice, first by assuming its existence into the future and second by investing in transportation fuel reductions that rely on that status quo.

D. Key Takeways: Life Cycle Analysis Assumptions and Applications

- **We need to decarbonize all sectors—including both agriculture and transportation—simultaneously**. California policymakers should work to ensure that interventions in one sector are not locking in or increasing emissions elsewhere.

- **Because the LCFS focuses on transportation sector emissions, the fact that the dairy digester intervention locks in emissions-intensive practices in the dairy sector has been given little attention.** CARB's life cycle analysis for biogas-derived fuels assumes the ongoing presence of industrial-scale confinement dairies with liquid manure management systems, locking these systems in both in theory and practice. Because the life cycle

58 Cal. Air Res. Board, Analysis of Progress Toward Achieving the 2030 Dairy and Livestock Sector Methane Emissions Target (March 2022), https://ww2.arb.ca.gov/sites/default/files/2022-03/final-dairy-livestock-SB1383-analysis.pdf.

59 *Id.*

60 *Id.*

analysis uses this dairying model as its baseline scenario, only dairies that use this model are eligible for lucrative LCFS credits.

- **The LCFS rewards captured (or "avoided") methane. This means that the more emissions dairy operations generate, the more they can capture, the more reductions they can claim publicly, and the more revenue they obtain through LCFS credits.**

- **The life cycle analysis used for transportation fuels is not an appropriate analysis to apply when analyzing overall dairy emissions, because it excludes the bulk of emissions from dairy operations.** The LCFS life cycle analysis was designed to measure the change in transportation sector emissions; it should not be used as the starting point for CARB's broader dairy mitigation strategy.

- **Dairy emissions and leaks from biogas systems are not actively monitored to groundtruth the LCFS' bottom-up estimates for captured methane despite concerns about fugitive emissions.**

IV. Consolidation and LCFS Credits

Dairy industry stakeholders argue[61] that the trend towards consolidation in dairy predates and is independent of the adoption of digester technology and Low Carbon Fuel Standard (LCFS) incentives. This is correct. Consolidation in the dairy industry is a consistent, long-term trend that far predates the LCFS and the embrace of dairy digesters. This fact does not preclude the possibility that LCFS incentives for digesters contribute to that trend in a meaningful way. This section describes the history, geography, and major drivers of consolidation in the American dairy industry. We cannot draw clear conclusions about the impact of the LCFS yet—the data needed to evaluate its effects will be released later in 2024 in the 2022 USDA Agriculture Census. Understanding the drivers of consolidation and pressures on dairy operations still provides essential context for understanding the stakes of incentivizing dairy digesters over other potential interventions.

Among other impacts, dairy consolidation has resulted in the loss of thousands of small and mid-sized farms, contributed to the decline of rural economies and communities, and increased environmental and environmental justice concerns by densely concentrating operations in a few parts of the country. Consolidation matters in the context of the LCFS and the dairy digester push for several reasons:

- First, consolidation of the dairy industry set the stage for the dairy digester push. The consolidation trend has resulted in the dominance of ever-larger, industrial-scale operations over the smaller-scale dairies that were dominant as recently as the 1980s. These factory farms rely on manure lagoons to store the manure they generate, which generates methane emissions for the duration of storage.

- Second, the credits provided by the LCFS may impact the consolidation trend, by encouraging the growth of already-large operations or encouraging operations to merge in order to take advantage of the lucrative credits available for operations that can manage a biogas control system.

- Third, even if the LCFS does not directly incentivize operations to grow or merge, it provides an additional revenue stream for the large-scale operations where digesters are an appropriate intervention. This impact would

61 Ermias Kebreab, Frank Mitloenher, and Daniel A. Sumner, *Meeting the Call: How California is Pioneering a Pathway to Significant Dairy Sector Methane Reduction*, UCDavis CLEAR Center (December 2022), https://clear.ucdavis.edu/sites/g/files/dgvnsk7876/files/inline-files/Meeting-the-Call-California-Pathway-to-Methane-Reduction_0.pdf.

not necessarily be limited to California, as LCFS credits are available to dairies nationwide.

A. Dairy consolidation is a long-term trend.

The trend towards consolidation in dairy is unmistakable and far predates the adoption of the LCFS (adopted in 2009).[62] The trend is clear both nationally and in California. A 2020 USDA report using data from the most recent USDA Agricultural Census (2017) found that since at least the late 1980s, the average dairy herd size has risen consistently, and the number of dairy operations has decreased consistently.[63] The decline in dairies and increase in herd sizes reflects the loss of small and mid-sized farms as production has shifted toward much larger farms.[64] Not only have larger dairies proliferated during this period, but frontier of what is considered "large" has progressively increased.[65]

1. Dairy consolidation coincided with a decline of small farms in the Midwest and the East and growth in industrial-scale operations in the West.

The dairy industry has trended towards consolidation nationally, but the geography of consolidation has varied. The Midwest and the Northeast have "long had many small commercial dairy farms, while production in the major Western Dairy States has revolved around large farms."[66] As the industry has consolidated, the decline of small commercial dairy farms has been "concentrated in the Midwest and the Northeast and in four states in particular: Minnesota, New York, Pennsylvania, and Wisconsin."[67] Alongside the decline in Midwestern and Northeastern small commercial dairies, "[p]roduction has shifted to Western States and is concentrated in a smaller number of counties."[68] That is to say: the decline of small farms in the Midwest and the Northeast (as well as California's dwindling pasture-based operations in Marin and Sonoma Counties)[69] have fueled the growth of the industrial-scale dairies that populate California's Central Valley and other western states.

62 Cal. Air Res. Bd., *Session 9: Overview of Low Carbon Fuel Standard & Dairy/Swine Manure Fuel Pathways* (March 29, 2022), https://ww2.arb.ca.gov/sites/default/files/2022-04/dairy-ws-session-9-CARB.pdf.

63 Commercial dairies declined at an annual average rate of 4.2 percent from 1978 through 2017.The median herd size increased dramatically over this period as well. The report found that the midpoint herd size has risen consistently from 80 or more cows in 1987 to 1,300 cows in 2017. James M. MacDonald, Jonathan Law, and Roberto Mosheim, *Consolidation in U.S. Dairy Farming*, ERR-274 (July 2020), https://www.ers.usda.gov/webdocs/publications/98901/err-274.pdf (this number is for dairies with over 10 cows which closely correlates to dairies that sell milk.)

64 *Id.* at Report Summary. The small commercial farms of 10-99 cows that were typical in 1992 have seen "large and persistent declines." *Id.* at 10. These operations have decreased by "over 80 percent in 1992–2017 for farms with 10–49 cows and over 70 percent for those with 50–99 cows." *Id.* at 10. In 2017 they made up only 12.6 percent of U.S. dairies. *Id.* at 10. Large dairies, on the other hand, make up a larger share of the industry than ever before. The USDA report found that, "In 1992, the census counted 564 farms with at least 1,000 cows, and those farms accounted for less than 10 percent of all cows. Twenty-five years later, nearly 2,000 farms had herds of that size, and they accounted for 55 percent of U.S. inventory." *Id.* at 11.

65 However, the total number of farms with at least 2,000 cows doubled between the 1997 and 2002 censuses, and then nearly doubled again between the 2002 and 2012 censuses, with continuing increases since. The frontier—the size of a dairy farm that we would call "large"—keeps expanding." *Id.*

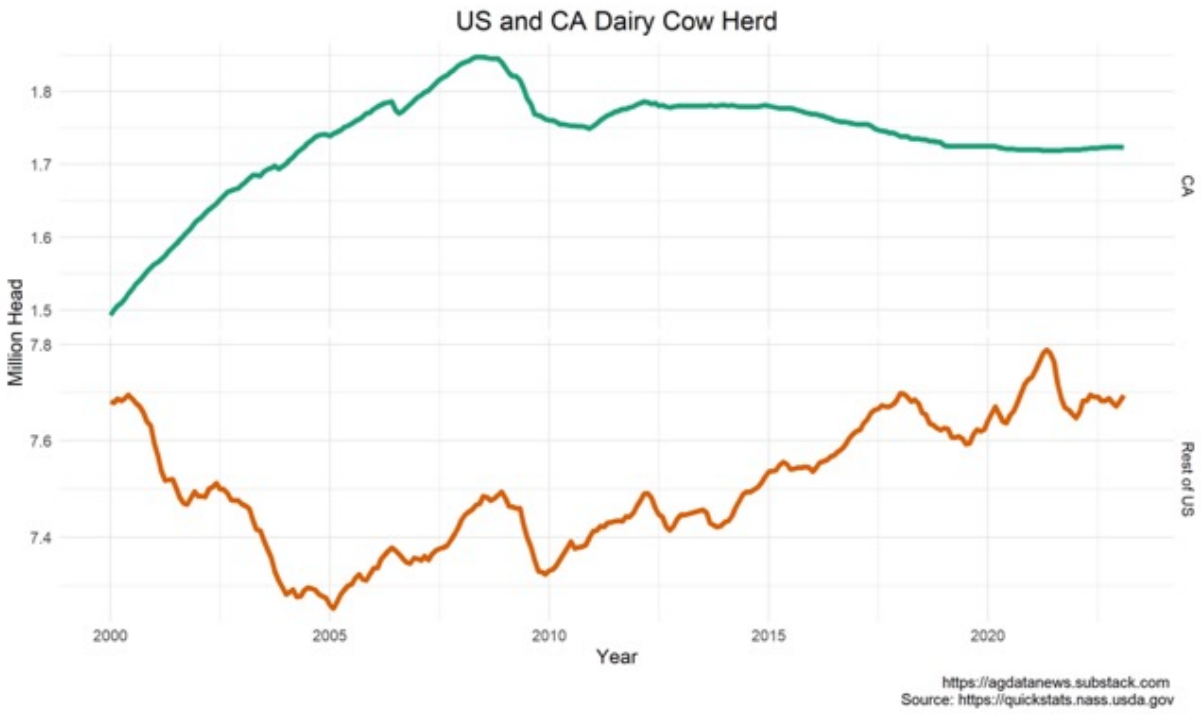

FIGURE 4 Via Aaron David Smith, Are Manure Subsidies Causing Farmers to Milk More Cows? (April 7, 2023), available at https://asmith.ucdavis.edu/news/are-digesters

The California dairy industry began consolidating before other major dairying states like Wisconsin and New York, generating pressure for other states to consolidate in order to compete with California's new mega-dairies. California surpassed Wisconsin as the top producer of milk nationally in 1993 and has held that position ever since.[70]

California led the way nationally in consolidating and industrializing the industry[71] for several reasons. The University of California provided essential research (as respective land grant universities did in other states); the intense urbanization pressures around Los Angeles County resulted in several cycles of "urban encroachment, farm relocation, and herd expansion" throughout the mid-century; and California's unique geography "created ideal conditions for growth, despite several setbacks related to land prices, water availability, and the relatively late start for the industry."[72]

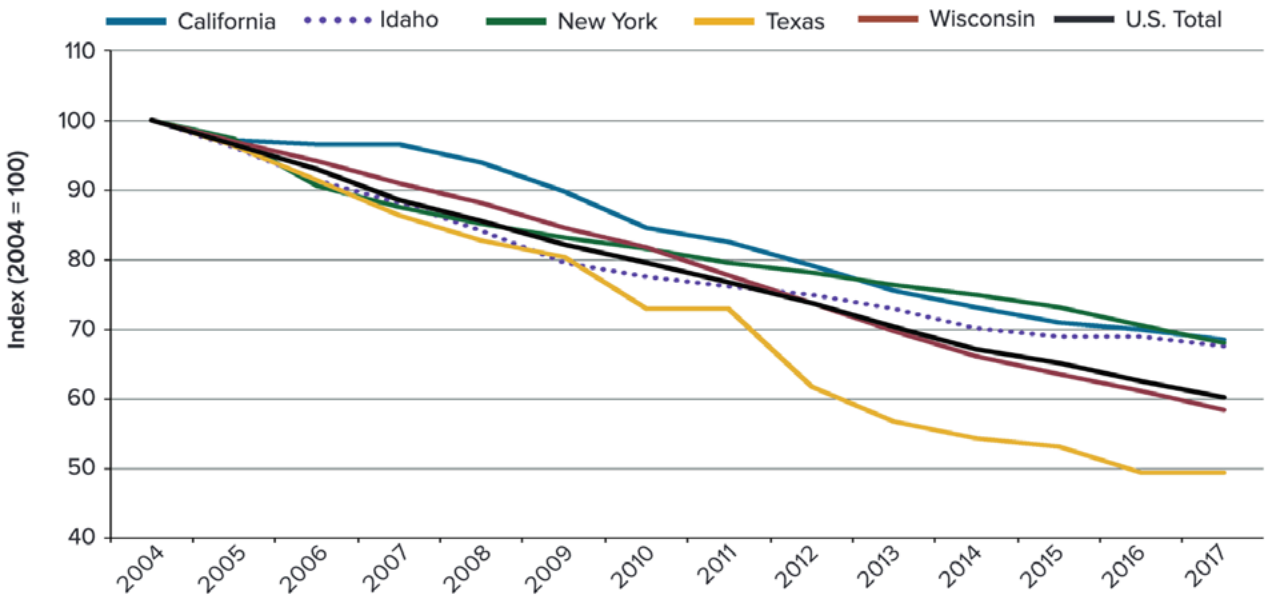
The industrialization of California dairies was facilitated by University of California research into "breeding and genetic experimentation to increase the productivity of cows and milkfat content of the milk and the development of dairy-farm building plans that were structurally appropriate

70 Sophie Barrowman, *Transformations in California's Dairy Industry: Mapping Regional Variations in Milk Production and Operations,* Master of Arts Thesis, University of Cal. Davis Geo. Dep't, https://escholarship.org/uc/item/4tx1m87s (citing Sumner 2020).

71 In California, dairies are concentrated in the San Joaquin Valley, in particular in Tulare and Merced counties. The dairies in this region are "almost all confinement-style dairies." There are also some remaining dairies in western San Bernadino and Riverside Counties, but these areas have seen significant decline due to urbanization. North of San Francisco, in Marin, Sonoma, and Humboldt Counties, there is a small cohort of smaller-scale pasture-based and organic dairies. Daniel A. Sumner, California Agriculture: Dimensions and Issues, Chapter 6: California Dairy: Resilience in a Challenging Environment, 143, https://s.giannini.ucop.edu/uploads/pub/2021/01/21/chapter_6_dairy_2020.pdf.

72 Sophie Barrowman, *Transformations in California's Dairy Industry: Mapping Regional Variations in Milk Production and Operations,* Master of Arts Thesis, University of Cal. Davis Geo. Dep't, (citing Butler andWolf 2000). *See also* James Sterngold, *Urban Sprawl Benefits Dairies in California*, New York Times (Oct. 22, 1999), https://www.nytimes.com/1999/10/22/us/urban-sprawl-benefits-dairies-in-california.html. Other contributing factors included: "the geographic isolation of the state requiring sufficient in-state processing facilities; the large and diverse population creating demand and labor for the industry; and the early adoption, or rather invention, of dairy science technology." *Id.*

for California's warmer climate."[73] The combination of advances in breeding, the pressures of urbanization, and the introduction of drylot feeding by Dutch immigrants pushed industrialization forward, beginning with Los Angeles County.[74] While urban encroachment in the broader Los Angeles area pushed farms out of the region, farmers were often able to sell land at high prices to developers giving them the capital needed to build out newer, larger facilities, often in the Central Valley.



Drylot feeding (also known as zero-grazing) is the "practice of concentrating cows into a small acreage and bringing their food to them." This practice was "revolutionary" for the dairy industry in California.[75] It was well-suited to California and particularly to the Central Valley, because "the abundance of local agricultural by-products like sugar beets and citrus and the availability of cheap hay made drylot feeding affordable, actually increasing milk production per cow compared to grazing."[76] The abundance of agricultural by-products remains a major benefit to California's dairy industry today.

California's climate also contributed to the unprecedented growth of the state's dairy industry. A UC Davis marketing memo from 1984 aimed at changing eastern and midwestern dairies' perception of California dairies as "heartless corporate farms," explained that the climate also facilitated regular expansion: "Due to the ideal climate, cows do not need the elaborate shelter that is required in other parts of the U.S. That means that when times are good, California dairy farmers add cows. In contrast, dairy farmers in other areas of the U.S. must add facilities before they can add cows."[77] Traditional dairying states like New York and Wisconsin experience weather variation throughout the year that requires modifying their practices, including but not limited to housing.

The California dairy industry only benefitted from the loss of small farms in the Midwest and East, however, until other states, particularly other western states, adopted the scale and industry structure that had given California dairies a competitive edge. In 2004, California dairies had the largest herd size in the country. Since then (through 2017, at least, the most recent year for which we have consistent USDA data) other major dairying states have increased herd sizes dramatically to compete, or as Sumner asserts simply: "dairy industries in other states have become more like those in California."[78]

2. *Drivers of consolidation include declining domestic demand, dismantling of supply management policies, trade policies that promote exports, and economies of scale.*

Major drivers of consolidation include declining domestic demand, changes to federal programs and subsidies, and economies of scale. Analyses of consolidation often point vaguely to "economic forces,"[79] but these economic forces have been constructed by policy choices. A Food and Power piece characterizes the problem like this:

> *Dairy farmers, particularly in the U.S. and Europe, are stuck in a cycle of consolidation and overproduction. Fewer, more powerful buyers, paired with declining domestic demand and dismantled supply management policies, have pushed the prices paid to farmers below their cost of production. In response, farmers seek to lower their costs per gallon and survive on high volumes. But as more farms seek a larger scale, milk production continues to increase, perpetuating oversupply, low milk prices, and a reliance on export markets.*[80]

The 2020 USDA report described "powerful cost incentives behind farm consolidation." Due to economies of scale, "larger farms are more likely to realize positive net financial returns to milk production..."[81] But economies of scale apply to most agricultural operations and the pace

79 See *e.g.* Ermias Kebreab, Frank Mitloenher, and Daniel A. Sumner, *Meeting the Call: How California is Pioneering a Pathway to Significant Dairy Sector Methane Reduction*, UCDavis CLEAR Center (December 2022), https://clear.ucdavis.edu/sites/g/files/dgvnsk7876/files/inline-files/Meeting-the-Call-California-Pathway-to-Methane-Reduction_0.pdf.

81 For more on economies of scale, *see* James Macdonald, *Scale Economies Provide Advantages to Large Dairy Farms* (August 3, 2020), U.S.D.A. Econ. Res. Service, https://www.ers.usda.gov/amber-waves/2020/august/scale-economies-provide-advantages-to-large-dairy-farms/.

of dairy consolidation "far exceeds the pace of consolidation seen in most of U.S. agriculture."[82]

One of the major developments that exacerbated the trend towards consolidation was the embrace of export markets in the early 2000s. Historically,[83] the American dairy industry was focused on the domestic market.[84] Around the turn of the 21st century this began to change. A 2016 USDA report on the dairy export[85] market explains: "From 2004 to 2014, the value of U.S. dairy product exports more than quadrupled."[86] This was a "significant change for an industry previously focused primarily on domestic rather than international demand."[87]

According to the 2016 USDA report, exports increased due to increasing incomes in developing countries ("demand"), free trade agreements opening up new markets (the North American Free Trade Agreement in particular), market-based reforms in China, and finally, a reduction of "domestic support and export subsidies for dairy products in recent years, bringing about greater openness of world markets."[88]

At the domestic level, major changes came to longstanding price supports for dairy, which had long set floors on dairy prices. According to the 2016 USDA report: "The Milk Price Support Program (MPSP) was established by the Agricultural Act of 1949 and was amended several times over the years. Through the program, the Federal Government purchased dairy products in order to support milk prices at specified levels."[89] The purpose of the program (ultimately repealed in the 2014 Farm Act) was to correct for an oversupply of dairy that made it impossible for dairy farmers to adequately support themselves.

Removing the price supports that made smaller-scale dairying possible was necessary to embrace export markets but created incentives for consolidation. Today, American dairies "must compete aggressively for a share of consumer food budgets and for resources and investment capital," not just in the United States but globally.[90] The growth of the export market and broader globalization of the dairy industry has also "tended to emphasize the strength of multinational dairy firms."[91] At the level of the individual dairy operation, industrial-scale facilities are better able to operate in this landscape and contend with the greater and demand price volatility.

At the international level, the Uruguay Round of the General Agreement on Tariffs and Trade concluded in 1994 "with an agreement that fundamentally changed the treatment of national agricultural policies under the multilateral rules of global trade."[92] The Uruguay Round Agreement on Agriculture[93] brought national agricultural policies under the purview of the newly formed World Trade Organization, such that "trade-distorting policies" could be disciplined or constrained.[94]

82 *Id.*

83 Protectionism in agriculture has often been framed as a national security concern (or more recently as food sovereignty). These concerns remain very live today. See, e.g. Dr. Krista Versteeg, *It's Time to Talk about Food and Agricultural Security* (March 21, 2023), U.S. Dep't Homeland Sec. Science and Tech., https://www.dhs.gov/science-and-technology/news/2023/03/21/its-time-talk-about-food-and-agriculture-security.

84 Jess Cessna, Lindsay Kuberka, Christopher G. Davis, and Roger Hoskin, *Growth of U.S. Dairy Exports*, U.S.D.A. Econ. Res. Service (November 2016), https://www.govinfo.gov/content/pkg/GOVPUB-A93-PURL-gpo75564/pdf/GOVPUB-A93-PURL-gpo75564.pdf.

85 Note that dairy exports are typically dry milk or milk powder, which is "traded internationally at higher volumes than liquid milk products, since liquid products are bulky and often perishable, making them costly to ship and store." Powdered milks are often reconstituted in low-income countries, but are also common products in other dairy products and can be used as animal feed. Other dairy products traded internationally include cheese, infant formula, butter or butterfat products, whey products, casein products, and lactose. *Id.*

Implementation was phased in over a 6-year period that concluded in 2000 – 2001, just as U.S. dairy exports began dramatically increasing.

The growth of the U.S. dairy export market has not only accelerated consolidation but resulted in "greater variability in demand and prices."[95] California's dairy industry exports "about a third of all U.S. dairy exports, about twice its share of national production," making it particularly susceptible to the pressures of the global market, as will be discussed in more detail in the leakage section.[96]

B. Data that can be used to analyze the impact of the LCFS will become available in 2024.

The USDA consolidation report uses the most recent agriculture census data from 2017, but the LCFS adopted the inclusion of fuels from dairy and swine manure in 2017.[97] The use of fuels from dairy and swine manure in California appears to have taken off in earnest in 2018,[98] and therefore the impacts on the industry as a whole are not likely to be observable in the 2017 agriculture census data. (UC Davis agro-economist Aaron David Smith notes, "Data from the 2022 census will enable us to see whether the number of cattle on large farms has increased during the digester boom, but it will not be released until next year.")[99] USDA recently announced that the 2022 Agriculture Census will be released on February 13, 2024.[100]

C. Key Takeaways: Consolidation and LCFS Credits

- **The data required to analyze the impact of the LCFS on dairy consolidation will not be available until February 13, 2024.** The most recent Agriculture Census year is 2017, which is too early to show the effects of LCFS credits on California dairy. Any impact from the LCFS would likely be small, but dairy operations operate on slim margins so even a small shift in incentives could accelerate the pre-existing trend.

- **Dairy consolidation is a long-term trend driven by policy choices.** Small and mid-sized dairies in the Midwest and the East declined dramatically over past decades, as mega-dairies concentrated in the West, and particularly in California, have ballooned. There are many causes of consolidation including the dismantling of supply side management programs and the opening of export markets, which multiplied economies of scale.

- **There is a symbiotic relationship between industrialization, consolidation, and the push for dairy digesters.** Consolidation has resulted in fewer, ever-larger dairy operations. The larger operations become, the more manure they must manage and the more likely they are to rely on a manure lagoon. Dairy consolidation has set the stage for the digester push as the California dairy industry has become dominated by industrial-scale operations with manure lagoons.

- **Investing in industrial dairies further bolsters the competitive edge of these mega-operations at the expense of more sustainable dairying models and burdens environmental justice communities.** Smaller-scale dairies and pasture-based dairies have been fighting to preserve their competitive edge, but the LCFS provides credits that are generally only available to the largest dairies. Industrial dairying also contributes to and exacerbates ongoing environmental justice harms (the EPA states: "The San Joaquin Valley has some of the nation's worst air quality, fail-

ing to meet federal health standards for both ozone (smog) and particulate pollution").[101] And because industrial dairying has been historically prevalent in California, California environmental justice communities in the Central Valley have long experienced these harms.

V. Emissions Leakage Risk

Industry stakeholders assert that regulating methane from dairies[102] will push dairies out of business or out of state, exacerbating overall GHG emissions.[103] The movement of an industry and its emissions to another jurisdiction in order to avoid regulatory costs is called emissions leakage, and could present legal concerns.

AB 32 (2006) requires CARB to "minimize leakage to the extent feasible" in regulations promulgated under Parts IV and V of the Global Warming Solutions Act of 2006.[104] This includes the LCFS, promulgated under Part IV as an early action measure. The statute defines leakage as "a reduction in emissions of greenhouse gases within the state that is offset by an increase in emissions of greenhouse gases outside the state."[105] SB 1383 (2016) also requires CARB to "minimize and mitigate leakage to other states or countries as appropriate" in any potential regulation of dairy methane.[106]

The claim that regulating dairy methane will result in leakage has two parts that demand scrutiny. The first is the predictive assertion that if regulation is implemented, facilities will a) not be able to bear the costs of doing business and b) will be adequately mobile to move. The second is the premise that California leads the nation in "climate-smart dairy farming." If California dairies generate more emissions than dairies in other states,[107] outmigration of dairies won't necessarily result in equivalent or increased overall GHG emissions.

Additional political concerns are sometimes wrapped into the legal leakage claims. Generally, these arguments slip other value-laden claims about the loss of California dairy operations into the discussion, including the loss of jobs, the economic and cultural loss of the dairy industry, and sometimes implications that industry moving out-of-state will result in greater environmental degradation beyond GHG emissions. These important points bear discussion, but they are distinct from the legal emissions leakage argument.

The argument that methane regulation could lead to emissions leakage holds water if:

a) Other states are a more appealing place to operate than California;
b) The industry is adequately mobile to move;
c) The move would result in equivalent or a net increase in emissions.[108]

Legally, regulators are not required to prevent leakage altogether. They are required to "minimize" leakage in the context of the LCFS and to "minimize and mitigate" leakage in the context

101 U.S. Env't Prot. Agency, EPA Activities for Cleaner Air, https://www.epa.gov/sanjoaquinvalley/epa-activities-cleaner-air.
102 Excluding dairies from the LCFS should not result in inter-state leakage, because out-of-state dairies are currently eligible for LCFS credits. That is: there is no existing benefit to California dairies that CARB could remove at their expense relative to out-of-state operations. The claim the adoption of new regulations will result in leakage, however, deserves more attention.
103 A Dairy Cares comment letter, for example, argued: *"The analysis also shows that misguided efforts to change course by forced conversion to pasture-based operations, direct regulation of dairy farms, or limitations on dairy digester incentives will not only fail to achieve the desired greenhouse gas emission reductions but will exacerbate the problem by causing significant emissions "leakage". As demand for dairy products continues to increase across the U.S. and world, the dairy industry is likely to respond to costly direct regulation by leaving for states with less costly regulations and less commitment to climate protection."* The Dairy Cares website, for example, asserts: "California leads the nation in climate-smart dairy farming, and cows leaving results in a "leakage" of methane emissions."
104 Cal. Health & Safety Code § 38562 (b)(8).
105 Cal. Health & Safety Code § 38562 (b)(8).
106 Cal. Health & Safety Code § 39730.7.
107 I use climate-friendly, rather than climate-smart to convey an industry generating fewer GHG emissions. Climate smart is a term favored by industry that doesn't require overall emissions to decrease but simply for the industry to employ "smart" technologies. As such, it does the work of defining success on the industry's terms while conveying a more general sense of climate-friendly practices.
108 The leakage argument typically focuses exclusively on GHG emissions, but a consideration of other forms of pollution is appropriate as well.

of new dairy methane regulations pursuant to SB 1383. This discussion surveys research on leakage risk generally before evaluating each of the three criteria above and offering a final analysis of the risk of legal leakage if methane regulations are enacted or LCFS credits are diminished.

A. Leakage Risk Generally

Emissions leakage describes the movement of industry, and by extension that industry's emissions, out of one jurisdiction and into another in response to emissions regulation.[109] Leakage is a greater risk in industries that are "trade-exposed"[110] and in industries that are mobile. Trade-exposed industries are competing on the slim margins of global market and, if they are mobile, able to relocate with relative ease.

There is very little evidence that leakage in response to emissions regulation is common in practice.[111] Despite significant theoretical backing for leakage, research has consistently found virtually no evidence of emissions leakage.[112] A CARB-commissioned analysis from 2016 found that most early empirical studies on the trade effects of pollution control regulations established "no relationship, or a counter-intuitive positive relationship, between energy costs and net imports."[113] One "more sophisticated" study determined that "for most industries, environmental compliance costs have been too small to affect trade flows in an economically significant way."[114] One explanation for the low rates of leakage is the effective use of various policy tools to mitigate leakage risk.[115] These tools will be discussed further below in the legal analysis section.

The concept of leakage rests on an idealized notion of a frictionless global market. In practice, uprooting industries comes with its own costs and global markets have not operated as seamlessly as in economics textbooks. Research has found that risk of leakage is linked to the measure of industry's mobility. The Fowlie et al. study cited above found that while more mobile industries are indeed susceptible to leakage, "pollution intensity is positively correlated with [industry's] measures of immobility."[116] That is: more mobile industries are susceptible to leakage but the most polluting industries tend to be the most immobile.

Additionally, while regulation can result in a decline of in-state industry, typically only a portion of the decline in in-state production ends up migrating out-of-state.[117] A different CARB analysis on leakage risk from several food sectors, including cheese processing, found that a $20 million carbon compliance cost in California

109 Meredith L. Fowlie, Mar Reguant, and Stephen P. Ryan, *Measuring Leakage Risk* (May 2016), https://ww2.arb.ca.gov/sites/default/files/cap-and-trade/meetings/20160518/ucb-intl-leakage.pdf. A 2016 CARB-commissioned analysis on mitigating leakage characterizes the basic concern as follows: "An increase in relative operating costs can, in turn, adversely impact the ability of regulated firms to compete in a global market. If this shifts production outside the regulated jurisdiction, any associated increase in emissions can undermine the effectiveness of regional policies."

110 RFF uses the term "trade-exposed industry" and one RFF reports notes that highly emitting industries and industries highly exposed to international competition are particularly prone to leakage. 116 *Id.*

117 Meredith L. Fowlie, Mar Reguant, and Stephen P. Ryan, *Measuring Leakage Risk* (May 2016), *supra* note 109 (about 1/6th of production decline moves out of state).

would lead to production decrease of .05% of the California cheese supply or 525.07 metric tons. That study further concluded that for cheese, 57% of that .05% California decrease would move out of state, resulting in a production leakage of 301.83 metric tons.[118] (Note that cheese processing is distinct from dairying, so these numbers, while instructive generally, are not directly on point for our purposes.)[119]

The food processing leakage study explained that emissions leakage can be determined from these production leakage numbers by "adjusting the market transfer effect for the relative emissions-intensity of the plants acquiring and losing market."[120] The authors refrained from making concrete predictions for cheese processing emissions leakage, instead citing variability in practices. They did, however, suggest that California food processing relies more on natural gas while other states rely more on coal, so some emissions leakage would likely occur in that sector.[121]

Overall, the research on emissions leakage suggests that the risk of major production leakage—of entire industries moving out of state—is low. Instead, depending on the costs of newly imposed regulation, the more likely outcome is a small decline in California production and some portion of that decline shifting out-of-state. Moving alone (production leakage), even because of emissions regulation, is not necessarily emissions leakage. Operations must move because of emissions regulation and must, in their new jurisdiction, emit as much or more methane as they had in California. In the context of dairy, the relevant comparison would be whether the practices of out-of-state dairies are more- or less-carbon intensive than in-state dairies.

It is impossible to predict what the costs of regulation and the attendant decline in California production might be, since no methane regulation for dairy has been proposed by CARB. In terms of LCFS credits, it is extremely unlikely that change to LCFS crediting would result in emissions leakage. Emissions leakage is causal[122] and depends on regulatory asymmetries, but LCFS credits are available to dairy operations nationally. This means a change in LCFS crediting would not result in the kind of regulatory asymmetries that cause leakage.

B. Relative Mobility of California Dairies

One study defines mobility as "an inherent characteristic of industry, which is closely related to the industry's own production and technical attributes, and reflects the ability of the industry to transfer flexibly among regions."[123] Measures of industry mobility appear to be relatively less studied than regulatory impacts on competitiveness, but one CARB-commissioned analysis used capital intensity as a proxy for immobility.[124] A study of Chinese industry mobility further identified several key measures of mobility including sunk costs, asset specificity, and difficulty of labor

118 Dr. Stephen F. Hamilton, Dr. Ethan Ligon, Dr. Aric Shafran, and Dr. Sofia Villas-Boas, *Production and Emissions Leakage from California's Cap-and-Trade Program in Food Processing Industries: Case Study of Tomato, Sugar, Wet Corn and Cheese Markets* (May 9, 2016), https://ww2.arb.ca.gov/sites/default/files/cap-and-trade/meetings/20160518/calpoly-food-process-leakage.pdf.

119 The CARB analysis was conducted for food processing sectors, rather than agriculture, because food processing is covered by cap-and-trade. CARB has pioneered efforts to reduce leakage in its cap-and-trade program.

120 Dr. Stephen F. Hamilton, Dr. Ethan Ligon, Dr. Aric Shafran, and Dr. Sofia Villas-Boas, *Production and Emissions Leakage from California's Cap-and-Trade Program in Food Processing Industries: Case Study of Tomato, Sugar, Wet Corn and Cheese Markets* at 43.

121 In the cheese processing plant study, the authors looked at general food processing statistics and assumed that, "[f]or the case of California food processors, the typical plant operates on natural gas; however, global food processing plants including those in other U.S. states rely on other sources such as coal and fuel oil." As a result, the authors suggested generally that food processing outmigration would result in increased net emissions, though they qualified that with the need for more specific data. *Production and Emissions Leakage from California's Cap-and-Trade Program in Food Processing Industries: Case Study of Tomato, Sugar, Wet Corn and Cheese Markets* at 43.

122 *Commentary: What is Carbon Leakage? Clarifying Misconception for a Better Mitigation Effort*, *supra* note 115.

Cleaner Prod. 105 (April 20, 2019), https://www.sciencedirect.com/science/article/pii/S0959652619301647?casa_token=w8DPvD0fDUEAAAAA:fCh8su48J0KAzSBZXru34w404UX2TyDro5xOoaHLJ6SiVTjZABtruzpOAZ4Afn1xYu6ftyhdXw#bib41 (citing Stem 2007).

124 Fowlie et al., *Measuring Leakage Risk*, *supra* note 109 ("Capital intensity serves as a proxy for immobility; highly capital-intensive firms tend to be harder to relocate.")

force transfer.[125] The same study found generally that more mobile industries are more likely move in response to regulation, while less mobile industries are more likely to innovate.

Industrial-scale confinement dairies are highly capital intensive (and intensification of capital, land, and animals is one of the major trends in dairying in recent decades).[126] Barns and lagoons require significant, long-term investments that become sunk costs. The addition of digesters makes these operations even more capital intensive and less likely to move. Livestock itself is mobile, but like other highly polluting industries, industrial dairies cannot simply pick up and move anywhere. They are limited to areas that are zoned for agriculture and where the addition of thousands of cows and their waste will not be challenged by local communities. Industrial-scale facilities relying on export markets must consider proximity to processing facilities and/or to ports, as well as attendant freight costs. Labor force transfer could impose additional challenges. The National Milk Producers Federation states "[e]ven as technology become a greater park of agriculture, much of dairy farming remains labor-intensive."[127] The dairy labor supply is currently tight. The industry is facing labor shortages "with no foreseeable end in sight."[128]

C. Relative Appeal of Other States

The likelihood of production leakage depends on whether other states' practices and environments—regulatory and otherwise—make them more appealing than California. There is a lot of talk about how challenging the landscape is for California dairies[129]; however, the dairy industry in California is doing relatively well compared to other states. California has remained the top milk producer in the country since 1993.[130] California houses one in five of the nation's cows and produces one fifth of the milk produced in the United States.[131] Dairy farming is the leading agricultural commodity in California, generating $7.57 billion cash receipts from milk (in 2021) and handily sells more milk than any other state.[132] The export value of California dairy was $2.5 billion dollars in 2021.[133] In the most recent agriculture census, Tulare County alone had $1.8 billion in milk sales—5% of milk sales nationally—and four out of five of the top counties for milk sales were in California.[134] None of these statistics suggest a baseline environment that is significantly worse for dairy operators in California than in other states.

There has been a slight decline in California production and cow inventories from 2007-2017

134 U.S. Dep't of Ag., *2017 Ag. Census Highlights: Dairy Cattle and Milk Production*, https://www.nass.usda.gov/Publications/Highlights/2019/2017Census_DairyCattle_and_Milk_Production.pdf.

(the year of the most recent USDA agriculture census), with production and inventory "rising noticeably in Idaho and in the Plains States of Texas, Kansas, and South Dakota."[135] Attrition of California dairy herds and gains in nearby states suggest that California is losing some of the comparative advantage it possessed for the past few decades, but does not validate claims[136] that such migration would be prompted by emissions regulation. Migration is already occurring with no emissions regulations on the books. The fact that the industry is already migrating suggests that hypothetical future emissions regulations would not be the sole cause of such migration, diminishing the case for leakage. There may be broader concerns about the environmental impacts of dairies moving out of state, but these concerns are distinct from the legal concern around emissions leakage.

Some of the commonly identified issues for California dairies include environmental regulation, drought, milk prices, fluctuating demand for dry milk (one of California's major exports),[137] and labor shortages.[138] A 2010 survey found that the top three concerns for both California and Wisconsin dairy operators were: environmental regulations, volatile milk prices, and high prices of inputs.[139] The remainder of this section will briefly survey these concerns.

1. Environmental Quality Regulation

Environmental regulations unrelated to GHG emissions will not influence whether an out-of-state move will result in GHG emissions leakage, but they can impact how appealing that initial move is. California's regulation of air and water quality are comparable to other agricultural states.

Like all states, California is subject to the federal Clean Water Act. At the federal level, the Clean Water Act does not require discharge permits (under the National Pollution Discharge Elimination System (NPDES) program) as a matter of course for agricultural operations.[140] Instead, permits are only federally required where operations are shown to have discharged. It can take extensive documentation of violations of the Clean Water Act and can entail multiple enforcement actions before a NPDES permit is required.

NPDES permitting authority is generally delegated to states. In California, NDPES permits are issued by Regional Water Control Boards. Accord-

135 A Dairy Cares comment letter on LCFS virtual community meetings states, "The regulatory burdens and resulting high cost of doing business in California and resulting economics of dairy production in a national market are driving consolidation, not the presence of LCFS incentives." Michael Boccadero, *Dairy Cares Comments on LCFS Virtual Community Meetings*, *available at* https://ww2.arb.ca.gov/approved-comments?entity_id=28876.

136 A UC Davis report, for example, asserts that "Ongoing attrition and consolidation in the state's dairy sector is evidence of leakage risk." While attrition is an indication of the general health of the industry, that is unrelated to the causal analysis of emissions leakage, which asks whether emissions regulations specifically have shifted or increased net emissions. Ermias Kebreab, Frank Mitloehner, and Daniel A. Sumner, *Meeting the Call: How California is Pioneering a Pathway to Significant Dairy Methane Reduction*, UC Davis CLEAR Center (Dec. 2022), https://clear.ucdavis.edu/sites/g/files/dgvnsk7876/files/inline-files/Meeting-the-Call-California-Pathway-to-Methane-Reduction_0.pdf.

140 In the early decades of the Clean Water Act, agricultural activities were deemed nonpoint sources. In the early 2000s, CAFOs of a certain size were designated as point sources and therefore were required to seek permits. Prompt litigation brought by the pork industry, however, resulted in a rebuttable presumption that CAFOs do not discharge and are therefore not federally required to obtain National Pollutant Discharge Elimination System (NPDES) permits (though states can still require them). In 2022, a large group of advocates petitioned EPA to rescind the rebuttable presumption that CAFOs do not discharge but EPA did not act on the petition. *Earthjustice Petition to U.S. EPA to Adopt a Rebuttable Presumption that Large CAFOs Using Wet Manure Management Systems Actually Discharge Pollutants Under the Clean Water Act* (October 2022s), *available at* https://earthjustice.org/wp-content/uploads/cafopresumptionpetitionfinal_oct2022.pdf.

ingly, much of the important water quality regulation occurs at the regional level.[141] Today, Central Valley Regional Water Control Board Order No. R5-2013-0122 applies to most dairies.[142] Order No. R5-2013-0122 requires existing dairies to enroll (unless they are not eligible because they have recently expanded). Dairies must submit waste and nutrient management plans and participate in groundwater monitoring to ensure they are in compliance.[143] Since the general order, new and expanding dairies in the region have been issued individual permits.[144] California's Porter-Cologne Water Quality Control Act also requires operations that discharge waste that could impact the quality of state waters to be permitted. (In 2022, only about 7% of California's 1,083 CAFOs were required to have NDPES permits; the rest were permitted under state general orders.)

The Central Valley's water quality permitting is not particularly onerous relative to permitting regimes in other agricultural states. In some respects, it is more lax, particularly given the concentration of CAFOs spreading waste in the Central Valley. For example, Order No. R5-2013-0122 allows dairy operations to apply potassium and phosphorus in excess of agronomic rates unless application causes "adverse impacts," at which point operations are to stop application.[145] This is a weaker standard than under federal regulations and in other states.[146] The Order generally does not require operations to submit their waste management plans to the permitting agency for review; nor are operations required to make their nutrient waste management plans available for public review.[147] By contrast, both Idaho and Texas require nutrient management plans to be approved by a regulating agency and South Dakota requires nutrient management plans to be made available for public review.[148] Industry complaints about water quality permitting are not unique to dairies in California. They are ubiquitous in many western dairying states.[149]

Air emissions like ammonia, volatile organic compounds (VOCs), and particulate matter from

dairies are a major concern generally and even more so in the Central Valley.[150] The state regulatory regime for air pollution is entwined with California's State Implementation Plans (SIPs), which are required to remedy the San Joaquin Valley's decades-long nonattainment of federal air quality standards under the Clean Air Act.

In 2003, SB 700 was passed to resolve a conflict between California and federal law. One of the changes the law made was to remove an air permitting exemption for agricultural operations. California now treats large dairy operations like other large sources of air pollutants and makes these farms subject to air district permits if emissions exceed half of a major source threshold.[151] In practice, 96% of dairies in the San Joaquin Valley obtain air permits.[152] The regulation of CAFOs as stationary sources is distinctive and a response to the San Joaquin Valley's severe air quality issues and the dairy industry's role in generating emissions. At least some research suggests that "air quality regulations have not raised farm costs significantly" for California dairies.[153]

California does not currently regulate GHG emissions from dairies, though CARB has the authority to do so as of January 2024. Industry stakeholders and even reporters often describe SB 1383 as imposing a regulatory burden on dairies.[154] But SB 1383 imposes no affirmative obligations on dairies currently. Instead, the law sets industry-wide targets and mandates that *CARB* implement a strategy to meet those targets.[155] Still, the potential for future methane regulations on dairies is viewed as a negative and statewide methane regulations on dairies are undoubtedly less likely to be promulgated in some other major western dairying states than in California.

2. Drought

Drought and overall lack of water resources in California presents serious challenges to the state's dairy industry.[156] Adequate water is important to irrigate feed crops (alfalfa is very water intensive) and to manage the flush systems many California dairies rely on. The lack of water is also a problem for manure spreading at agronomic rates—if there's no water to grow crops, there is no crop to uptake the nutrients and spreading could result in groundwater contamination. Geoff Vanden Heuvel of the California Milk Producer Council observes: "Because the predominant method of manure disposal or utilization as it was, was fertilizer on crops, which if the water supply becomes limited to grow those crops, then that creates a problem."[157]

157 *California Water Crisis Challenges Dairy, Vanden Heuvel Says*, Nat'l Milk Prod. Federal Dairy Defined Podcast (Sept. 12, 2022), https://www.nmpf.org/california-water-crisis-challenges-dairy-vanden-heuvel-says/.

While drought and inadequate water is first and foremast a climactic problem, California's system of water use is often viewed as another source of burdensome regulation by dairy operators.[158] State regulators have to step in in order to manage the water supply and protect the state's water resources. Overdrawn basins have had to submit implementation plans under the Sustainable Groundwater Management Act of 2014.[159] Combined with drought years, this has put increasing pressure on dairies, particularly in the southern San Joaquin Valley.[160]

At least one state (Iowa) touted its "abundant water" at California's dairy expo in an attempt to entice dairy operators to move.[161] But drought and water resources issues generally are also major concerns in many of the western dairying states where California dairy operations might be likely to move.[162]

3. *Milk Prices*

Milk prices are an essential part of what makes a given state more or less appealing to dairy operations. About 75% of U.S. milk production is covered the Federal Milk Marketing order (FMMO).[163] The FMMO applies to and establishes minimum uniform prices for the exchange of milk from dairy operations to dairy processers within specific areas.[164] There are 11 different FMMO regions in the United States. Historically, California set its prices in a separate but similar program,[165] but joined the FMMO in 2018.[166] California comprises its own region in the FMMO. At least some dairy operators seem to think the FMMO has improved California milk prices relative to the old system.[167] There has also been pushback to the new system.[168]

Under both systems, California's milk prices have been relatively low. Daniel Sumner asserts that California's relatively low milk prices stem from its role as a net exporter and the cost pressure on milk processers here. He cautiously predicts that, because these specific pressures are unlikely to change in the near future, "a return to rapid growth of California milk production seems unlikely. However, the inherent strengths of the California dairy industry remain. Therefore, it also seems unlikely that significant aggregate declines in California milk production are on the horizon."

158 *Id.* ("It's a combination of droughts, but also what we call manmade drought.")

159 *Id.* ("And then those agencies in critically overdrafted basins, which is most of the Central Valley, had a requirement that by January 31 of 2020, they had to submit a plan that would show how that area was going to become sustainable by the year 2040.")

160 *Id.* "And in the Southern San Joaquin Valley, south of Fresno is just naturally drier than the northern part of the Central Valley. And so it's facing kind of the crunch quicker than maybe other areas, but we have a lot of dairy in the Southern San Joaquin Valley."

4. *Demand, Trade Exposure, and California's Comparative Advantage*

California carved out its place in the national market by pioneering industrial drylot dairies, but newer dairying states in the West and some older dairying states in the Midwest, like Wisconsin, have now adopted the California model, eroding California's competitive advantage. Traditional dairying states have followed the pattern of consolidation and increased herd sizes to an extent since the early 2000s; however, they've also made greater progress in milk yields. One analysis suggests that traditional dairying states may have focused gains on milk yields rather than increases in herd sizes to the extent of modern states, like California, because of a more stringent regulatory environment:

> *The fact that milk yield in traditional states grew more rapidly after the introduction of genomic testing in dairy genetics suggests that genetics may have played a role in the observed yield increase. It is also possible that, due to zoning and environmental regulations, traditional dairy states are simply more limited in their ability to grow cow numbers. Having exhausted their ability to grow production through cow numbers, they are instead turning to improving yield. This mirrors a larger trend in US crop production where output growth is driven mostly through productivity gains rather than putting more acres into production.*[169]

The overall dairy herd size nationally also appears to be leveling off.[170] Demand for fluid milk is down among younger people[171] and the dairy industry saw a major change[172] in demand nationally and major price fluctuations[173] over the course of the COVID-19 pandemic. This included a "relative shift towards production of storable dairy products." This shift may have helped fuel the gradual move towards the center of the country. Milk production was historically concentrated on the coasts because the perishability of milk required the cows to be near market. This is changing as the dairy industry shifts away from fluid milk.[174]

California's role as a net exporter[175] also results in relatively greater trade exposure and

169 Jared Hutchins and Joe Janzen, *Production Trends in the US Dairy Sector*, FarmDocDaily (Oct. 30, 2023), https://farmdocdaily.illinois.edu/2023/10/production-trends-in-the-us-dairy-sector.html.

170 *Id.* ("In the past two years, cow numbers have begun to level off, perhaps reacting to uncertainty the ability and willingness of the supply chain to continue to accept the volume of milk that it does. It may also be that the total number of dairy cows in the country is reaching a long-run, stable level. This is especially the case if zoning and environmental regulation prevent modern dairy states from expanding cow numbers as they have in the past two decades. If growth in the US dairy herd does level off, we may even see modern dairy states follow the lead of the traditional states and drive growth through yield improvement rather than more cows.")

173 The large fluctuations in the cheese and all-milk prices seen in Figures 4 and 5 underlie the broader effect of the COVID-19 pandemic on dairy prices. Daniel A. Sumner, Tristan M. Hanon, and Scott Somerville, *Effects of the COVID-19 Pandemic on the Western Dairy Industry,* Western Econ. Forum (June 2021), https://ageconsearch.umn.edu/record/311305/?ln=en.

174 *As California Farmers are Pressed, Dairy Cows Flee for Texas and Arizona,* The Bullvine (Sept. 21, 2022), https://www.thebullvine.com/news/as-california-farmers-are-pressed-dairy-cows-flee-for-texas-and-arizona/. ("According to Boccadoro, milk production has been moved to the Midwestern states as a result of a decline in the demand for fluid milk and a rise in the demand for cheese, yogurt, butter, whey protein, and other milk-related products. Since the pandemic started in 2020, demand for dairy products has grown by 2000%.")

175 This section has focused on inter-state rather than international outmigration. That said, it is notable that the United States is a net exporter of dairy. Int'l Dairy Foods Ass'n, The Importance of Trade for U.S. Dairy, https://www.idfa.org/trade. A UC Davis blog asserts: "While the rise in greenhouse gas emissions in developing countries is largely due to domestic growth, it's no secret that companies from wealthy countries set up factories in foreign countries to cut costs and avoid regulations, thus further contributing to global pollution." In the context of dairy, however, recent years have seen a surge in U.S. dairies catering specifically to the Chinese export market. Agricultural exports to China and the value of agricultural exports has increased every year since 2018, rather than vice versa. U.S. Dep't of Ag. Foreign Ag/Serv., Record U.S. FY 2022 Agriculture Exports to China (Jan. 6, 2023), https://fas.usda.gov/data/record-us-fy-2022-agricultural-exports-china; Amanda Lockwood, *Everything to Know Before Exporting to China*, Dairy Foods, https://www.dairyfoods.com/articles/96607-everything-to-know-before-exporting-to-china. China is the leading importer of nearly every major dairy product. Aidan Connolly, *China is Sneezing, Will it Give the U.S. Dairy Industry a Cold*, Dairy Herd Management (Nov. 29, 2023), https://www.dairyherd.com/news/business/china-sneezing-will-it-give-us-dairy-industry-cold. In recent years, western states have seen the growth of export-only factor dairies. Lynne Terry, *While Small Dairy Farms Shut Down, This Mega-Dairy is Shipping Milk to China*, Civil Easts (Nov. 27, 2018), https://civileats.com/2018/11/27/while-small-dairy-farms-shut-down-this-mega-dairy-is-shipping-milk-to-china/. Moreover, the U.S. dairy industry's major competitors in the Chinese market are the European Union and New Zealand, not developing countries. U.S. Dairy Export Council Staff, *Slow Whey Demand in China Holds Back U.S. Dairy Exports in July*, The U.S. Dairy Exporter Blog (Sept. 7, 2023), https://blog.usdec.org/usdairyexporter/slow-whey-demand-in-china-holds-back-us-dairy-exports-in-july-0. While new emissions regulations could (and probably would) influence these trends, the baseline situation is one in which the U.S. already is better situated to produce and export.

consistently lower prices than the national average.[176] Given this role, tariffs imposed on U.S. dairy products by Mexico and China during the Trump administration may have taken a disproportionate toll on California dairies.[177] As in the discussion of consolidation above, however, the data here is largely from the 2017 USDA Agriculture Census and so will not show the impacts of the LCFS. Additionally, Chinese demand has decreased in recent years, depressing global milk prices.[178] As a net-exporter, California has been particularly impacted as dry milk prices have fallen.[179]

There are also factors that cut against departure for California dairies. California's location on the West Coast and the Central Valley's proximity to urban markets have long been important to the industry. One analyst argued, "California has the second largest population in the country. You need to have milk close to the population, and because there's already infrastructure there, there will always be dairy in California."[180]

The California dairy industry is unlikely to find that other states can replicate the benefits of the Central Valley without any of the perceived challenges. One analyst suggested: "I think we'll continue to see consolidation in the dairy industry in California, the smaller herds are going to really have a tough time of it like they have for the last 10 or 15 years. I still think we'll see some producers migrate out, but it'll continue, I think to be a trickle. I'm not sure that it's going to accelerate significantly."[181]

D. Emissions Implications of Dairies Moving Out of State

Production leakage does not necessarily entail emissions leakage, the focus of the legal leakage concerns. Production leakage only results in emissions leakage where the state that hosts the influx of new dairy operations has a more highly emitting dairy industry and model. Emissions from different dairying models vary based on the regulatory regime, but also from the practices commonly employed, standard operation size, soil characteristics, and regional climate.[182]

Some stakeholders assume that California has a stricter regulatory regime for dairies in California and that California dairies emit fewer GHGs. But California currently does not regulate methane from dairies. Anaerobic digesters capture emissions, but they capture emissions from the high baseline generated by industrial-scale facilities.

There is little evidence that California's baseline model of dairying—confinement-based operations with liquid manure management—emits fewer GHGs than other models. On the contrary, confinement dairies with liquid manure

180 *Are California Farmers Leaving for Greener Pastures?* Dairy Herd Management (Dec. 23, 2022), https://www.dairyherd.com/news/business/top-10-stories-2022-are-california-farmers-really-leaving-greener-pastures.

181 *Id*. *See also* quote from Mike North in the same article ("Mike North of ever.ag says dairy farmers who are in a water deficit area may be forced to relocate, but he says there will always be dairy cows in California. However, consolidation is something he thinks will continue to happen in the state, largely due to the drought. "What's happening is the people that are water threatened may be looking to reduce their herd, but producers who aren't water threatened are buying their cattle and quotas. So, you won't see the number of dairy cattle in California dramatically drop," says North").

182 Rotz et al. ("No clear trends were found that indicated that a given management approach or farm size consistently provided lower environmental footprints. Often differences occurred due to differences in soil characteristics and climate, so a management approach that produces lower footprints for one environmental metric in one region may not function well for other metrics or locations. For example, NH3 and other manure emissions can be a concern for open lot dairies in the west with long-term manure storage, whereas nutrient runoff and water quality issues are often the greater concern for eastern farms using tie stall and free stall barns with less or no storage of manure.")

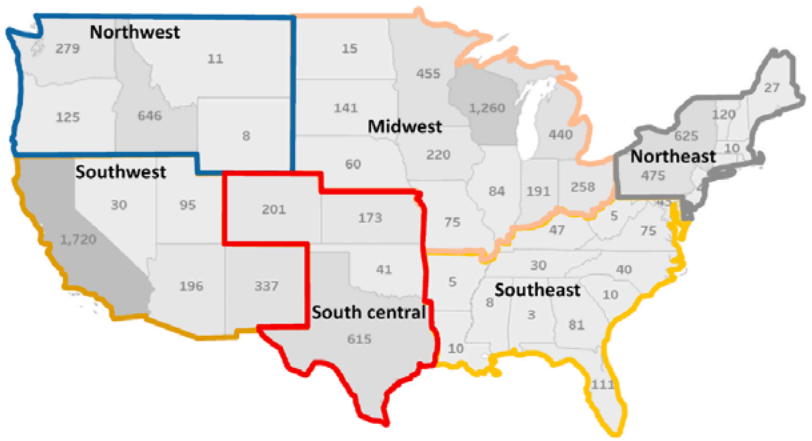

Fig. 1. Dairy regions of the United States used in our evaluation of the environmental footprints of dairy farms. Numbers are thousands of dairy cows in each state (NASS, 2020).

Table 1
Number of each type of dairy farm simulated to represent each region of the U.S.

Region	Amish	Organic	Grazing	Semiconfined	Confined <1000 cows	Confined 1000+ cows
Northeast	1	2	4	6	4	3
Southeast	0	0	5	9	4	2
Midwest	1	2	2	3	8	4
South central	0	1	2	3	6	8
Northwest	0	1	2	0	5	12
Southwest	0	1	1	0	1	17

FIGURE 10 Via A. Rotz et al., Environmental Assessment of U.S. Dairy Farms, supra note 150.

management systems are associated with higher emissions than other dairying systems.[183] This model is more common in the Southwest, and in California in particular, than in other parts of the country.[184] The dairying practices associated with the lowest GHG intensity are smaller grazing operations, which are primarily found in the East and the Midwest.[185]

The adoption of anaerobic digesters significantly reduces the GHG intensity of the California dairying model by capturing emissions generated by the long-term storage of liquified manure in lagoons. But it reduces the emissions from a high baseline relative to other common dairying models. Additionally, while anaerobic digesters capture emissions from manure lagoons, they do not address environmental harms, including but not limited to GHG emissions, beyond the lagoon.

Confinement-based dairies rely heavily on purchased feed. According to the Rotz et al. analysis, about 67% of the total fossil energy consumption by dairies nationally was used to

183 The study also determined that each of these farm management styles resulted in different environmental footprints generally and GHG emissions specifically. The results of the study provide insight into both the leakage discussion and the broader concerns about the LCFS: "Farms with the lowest intensity were often smaller grazing operations with little or no long-term storage of manure. For example, five grazing dairies in the northeast had a mean footprint of 0.88 kg CO2e/kg FPCM. Larger dairies that used an anaerobic digester also had below average intensities (0.69–0.87 kg CO2e/kg FPCM). Dairies with the greater intensity were often confinement operations with long-term liquid manure storage (i.e., large lagoons or retention ponds), particularly in the warmer regions of the country (six operations in the southwest averaged 1.09 kg CO2e/kg FPCM). Often the greatest intensities were associated with dairies that had lower FPCM production per cow along with the use of long-term manure storage." A. Rotz et al., *Environmental Assessments of U.S. Dairy Farms*, J. of Cleaner Prod. 315 (2021) 128153, https://www.sciencedirect.com/science/article/pii/S0959652621023714.

184 One study that determined the environmental footprint of dairy nationally found that the largest confinement dairies were found in the southwest region, where dairies were concentrated in California. The northwest region also had similar concentrations of the largest confinement operations but the other regions had a more varied breakdown, that typically included some smaller confinement operations, semiconfined operations, grazing, and organic operations.

185 A. Rotz et al., *Environmental Assessment of U.S. Dairy Farms*.

produce feed. About 97% of blue water consumption by dairies nationally was used to produce feed. Confinement-based dairies typically lack adequate land to spread manure regularly, necessitating long-term storage of manure which results in greater GHG and ammonia emissions.

The geography and climate of the southwestern region also influences environmental impacts in California, particularly when paired with the dominant model of confinement dairying. The amount of freshwater withdrawals varies regionally, but is highest in the Southwest. Overall, less water is consumed in regions that produce most of their feed on the farm without irrigation. Dairies on the West Coast rely heavily on irrigated feed crops.[186]

In terms of NOx emissions, "portions varied across the country, with less NH3 emission and greater NO3 loss in the eastern regions and greater NH3 emission and less NO3 loss in the dry conditions of the west."[187] In terms of GHG emissions, "manure contributed a lower proportion in the Northeast (17%) due to cooler temperatures and less use of long-term storage, and manure contributed a greater portion in the Southwest (28%) due to warmer temperatures and more use of long-term storage (IPCC, 2006a; Rotz, 2018). The enteric CH4 portion was also greater in the two eastern regions (47%) due to greater use of forage in cow diets."[188]

A comparison between California, as the nation's top dairy producing state, and Wisconsin, the second, illustrates California's role as leading the industrialization of dairy. California dairies are larger and the industry is more consolidated than in Wisconsin. A 2010 survey of California and Wisconsin farmers found that "While farms in Wisconsin are mostly medium-sized family farms, Californian farms operate on a much larger scale but are still owned by the family."[189] In 2014, Wisconsin had almost seven times more licensed dairy herds than California, but the average herd size was about 10 times smaller than the average herd size in California.[190] California first surpassed Wisconsin in dairy production in 1993 after a period of rapid growth and concentration in California (increasing production from 16.6 billion pounds of milk in 1988 to 22.9 billion pounds in 1993).[191] As discussed, the pressures of urbanization in Southern California in the early 1990s resulted in the loss of dairies in that region, but it also allowed them to sell their land at very high prices which they could use to build larger operations in the Central Valley.[192]

There is little evidence to suggest the baseline system of dairying in California is more climate-friendly or environmentally friendly than dairying nationally. However, the states the industry would be most likely to move to may not reflect the national average either. The states that have seen the most dairy growth in recent years are other western states adopting the California model of confinement-based operations with liquid manure management. Therefore, their practices may be similar to the practices of California dairies and, it is likely that they have fewer incentives for digesters, which is the primary method of reducing emissions from these dairies without otherwise altering practices. LCFS credits are available to any operation in the continental

186 Rotz et al. ("The lowest consumers were farms in the Midwest, Northeast, and Southeast regions that produced most of their feed on the farm without irrigation. The greatest consumers were farms in the Northwest and Southwest that relied almost entirely on irrigated feed crops.")

192 *Id.* ("Of course, they did not just move their 500 to 1000 cows. Instead, they built new and bigger and the strip from Bakersfield north to Sacramento sprouted new dairies, many of them 2,000 to 5,000 cows in size and all housed in freestall barns (copied from the new dairies being built in the Midwest) and away from the mud and rains of the corral type housing used in their former location.").

United States through book-and-claim accounting and federal incentives to support the construction of digesters are available, but California also offers substantial assistance for digester construction in the form of loans and grants.

E. Legal Leakage and Mitigation Measures

The nature of the leakage risk depends on the specific approach to GHG regulation, but several policy tools are available to reduce the likelihood of leakage generally. The primary tools are production incentives/output-based rebating and border climate adjustments.

Border climate adjustments "impose a fee on imported energy-intensive and trade-exposed products and a refund for exports of the same products."[193] They have been challenging to implement in practice.[194] Border climate adjustments are unlikely to be feasible for intra-American leakage, because they would impose a carbon tax on imports from other states, almost certainly generating litigation under the Dormant Commerce Clause.

Output-based rebates "consist of payments to energy-intensive and trade-exposed firms based on their production."[195] They have been found to "significantly reduce simulated emissions leakage."[196] Output-based rebating is similar to free allocations of emissions allowances, such as those used by California's cap-and-trade program.[197] Allocating allowances to regulated industry in the cap-and-trade program is intended to give enterprises time to transfer to less GHG-intensive technologies but also to prevent leakage. The level of allocations "will decline over time to settle at a level needed to prevent leakage."[198]

Output-based rebating has two side effects that make it important to carefully target subsidies to the industries actually at risk of leakage: "First, an opportunity cost is incurred when allowances are allocated for free or tax revenues are recycled to industrial producers. Second, output-based rebating dilutes the carbon price signal received by firms receiving the subsidy."[199]

While these tools have been effective in preventing leakage in other jurisdictions, it's crucial that they accurately target sectors seriously at risk of leakage. It's not clear that this is the case for dairy—further empirical research would be required. Moreover, the effectiveness of these policies in preventing leakage is due to the fact that they shield "key industrial sectors, which is incompatible with deep decarbonization."[200]

In the context of dairies, CARB would have to more deeply analyze how methane regulations would influence dairy operator behavior—in the absence of a specific regulation, it's challenging to determine whether it would actually prompt dairies to leave beyond the pre-existing decline. If it was determined that methane regulations were going to prompt industry departure, this kind of rebate could be carefully tailored to, for example, compensate dairies just enough to make the costs of leaving unappealing. Such rebates could also be tied to ongoing compliance with methane regulations.

In addition to the policy tools designed to address emissions leakage, policymakers should also consider that trade-exposure is one of the major leakage risk factors. The major changes

to the dairy industry's export market over the past few decades have, therefore, increased the risk of leakage. As discussed, the opening of the export market also contributed to price depression and consolidation in the dairy industry. There are several farmer-led movements in the Northeast and the Midwest calling for a return of supply-side management programs specifically in order to preserve a healthy dairy industry and to reduce the environmental harms associated with confinement dairying.[201] This push is in line with the recent political trends, including resurgence in interest in industrial policy[202] and bipartisan pushback[203] against the free-trade line that has dominated U.S. politics for several decades.

The impact of free trade agreements makes it challenging to address the export market and supply-side management issue that has contributed to depressed milk prices, but it should prompt a deeper consideration of how California dairying can both be economically robust and sustainable into the future. These concerns should be especially important given the need to consider food security and the resilience of regional food systems in the face of climate change.

Overall, the likelihood of methane regulation and certainly of any changes to LCFS crediting running afoul of the legal requirement that CARB minimize leakage is low. Each step in the process—that dairies would leave the state in large numbers, that they would generate significantly more emissions out-of-state, and that CARB would not have policy options to minimize these events—is unlikely.

F. Key Takeaways: Emissions Leakage Risk

- **Research tells us that leakage is much less likely in practice than in theory.** Most of the literature on leakage suggests that it is very limited in practice. The textbook economics that envisions leakage imagines a frictionless global market, but uprooting industries incur additional costs that operators may not be willing to bear. Additionally, there are effective mitigation measures available that are commonly employed to reduce leakage risk. Multiple studies have found that while compliance costs can result in small in-state decreases, only a portion of those decreases are accounted for by moves out of state. For more on the risk of leakage in practice, see the CARB-commissioned *Mitigating Leakage Risk.*

- **Leakage risk is also closely tied to industry mobility. Industrial-scale dairying is capital-intensive, requires substantial sunk costs, and is facing a labor shortage, all of which erect barriers to mobility.** Dairy is more mobile than oil and gas production, which requires location at the source of fossil fuels; however, several characteristics of industrial-scale dairies are impediments to mobility.

- **California's Central Valley still offers many benefits to dairy operators. Many of the challenges facing California dairies exist nationally or in other western states.** Dairies have struggled nationally for decades, but California has remained the top dairy producer in the country since 1993. On most metrics, California's dairy industry is the most successful in the country. While there are real challenges facing California dairies, many of these challenges are also facing dairies nationwide (like the ongoing trend towards consolidation) or in other western states (like drought and access to adequate water). Dairy operators may find policymakers less likely to directly regulate methane in Texas or in Kansas, but by moving, they would lose benefits like close proximity to urban markets and ports, cheap by-product feed, proximity to major transportation corridors, a milder climate etc.

- **While there has been a decline in California dairy operations in recent years, this movement is caused by a range of pre-existing factors.** Emissions leakage is a causal phenomenon. Outmigration followed by increased net emissions is only leakage if it was caused by emissions regulation. If anything, the fact that the industry has been moving out of state *prior* to any emissions regulations diminishes the likelihood that emissions regulations alone will cause outmigration and attendant emissions leakage. There are other valid and important concerns about the outmigration of dairy operations, but the legal leakage issue is not raised by these departures in the absence of any emissions regulation. Some of the reasons dairies have left California include: California slowly losing its competitive edge as other western states adopt its model of industrial-scale dairying, lack of reliable access to water, increased feed and manure management costs, and increased urbanization pressures.

- **The industry moving out of state ("production leakage") on its own does not necessarily result in emissions leakage. Despite stereotypes of California as a strict environmental regulator, it's not assured that dairies would emit more GHGs if they moved to other states.** Emissions leakage occurs when emissions regulations push and industry and their emissions out of state. This means emissions leakage requires that net emissions stay the same or increase as the result of the move. California-style dairies, however, generally have higher baseline emissions overall and per-cow than small and mid-sized dairies. California pioneered the most industrialized and highest emitting model of dairying in the country. California-style industrialized dairies are proliferating nationally, but they still are not the norm in many "traditional" dairying states, where smaller-scale, lower-emitting models remain more common. It's unlikely that California dairies would move to traditional dairying states, but if they did, net emissions could actually be reduced.

- **Mega-dairies outside of California are increasingly likely to employ anaerobic digesters.** California's main contribution to mitigation of dairy emissions has been the push for dairy digesters. The incentives provided by LCFS credits are available to any dairy operation nationally that plugs into a common carrier pipeline or the grid, however, not just California dairies. This means the LCFS does not incentivize climate-friendly behavior in California more than in any other state. Where California does have an edge is in grant funding for digesters through the

DDRP program. Other states have comparable programs. While other states' programs are less-well funded, this may reflect in part the fact that no state has more industrial dairies than California. Federal funding for digesters is also available, as is private funding.[204]

California dairies are more likely to relocate to other "modern" dairying states in the West, which have generally attempted to replicate California-style mega-dairies. Many of these states are also embracing digesters now, sometimes with the help of California-based companies like Brightmark (which has digester projects in South Carolina, Iowa, Michigan, Washington, Wisconsin, Florida, New York, and South Dakota)[205] and California Bioenergy (which has about 50 projects in California and has recently ventured to South Dakota).[206] A few indications of the surge in digesters in states that would be likely destinations for dairies exiting California:

- In Idaho, a "goldrush" to build dairy digesters specifically due to LCFS credits;
- In Washington, an "explosion of growth" and $22 million public investment in dairy digesters based on a CARB report touting its success;
- In Iowa, a "huge uptick" in dairy digesters from 2022 to 2023
- In Arizona, dairy digesters are a "hot investment;"
- In South Dakota, $150 million in private funding from California Bioenergy goes to three new dairy digester clusters in 2023;
- In Kansas, one of the top states for dairy growth, Shell is constructing a dairy digester;
- In Oregon, where "manure is big business," public funds and a Biomass Tax Credit program have incentivized digesters.

- **California regulators are obligated to minimize emissions leakage to the extent reasonable, not to ensure zero leakage.** Legally, CARB is only required to minimize or mitigate leakage, and there are policy tools available to help do this, like carefully designed output-based rebates. More generally, the dairy market is global, so leakage is possible from virtually any jurisdiction seeking to regulate dairy emissions. The question should be whether the amount of emissions leakage is so great as to frustrate the emissions reductions sought by the regulation.

VI. California's Climate Targets and Credits for Dairy Digesters

Some[207] have argued that California cannot meet its climate targets without LCFS incentives for biogas from dairy manure. The implication is that by eliminating LCFS incentives for biogas, advocates would jeopardize climate progress. More specifically, the argument is that reducing incentives will make dairies less likely to construct biogas control systems and, as a result, methane from existing manure lagoons will continue to be vented. This section examines the two relevant sets of targets—California's overall climate targets established under SB 32 and California's 2030 methane targets set by SB 1383—and evaluates the extent to which this claim is accurate.

A. California's Overall Climate Targets

California's most recent update to the Scoping Plan calls to cut greenhouse gas emissions by 48 percent below 1990 levels by 2030 and 85 percent below 1990 levels by 2045.[208] The Scoping Plan "approaches decarbonization from two perspectives: (1) managing a phasedown of existing energy sources and technology and (2) ramping up, developing, and deploying alternative clean energy sources and technology over time."[209]

Short lived climate pollutants,[210] like methane, account for "about one-third of the cumulative GHG emissions reductions the State is relying on to achieve the statewide 2030 GHG emissions target established under SB 32."[211] The dairy and livestock sectors contribute more than half of the state's methane emissions.

B. California's Dairy Methane Targets

The three largest sources of methane emissions in California are the dairy and livestock industry, landfills, and oil and gas systems.[212] CARB took early action measures to address landfills and oil and gas directly (the Landfill Methane Regulation, Cal. Code of Regs., tit. 17, §§ 95460, et seq. and the Oil and Gas Methane Regulation, Cal. Code of Regs., tit. 17, §§ 95665–77) but declined to do so for the dairy and livestock sectors.

The SLCP Strategy's approach to dairy and livestock was characterized by CARB as a "carrot-then-stick" approach, prioritizing voluntary, incentive-based mechanisms in early years to "overcome technical and market barriers."[213] In the 2022 Scoping Plan CARB explained, "Under this "carrot-then-stick" strategy, incentives are replaced with requirements as the solutions become increasingly feasible and cost-effective."[214] Theoretically, the stick element could be implemented as of January 2024, per SB 1383. However, CARB has not indicated it intends to begin rulemaking on this issue.

SLCP reductions are "necessary to achieve the State's 2030 GHG emissions target, as described in the 2017 Scoping Plan Update, as well as the mid-century carbon neutrality goal."[215] The 2017 Short-Lived Climate Pollutant Reduction Strategy included a target of 40% reduction in total methane emissions as well as a separate 40 percent reduction in methane specifically from dairy and

213 *Id.*

214 *Id.*

215 Cal. Air Res. Board, *Analysis of Progress Toward Achieving the 2030 Dairy and Livestock Sector Methane Emissions Target, supra* note 211.

livestock operations.[216] California's target of a 40 percent methane reduction below 2013 levels for the dairy and livestock sector by 2030 constitutes a reduction of 9 million metric tons carbon dioxide equivalent (MMTCO2e).[217]

California is not on track to meet these targets for dairy and livestock even with the LCFS incentives. The progress report projects that the dairy and livestock sector will achieve "just over half of the annual methane emissions reductions necessary to achieve the target by 2030 through modifications to manure management systems—primarily using anaerobic digesters—and additional reductions through decreases in animal populations."[218] The SB 1383 progress report concludes that, to meet SB 1383 targets, "approximately 230 additional digesters may be needed, at a cost between $0.7 and $3.9 billion depending on the types of technologies selected."[219] The report also finds, on the other hand, that "based on currently funded projects and reduction trends observed to date, staff's analysis indicates that the State would be unable to achieve the 2030 dairy and livestock sector target through deployment of alternative manure management practices alone."[220] That is, according the CARB's projections, California cannot meet its goals with just digesters or with just alternative manure management practices.

The intra-agency Dairy and Livestock Greenhouse Gas Emissions working group, which consisted of CARB, CDFA, California Energy Commission, and CPUC principals, convened three stakeholder subgroups in 2017 and 2018. Subgroup 1 provided recommendations on non-digester manure management practices, Subgroup 2 provided recommendations on overcoming barriers to implementing livestock digester projects, and Subgroup 3 provided recommendations on research needs related to dairy and livestock emissions reductions. CARB has pursued dairy digester projects as the Board's primary tool to reduce dairy emissions since the recommendations were made final in 2018.[221] Subgroup 3 published a Dairy research Prospectus to Achieve California's SB 1383 Climate Goals.[222]

Beginning January 1, 2024, CARB has authority to regulate GHG emissions from agriculture, "provided that CARB, in consultation with CDFA, determine the regulations are technologically and economically feasible, cost-effective, include provisions to minimize and mitigate potential leakage, and include an evaluation of the achievements made by incentive-based programs."[223] "SB 1383 intends to prioritize the use of voluntary and incentive-based measures to achieve those reductions before regulations are implemented"; however, the progress report projects that California is on track to reach less than half of dairy and livestock reduction targets by 2030.[224] Additionally, the progress report concludes that meeting targets will "require implementation of additional methane emissions reductions strategies, and continued collaboration among agencies and other stakeholders," but the Board has made no indication that it intends to initiate rulemaking.[225]

C. Key Takeaways: California's Climate Targets and Credits for Dairy Digesters

- **Dairy digesters are necessary for California to achieve its GHG reduction targets at this point, but so are a range of non-digester interventions that have not been seriously pursued.** Methane captured by digesters accounts for most of the reductions counted towards the methane reduction targets for dairy and livestock, but even with these large reductions California is not on track to meet targets for dairy and livestock. California policymakers should look to the report by the 2018 CARB-convened working group on non-digester tactics to reduce dairy methane emissions to understand alternative, more holistic approaches to reduce GHG emissions from dairies.

- **CARB will not be able to accurately assess and select interventions if it relies on the LCFS life cycle analysis for manure biogas to analyze dairy emissions.** The life cycle analysis CARB uses measures the carbon intensity of transportation fuels produced from manure biogas, not the carbon intensity of milk (this is discussed at length in the carbon intensity discussion). A holistic life cycle analysis of milk produced on California dairies and feed production would prompt different kinds of interventions, since more emissions are generated from enteric fermentation than from manure management. The life cycle analysis for transportation fuels used by the LCFS *assumes* the dairy industry is static—the dependent variable in that analysis is the change in transportation fuel from conventional fuels to manure-derived biogas. This is a valid assumption to make in the context of a transportation program, like the LCFS, but should not drive the broader strategy to achieve emissions reductions from the dairy industry. California policymakers should be considering a suite of options to reform and support the dairy industry transition to a less-emitting model.

Abstract The aim of this review is to summarize the current knowledge of nitrous oxide (N_2O) production from manure. The article investigates the scientific literature regarding N_2O emissions according to different factors, such as microclimate, season, manure composition, microbial population, management, storage conditions, and type of digestion. Nitrous oxide is formed through the microbiological processes of nitrification and denitrification. The amount of N_2O produced from manure storage depends on type of manure management. The anaerobically stored farm yard manure (FYM) emitted more N_2O emissions than the composted FYM. The anaerobic storage of liquid manure reduces N_2O production. Covering the slurry store (SLR) with a chopped straw increased N_2O emissions. Finally, emission factors from manure treatment and management are listed in table.

Keywords: nitrous oxide, manure, slurry, housing

Introduction

Contemporary agriculture is characterized by the intensive production of livestock in confined facilities and land application of stored waste as an organic fertilizer. Animal agriculture potentially contributes up to 50 % of total agricultural nitrous oxide (N_2O) emissions (Klein de and Eckard 2008). The anthropogenic greenhouse gas emission from animal manure is estimates on 20 % of N_2O (Sommer and Moller 2000).

N_2O emissions from nitrogen (N) excreted as animal waste alone could be as much as 30–50 % of the global agricultural N_2O emissions, suggesting that the contribution of animal agriculture to total agricultural N_2O emissions could be in excess of 50 % when including emissions from N fertilizer use (Oenema et al 2005; Klein and Eckard 2008). N_2O emissions occur high when N fertilizers are used for production of concentrates to feed the animals, as well as from excretal returns (Davidson 2009; Petersen and Sommer 2011).

N_2O is produced during several microbial processes in the nitrogen (N) cycle of terrestrial and aquatic systems. Typically, 70 % to 90 % of the N ingested by herbivores is excreted, either during grazing or via application of manure collected outside grazing periods (Schils et al 2013). Housed animals excrete as dung and urine according to Paustian et al (2004) 80 to 95 % of the N in their diet, and some proportion of this N is emitted as N_2O during collection, storage, and application. Ruminants excrete between 75 and 95 % of the N they ingest, with excess dietary N increasingly excreted in the urine, while dung N excretion remains relatively constant (Castillo et al 2000; Eckard et al 2007).

In animal husbandry, N_2O emissions are associated with manure management and the application and deposition of manure in crop or pasture land. Manure treatment can be an important source of N_2O emissions, accounting for an estimated 5 % of global N_2O emissions (Owen and Silver 2015). Major agricultural manure emission sources are reported to be N_2O from poultry sheds and from beef feedlots (Pratt et al 2014).

Collected manure may be handled in solid (farmyard manure, deep litter) or liquid form (slurry with typically 1 % to 10 % of dry matter) (Schils et al 2013). Dung and urine are often separated to solid stacked manure and slurry (SLR), with or without subsequent composting of the stacked manure and (anaerobic or aerobic) treatment of the SLR. In other production systems, effluent from barns is transferred into open anaerobic ponds (lagoons) where the effluent is typically stored for many months, with the potential of generating large quantities of emissions (McGahan et al 2016).

N_2O is released from excrement and urine excreta, from SLR applied for crop or pasture production, and aerobic and anaerobic degradation of livestock waste in the lagoons and dry manure pile (Saggar et al 2004; Fabbri et al 2007; Borhan et al 2011; Redding et al 2015).

Formation N_2O

DOI http://dx.doi.org/10.14269/2318-1265/jabb.v5n1p13-19

The various pathways of N_2O formation could describe for apply to the manure environment, but the potential for N_2O emissions will depend on manure management practice. Manure contains most elements necessary for stimulating soil nitrification and denitrification processes that form N_2O. These processes are transient, depending on the amount and form of available N (NH_4^+ or NO_3^-), soil oxidation–reduction potential, degradable carbon (C) sources, soil temperature, water content, and microbial population (Montes et al., 2013). Poor correlations between N_2O efflux and soil physicochemical variables and fertilizer loading rate point to the complexity of interacting factors affecting N_2O production and emission (Whalen 2000).

The main sources of N_2O from agriculture are nitrification and denitrification processes in soil. Farms primarily emit N_2O arising mainly from nitrogen fertilizer (organic manures or inorganic fertilizers) application to soil, direct N deposition by grazing animals, or manure storages (Whalen et al 2000; Crosson et al 2011; Adler et al 2015). Nitrous oxide can also be produced indirectly when manure N is lost through volatilization as NH_3, NO, and N_2O and is nitrified and denitrified in soil following redeposition (Montes et al 2013). The smaller contributions from barn floors, where both aerobic and anaerobic conditions can exist (Chianese et al 2009; Van Middelaar et al 2013; Eckard et al 2003).

The major N_2O contributor is normally the denitrification process under anaerobic conditions, but nitrification under aerobic conditions may also contribute. Nitrification and denitrification rates are affected by numerous soil and climatic or seasonal factors (Monaghan and Barraclough 1993; Chadwick et al 2000; de Klein and Eckard 2008). The rate of formation and emission of N_2O varies through time with changes in the porosity, moisture content, temperature, amount of solids in the manure, and N or dietary protein content of the soil or manure substrate (Külling et al 2001; Kebreab et al 2006; Chianese et al 2009; Li et al 2014). Anaerobically stored solid manure emitted much more N_2O than the compost (Amon et al 1998a). Chadwick et al (2000) also reported that immediate emissions of N_2O from the beef manure was likely due to rapid nitrification of ammonium or denitrification of nitrate already in the manure.

Most of the N_2O resulting from manure is produced in manure-amended soils through microbial nitrification under aerobic conditions and partial denitrification under anaerobic conditions, with denitrification generally producing the larger quantity of N_2O (Montes et al 2013). Nitrogen in liquid manure is mostly in the form of ammonium (NH_4^+) and organic N, and though anaerobic lagoons are generally anaerobic, aerobic conditions which could promote denitrification exist at inlets. Other N_2O formation reactions are also possible, such as denitrification of nitrate (NO_3^-) (Owen and Silver 2015).

Mahimairaja et al (1995) examined the denitrification loss of N from fresh poultry and animal (dairy, sheep, pig and horse) manures, and from poultry manure during composting with different amendments. The results indicated that during denitrification, the amount of N_2 produced is generally greater than that of N_2O. The ratio of N_2O:N_2 varied from 0.09 to 0.21.

Factors affecting N_2O releasing

When fecal matter is excreted by animals, it undergoes a series of reactions such as decomposition, hydrolysis, nitrification, denitrification, fermentation etc., from which N_2O can be produced. Based on the principles of thermodynamics and reaction kinetics, these reactions are commonly controlled by a group of environmental factors such as temperature, moisture, stacking, density, litter addition, mixing, composition, and aerobic decomposition during storage of the manure, also redox potential, pH, substrate concentration gradient, etc. (Oenema et al 2005; Yamulki 2006; Kebreab et al 2006; Li et al 2012; Rzeźnik and Mielcarek 2016). The influencing factors appeared to be also the manure removal frequency, dry matter content, and time deposit of the manure (Fournel et al 2012). After 6 weeks of storage N_2O emission from farmyard manure (FYM) and deep litter manure reached a maximum (Külling et al 2002).

N_2O emissions are strongly correlated with all these parameters (Mihina et al 2012; Owen and Silver 2015). This suggests that in FYM, at least a portion of the N_2O fluxes were derived from denitrification, which requires the same general environmental conditions as methanogenesis (warm temperatures, abundant labile C, anaerobic conditions) (Owen and Silver 2015).

One main factor influencing the amount of N_2O emissions seems to be the manure temperature. This would explain why under summer conditions the emission rates of N_2O are different than under winter conditions (Jungbluth et al 2001). Sommer and Moller (2000) studied composting of pig deep litter during a 4-month period. Emissions of N_2O were only significant in the low temperature phases. N_2O was also produced in the center both initially and after the temperature of the compost had dropped to below 45 °C (Sommer and Moller 2000).

The initial C: N ratio and dry matter content of the stored FYM are also the most important factors affecting N_2O emissions. The greater C content in the organic FYM compared with the conventional FYM corresponded to a reduction in total N_2O emission (Yamulki 2006). N_2O emissions increase with the N content of waste, the extent to which waste is allowed to become aerobic (allowing the

initiation of nitrification-denitrification reactions) and the length of storage (Mosier et al 1998). Further, owing to interactions between available C and N sources in the correct oxidation form, semi-permeable manure storage covers can enhance N_2O formation (Hansen et al 2009; Nielsen et al 2010; Gerber et al 2013).

Table 1 N2O production and emission factors from manure storage facilities (per animal)

Cattle manure, without covering; 0.78 mg.m^{-2} h^{-1} (Ross et al 1999, cited by Jungbluth et al 2001).
Manure, summer, 3.5 t, winter, 7 t; anerobically stored vs. composted, 3 times per week, ODC, 74.7 g.t^{-1} vs. 49.8 g.t^{-1} (Amon et al 1998a).
Cattle manure (housing, storage, spreading); ODC, FTIR; yearly average 0.62 g.LU^{-1}.d^{-1} (Amon et al 1998b, cited by Amon et al 2006a).
Dairy solid manure system; 25.8 mg.LU^{-1}.h^{-1} (Amon et al 1999; cited by Amon et al 2006a).
Dairy liquid manure system; 25.4 mg.LU^{-1}.h^{-1} (Amon et al 1999; cited by Amon et al 2006a).
Dairy SLR, storage, 1200 m^3; winter, TDL; 14 mg.m^{-3}.d^{-1} (Hensen et al 2006).
12 Brown Swiss, 52 DIM, 637 kg LBW, 30,9 kg MY, individual stalls, slatted floor, TMR, 4 MS (DL, SLR, urine-rich SLR, FYM); 7 wks, TDL; according MS: 9.3 ng.m^{-2}.s^{-1}, 5.6 ng.m^{-2}.s^{-1}, 12.1 ng.m^{-2}.s^{-1}, 556.4 ng.m^{-2}.s^{-1}; (DL, SLR, FYM) 42 mg.d^{-1}, 12 mg.d^{-1}, 886 mg.d^{-1} (Külling et al 2001).
Pig manure, without covering; from containers (0,5 m^3) closed for 1 h gas measurement, summer, GC; 0.67 mg.m^{-2}.h^{-1} (Ross et al 1999, cited by Jungbluth et al 2001).
Pig manure, with straw covering; from containers (0,5 m^3) closed for 1 h gas measurement, summer, GC; 0.95 mg.m^{-2}.h^{-1} (Ross et al 1999, cited by Jungbluth et al 2001).
Pig manure, without covering; winter, FMC, GC; 0.35 mg.m^{-2}.h^{-1} (Ross et al 1999, cited by Jungbluth et al 2001).
Pig manure, with straw covering, winter, FMC, GC; 0.30 mg.m^{-2}.h^{-1} (Ross et al 1999, cited by Jungbluth et al 2001).
160 fattening pigs, uncovered SLR vs. covered SLR; warm, FC; after 50 days, 23 g.m^{-3} vs. 30 g.m^{-3}; after 200 days, 119 g.m^{-3} vs. 114 g.m^{-3} (Amon et al 2007).
160 fattening pigs, uncovered SLR, covered SLR; cold, FMC; after 50 days, 36 g.m^{-3} vs. 18 g.m^{-3} (Amon et al 2007).
Fattening pigs; FS housing, anaerobic effluent pond, short hydraulic retention tank; 2x30 ds; N_2O from housing and pond, or below the detection limits, total emissions from the short hydraulic retention tank: winter 0.001 mg N_2O-N.LU^{-1}.d^{-1}, summer 5.9 mg N_2O-N.AU^{-1}.d^{-1} (McGahan et al., 2016).
3 fattening pigs farms; SLR lagoons; every M, MBIGA; lagoon concentration 636.8 mg NH_4-N kg^{-1}, 201.0 mg NH_4-N kg^{-1}, 236.6 mg NH_4-N kg^{-1}, 0.3 kg N_2O-N ha^{-1} d^{-1}, 0.4 kg N_2O-N ha^{-1} d^{-1}, 0.0 kg N_2O-N ha^{-1} d^{-1} (Harper et al 2004).
Manure, fattening pigs, DL, stored 113 ds; every wk, RC (tent), GC; d 11: 28 mg N_2O-N.kg DM^{-1} d^{-1}, after d 40: 6 mg N_2O-N.kg DM^{-1} d^{-1} (Wolter et al 2004).

The increase in manure organic matter accelerates soil metabolism, depleting oxygen, triggering denitrification and N_2O emissions (Hristov et al 2013; Gerber et al 2013). On the contrary, anaerobic digestion, or separation of manure solids, lowers the organic content of manure, which generally results in lower emissions of N_2O (Clemens et al 2006; Velthof and Mosquera 2011; Gerber et al 2013). Manure affects the balance between NH_3 and N_2O emissions. This interaction may be positive (e.g., both emissions are reduced by an airtight cover during storage and stimulated by composting), or negative (e.g., direct N_2O emissions from soil will potentially increase if losses of NH_3 are prevented during storage or field application) (Petersen and Sommer 2011). N_2O release from stored manure was low when NH_3 was high (Külling et al 2002).

The amount of N_2O produced from manure storage depends on the amount of N excreted and duration of storage (Merino et al 2011). Solid manure rich in high fiber bedding material has a high porosity that promotes aerobic fermentation, and heat, which can stimulate N_2O emissions (Petersen et al 1998). Also, the higher the density the lower the emission of N_2O (Oenema et al 2005). However, covering delayed aeration of the stored manure; this reduced internal heat production, degradation of organic matter, and emission of greenhouse gases and ammonia (Hansen et al 2006). At the study of Sommer and Moller (2000) was production of N_2O restricted to the surface layers during the thermophilic phase of composting (Sommer and Moller 2000). Brown et al (2000) found that the mean N_2O-N fluxes were between 0 and 0.33 g N m^{-2} d^{-1}, and N_2O was only generated in samples from the top two layers of the dairy FYM pile. Manure samples from the 30 to 45 cm depth were adjusted by amendment with chopped straw to 70, 75, and 80 % water content. These samples produced twice as much N_2O-N as the unamended samples.

Slurry separation reduces emissions if losses during storage of the solid fraction can be kept on a low level (Amon et al 2006b). At the study of Hansen et al (2006), emissions of N_2O from an uncovered and covered heap of solid manure separated from pig SLR were compared, and related to the oxygenation level inside the manure heap. Approximately 15 % of the initial nitrogen content of the solids separated was found to be lost when the separated solids were stored uncovered. Almost 5 % of the initial N content was found to be lost as N_2O. Emissions of N_2O were reduced by 12 %, when the manure heap was covered with

DOI http://dx.doi.org/10.14269/2318-1265/jabb.v5n1p13-19

an airtight material. The oxygenation level inside heaps of solids separated from pig SLR was found to influence the production and emission of greenhouse gases during the storage period (Hansen et al 2006).

In contrast, in liquid manure lagoons particulate organic matter is a physical barrier against gas exchange when a surface crust forms (Petersen and Sommer 2011). Anaerobic digestion is in fact an effective means to reduce greenhouse gas emission (Amon et al 2006a). However, the anaerobically stored FYM emitted more N_2O emissions than the composted farm yard manure (Amon et al 1998a; Amon et al 2001).

Covering the SLR store with a layer of chopped straw increased greenhouse gas emissions mainly by increasing N_2O emissions. When liquid manure stored as anaerobic SLR, N_2O emission is low, but NH_3 and CH_4 emissions are high, depending on the cover of the slurry and mixing rate (Oenema et al 2005). N_2O emissions can occur from SLR when a dry crust is formed on the surface with combination of anaerobic and aerobic micro-sites (Philippe and Nicks 2013). Therefore, straw cover and SLR aeration showed negative environmental effects (Amon et al 2006b).

Natural surface crusts may develop into a porous matrix with high O_2 availability that harbors an active population of aerobic microorganisms. The occurrence of NO_2^- and NO_3^- in the crusts also indicate the presence of actively metabolizing NH_3^- oxidizing bacteria (Nielsen et al 2010). The floating crust is important because it provides a substrate that spans anaerobic and aerobic environments, where N_2O production can occurs (Petersen and Sommer 2011).

Floating crusts on manure storages are environments with intense microbial activity, and microbial processes are governed by the extent of oxic conditions that are governed by the moisture of the crust. Hansen et al (2009) study investigated whether physical properties of the crust or crust microbiology had an effect on the emission of the N_2O when crust moisture was manipulated (dry, moderate, and wet). However, an increase in N_2O emission was observed in all crusted treatments exposed to anoxia, and this was probably a result of denitrification based on NO_x that had accumulated in the crust during oxic conditions.

Comparison of manure types

The type of manure can be crucial factors in reducing the extent of nitrogen lost (Bell et al 2016). The amount of N_2O produced from manure storage depends on type of manure management (Yamulki 2006; Merino et al 2011; Rzeźnik and Mielcarek 2014). Total manure emissions are the product of the amount of N excreted during storage multiplied by the associated emission factor for that manure management system and animal population (Crosson et al 2011).

A lower dietary protein content furthermore reduced N_2O emission rates in most manure types but increased CH_4 emission from urine-rich SLR. In deep litter manure, characterized by the highest C: N ratio, emission rates of total N, N_2O values were intermediate. Substantial emission of N_2O occurred with FYM. C: N ratio of manure was shown to be suitable to predict total N loss during storage in all manure types whereas urine N proportion and manure pH were only of use with liquid manures (Külling et al 2002).

Amon et al. (1998b) compared N_2O emission in solid and liquid manure management systems. In the tie-stall housing of dairy cows no differences were found between a SLR based and a straw based system. Only deep litter systems with straw showed higher N_2O emissions. This reflected the higher microbial biomass content and approximately neutral pH at FYM field (Mogge et al 1999).

N_2O synthesis needs close combination of aerobic and anaerobic areas. These heterogeneous conditions are not met within SLR but deep litter (Philippe and Nicks 2013). Therefore, for waste of a given N content, anaerobic lagoons will result in the least N_2O emissions whereas solid storage and dry-lot handling will promote emissions (Paustian et al 2004). The anaerobic nature of liquid manure systems reduces N_2O production (Kebreab et al 2006).

Majority of swine production systems use anaerobic or liquid-slurry systems for waste holding or disposal (Harper et al 2000). A model has been developed to predict pig manure evolution (mass, dry and organic matter, and N contents) and related gaseous emissions nitrous oxide (N_2O) from pig excreta up to manure stored before spreading. This model simulates contrasted management systems, including different options for housing (slatted floor or deep litter), outside storage of manure and treatment (anaerobic digestion, biological N removal processes, SLR with straw and solid manure composting (Rigolot et al 2010).

The results of Fournel et al (2012) showed that liquid manure from deep-pit housing systems produces greater emissions of nitrous oxide (N_2O) than natural and forced dried manure from belt housing systems. The study of Cabrera et al (1994) on N_2O emissions from poultry litter compared pellets or fine particles. Cumulative emission of N_2O was slightly higher for pelletized (6.8 % of applied N) than for fine-particle litter (5.5 %). Authors indicate that the effect of poultry litter physical characteristics on N_2O emissions can be expected to vary depending on the soil water regime (Cabrera et al 1994).

Application method

N_2O emissions are strongly dependent on the method and timing of fertilizer application. Manure incorporation

increased N_2O emissions and yield for the perennial system, but both effects were dependent on the interannual weather variability and crop growth (Webb et al 2014). High temperatures, high wind speed and low rainfall immediately following manure application promote emissions from manures containing a high amount of readily available N. Emissions of N_2O were significantly affected by the timing of manure application, with greatest N_2O emissions measured from manures applied and incorporated into bare soil in warmer and wetter autumn conditions. Mean annual N_2O emissions across all manure treatments were greater from autumn (2 kg N_2O–N ha^{-1}) than spring (0.35 kg N_2O – N ha^{-1}) applications (Bell et al 2016).

The more frequent soil application may increase N_2O emissions, if application occurs during prolonged periods with warm temperature, wet soil and low plant-N uptake. Therefore, a combination of decreased storage time in warm weather and extended winter storage is a viable option in many regions (Hristov et al 2013; Gerber et al 2013). Following field application, infiltration of liquid is influenced by manure organic matter, and retention of ammoniacal N at the soil surface will enhance NH_3 volatilization (Petersen and Sommer 2011).

Final considerations

Farms emit N_2O arising mainly from manure application to soil, faces deposition by grazing animals, or manure storages. The various pathways of N_2O formation described above also apply to the manure environment, but the potential for N_2O emissions will depend on manure management practice. Nitrification and denitrification rates of manure are affected by numerous soil and climatic or seasonal factors.

Emissions of N_2O are significantly affected by the timing of manure application, with greatest N_2O emissions measured from manures applied and incorporated into bare soil in warmer and wetter autumn conditions. Straw cover, floating crust and aeration of slurry showed negative environmental effects. An extended review revealed that more data are needed to better quantify emissions from manure management.

RETHINKING MANURE BIOGAS

Policy Considerations to Promote Equity and Protect the Climate and Environment

Ruthie Lazenby

VERMONT LAW & GRADUATE SCHOOL
CENTER FOR AGRICULTURE & FOOD SYSTEMS

AUGUST 2022

AUTHORS & ACKNOWLEDGMENTS

This report was produced by the Center for Agriculture and Food Systems at Vermont Law and Graduate School. The author of this report is **Ruthie Lazenby** (she/her), LLM Fellow and Staff Attorney at the Environmental Justice Clinic at Vermont Law and Graduate School.

This report was made possible with support from the National Agricultural Library, Agricultural Research Service, US Department of Agriculture. The report benefited from significant writing, input, and editing support from several members of the Center for Agriculture and Food Systems at Vermont Law and Graduate School, including **Laurie J. Beyranevand**, Director and Professor of Law; **Lihlani Nelson**, Associate Director and Research Fellow; **Claire Child**, Assistant Director and Research Fellow; **Whitney Shields**, Project Manager; and **Molly McDonough**, Environmental Communications Specialist.

About the Center for Agriculture and Food Systems

Vermont Law and Graduate School's Center for Agriculture and Food Systems (CAFS) uses law and policy to build a more sustainable and just food system. In partnership with local, regional, national, and international partners, CAFS addresses food system challenges related to food justice, food security, farmland access, animal welfare, worker protections, the environment, and public health, among others. CAFS works closely with its partners to provide legal services that respond to their needs and develop resources that empower the communities they serve. Through CAFS' Food and Agriculture Clinic and Research Assistant program, students work directly on projects alongside partners nationwide, engaging in innovative work that spans the food system. Please visit www.vermontlaw.edu/cafs to learn more.

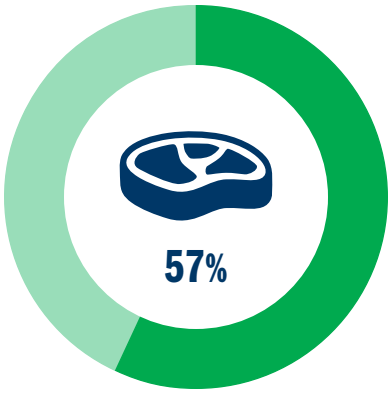
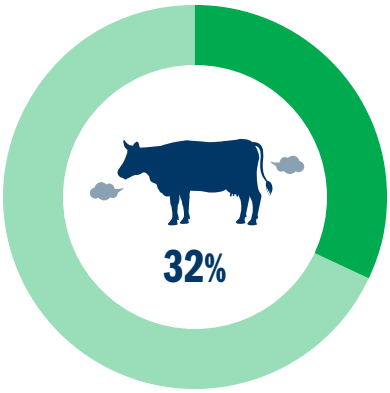
INTRODUCTION



THE WORLD IS ON TRACK TO EXCEED A 2° C INCREASE DURING THE 21ST CENTURY, an outcome scientists have described as catastrophic.[1] Direct impacts on the food and agriculture sectors will be far-reaching.[2] Already, climate-related impacts to farming include "observed changes in extremes such as heatwaves, heavy precipitation, droughts, and tropical cyclones."[3] These changes impact both crop and livestock production. Experts predict that further warming will continue to dramatically affect the "global water cycle and its variability, global monsoon precipitation and the severity of wet and dry events."[4]

In regions like eastern North Carolina, home to the United States' top two pork producing counties,[5] producers will experience more regular hurricanes of greater magnitude.[6] California's Central Valley, which provides cropland for over 250 different crops[7] and houses 80 percent of the state's milk cows,[8] already relies on the second most over-pumped aquifer in the nation while facing substantially drier conditions as a result of climate change.[9] These impacts will disproportionately harm vulnerable populations[10] in addition to historically marginalized farmers, who will be the first to lose their livelihoods.[11] Climate change will force agriculture to adapt—either now, through innovation to mitigate increased warming, or later, as regional climates become incompatible with existing models of food production.[12]



It is clear that the food and agriculture sector will bear significant impacts from climate change, but this sector is also a major contributor of greenhouse gas (GHG) emissions. Animal agriculture, in particular, is responsible for approximately 20 percent of global GHG emissions and 57 percent of food related emissions.[13] Animal agriculture's primary contributions to climate change result from methane and nitrous oxide emissions. Methane has a global warming potential 28 to 36 times that of carbon dioxide on a 100-year timescale and nitrous oxide has a global warming potential 265 to 298 times that that of carbon dioxide on a 100-year timescale.[14] Moreover, while emissions from the energy sector have decreased as a result of emission reduction policies, GHG emissions from agriculture have increased over recent decades with this trend projected to continue.[15] Consequently, addressing emissions from agriculture is increasingly critical.

Percent of global greenhouse gas emissions caused by animal agriculture

Percent of global food-based emissions caused by animal agriculture

Percent of global methane emissions caused by livestock manure and enteric fermentation

One approach to reducing atmospheric GHGs from livestock involves capturing emissions from manure through the use of anaerobic digesters.[16] Proponents of this approach herald it as a win-win. Manure biogas systems reduce GHG emissions by capturing GHGs that would otherwise be emitted and can displace the use of fossil fuels. Additionally, this new fuel source (biogas) creates a new revenue stream from a former waste product. In a 2017 press release announcing federal funding to help farmers construct biogas systems, the United States Department of Agriculture (USDA) articulated the conventional wisdom of the emissions reduction claim, stating:

> "Anaerobic digesters actually provide two-fold greenhouse gas reduction. First, they capture methane that otherwise would be emitted from the manure into the atmosphere. . . . Second, by utilizing the trapped biogas as a renewable energy source, digesters displace the need for additional fossil fuels."[17]
>
> **– LAURA MELLING**

While these claims sound promising, they omit important nuance. **Animal agriculture generates emissions throughout the operation—from land conversion to enteric fermentation (the emissions generated from ruminant burps), to transportation.** It is imperative that policymakers and others recognize that manure biogas systems reduce emissions from only one part of this system—manure management. At the same time, manure biogas systems rely on the ongoing production of large quantities of livestock manure—the source of manure management emissions—to function. Espousing these systems to the exclusion of other emissions mitigation measures can foreclose the potential to make important modifications throughout the livestock life cycle. Ultimately, this reinforces current conventional models of livestock production at the expense of farmers using more sustainable production models.

Currently, policymakers are dedicating increasing amounts of public funding and attention to manure biogas as compared to other policy interventions that can reduce livestock emissions. Recently, the American Biogas Council suggested that the US could support at least another 13,740 potential new biogas systems, including 8,300 on farms, in addition to 4,000

What is Methane?

"Methane is produced as part of normal digestive processes in animals. During digestion, microbes resident in an animal's digestive system ferment food consumed by the animal. This microbial fermentation process, referred to as enteric fermentation, produces CH4 as a byproduct, which can be exhaled or eructated by the animal. The amount of CH4 produced and emitted by an individual animal depends primarily upon the animal's digestive system, and the amount and type of feed it consumes."

Source: Inventory of US Greenhouse Gas Emissions and Sinks (1990-2020), Environmental Protection Agency

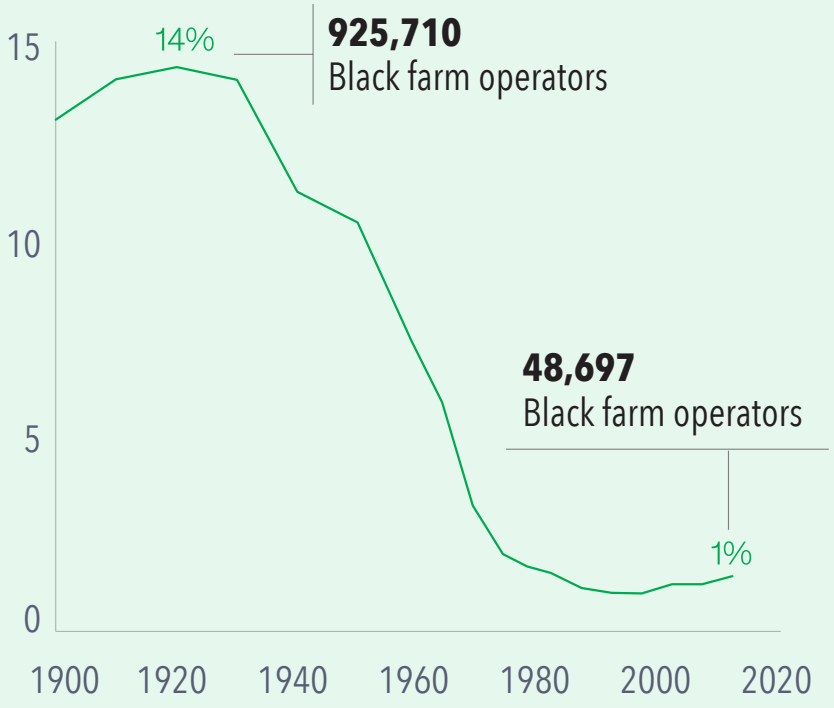
What is Enteric Fermentation?

"Enteric fermentation is fermentation that takes place in the digestive systems of animals. In particular, ruminant animals (cattle, buffalo, sheep, goats, and camels) have a large "fore-stomach," or rumen, within which microbial fermentation breaks down food into soluble products that can be utilized by the animal."

Source: AP-42: Compilation of Air Emissions Factors, Environmental Protection Agency

What are Biosolids?

"Biosolids are a product of the wastewater treatment process. During wastewater treatment the liquids are separated from the solids. Those solids are then treated physically and chemically to produce a semisolid, nutrient-rich product known as biosolids. The terms 'biosolids' and 'sewage sludge' are often used interchangeably."

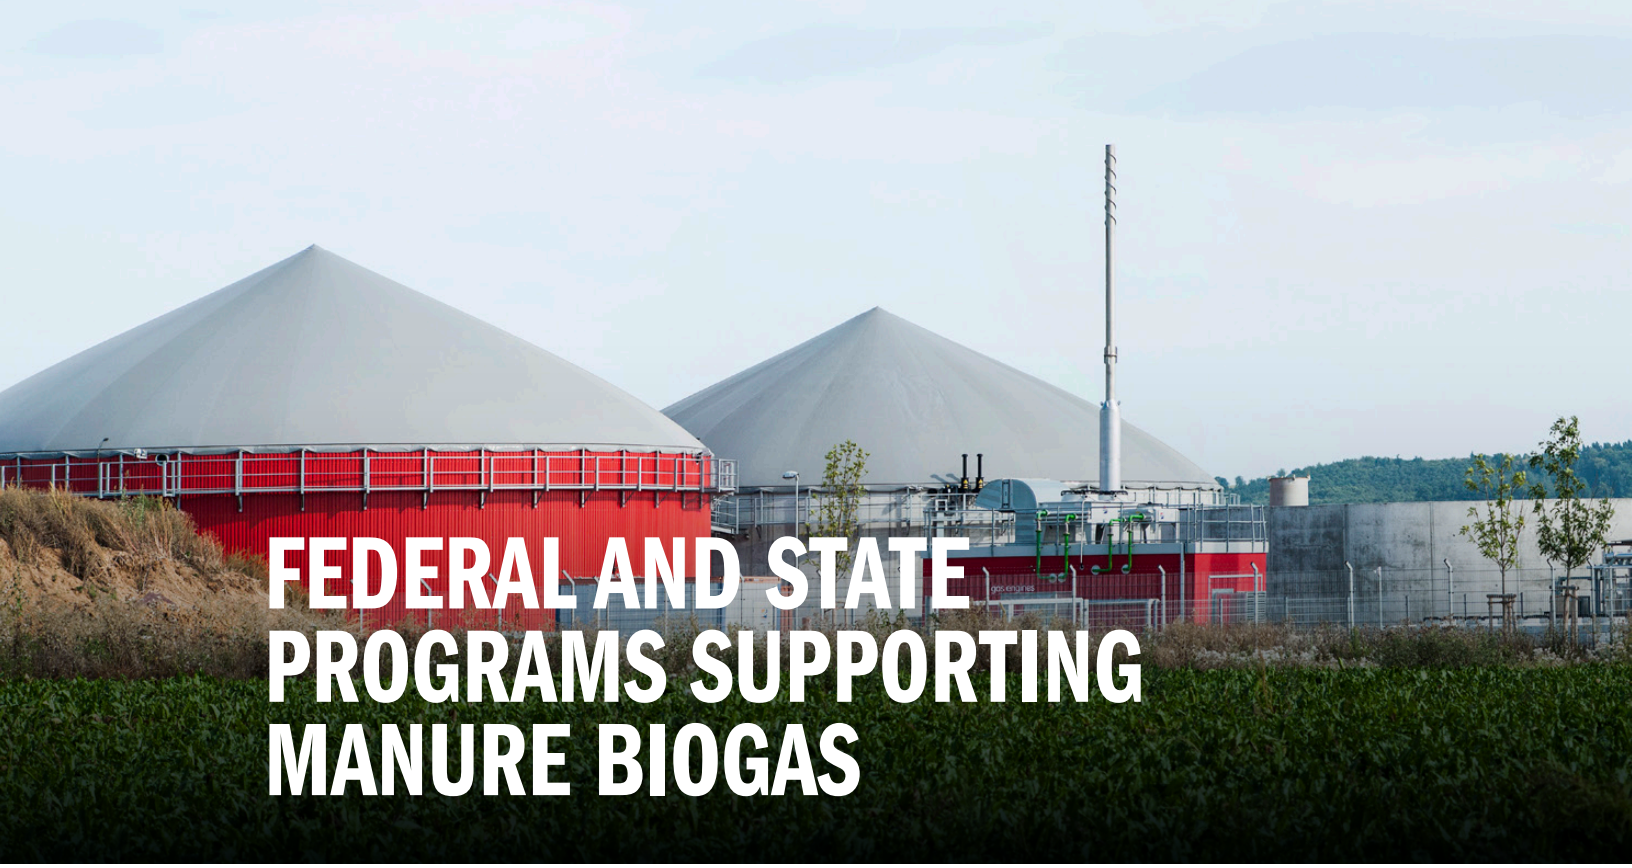


Source: Environmental Protection Agency

for wastewater, 1,000 for food scraps, and 440 for landfills.[18] Biogas systems are expensive to construct and operate. They require substantial investment into long-lasting, durable infrastructure such as pipeline interconnections and facilities upgrades. As more public and private resources are dedicated to this infrastructure, the incentives to continuing using these systems will increase.

To date, many discussions on the benefits of manure biogas fail to account for the concerning and negative implications associated with widespread adoption of manure biogas systems. For example, the climate implications resulting from the need for these systems to engage in long-term production of massive quantities of livestock manure (or other biosolids) to recoup the fixed upfront costs of installation and continued revenue generation is rarely addressed. To illustrate this point, the public programs subsidizing production and sale of biomethane from these operations provide incentives for the ongoing production of the core input—livestock manure—even as climate scientists warn that greater reductions from animal agriculture are necessary.[19] Promoting widespread investment in and adoption of manure biogas systems will inevitably impact livestock agriculture for years, if not decades, into the future, creating potential barriers for more substantial and systemic climate mitigation measures for the sector.

Moreover, because manure digesters are typically feasible only for industrial-scale livestock operations, the largest confined animal feeding operations will reap the financial and public relations benefits that accompany the installation of digesters. This is not a new trend: today and historically, large-scale commercial operations have benefited from the lion's share of federal funding for agriculture. Due to decades of discriminatory lending by USDA,[20] the majority of these operations are owned by white farmers.[21] Racism and discriminatory lending by the federal government over the past century has resulted in a dramatic loss of Black-owned land and farms across the board (one recent analysis calculated this dispossession to total $326 billion).[22] This disparity is even more pronounced for larger agricultural operations.[23] However, in some parts of the country, the substantial environmental impacts generated by these larger agricultural operations disproportionately harm Black, Indigenous, and communities of color.[24]



The share of Black farmers has declined significantly over the last century. Today just 1.4 percent of farmers identify as Black.

Source: Black farmers in the US: The opportunity for addressing racial disparities in farming, McKinsey & Company

Anaerobic digesters, in contrast to alternative mitigation measures, are an appealing means to reduce livestock emissions in industrial animal agriculture because they require no change to the structure of conventional livestock operations and manure management. On the contrary, these systems function by ensuring the continuity of both the existing system and its beneficiaries. This fails to consider and plan for the systemic changes needed in conventional operations and manure management due to the current, near, and long-term impacts of climate change.[25] Consequently, policymakers should immediately begin to proactively plan for the future by assessing the full range of suitable mitigation measures and supporting those that will provide for long-term sustainability and climate mitigation. As part of this process, policymakers must also critically evaluate the environmental justice impacts to neighboring communities and equity implications of elevating biogas systems over other mitigation measures.

This report analyzes and evaluates the extensive adoption and support of manure anaerobic digesters with a specific focus on the resulting equity implications, a goal explicitly aligned with two executive orders issued by the Biden Administration—Executive Order 14008: Tackling the Climate Crisis at Home and Abroad[26] and Executive Order 13985: Advancing Racial Equity and Support for Underserved Communities Through the Federal Government.[27] The report begins by surveying existing funding opportunities for manure biogas systems and the fuels they produce. It then addresses the direct environmental impacts of installing and operating these systems, including a brief discussion about the methodology used to account for life cycle emissions. The next section evaluates alternative methods to reduce livestock emissions, indirect environmental impacts of adopting manure biogas as the primary means to reduce GHG emissions from livestock operations, and the equity impacts. The report concludes with a set of recommendations for policymakers and regulators as they consider the role this technology should play in shifting livestock agriculture toward a more equitable, just, and climate-smart model.

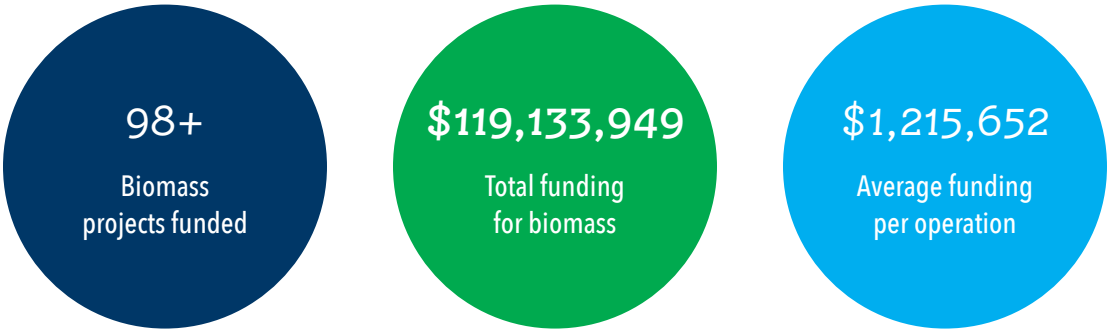
FEDERAL AND STATE PROGRAMS SUPPORTING MANURE BIOGAS

THE BIDEN ADMINISTRATION HAS CONSISTENTLY EMPHASIZED ITS COMMITMENT TO CLIMATE-SMART AGRICULTURE and tasked a number of federal agencies with collecting input from stakeholders and developing plans to address the climate crisis.[28] USDA was directed to submit a report to the administration laying out an "agricultural and forestry strategy."[29] In USDA's 90-Day Progress Report on Climate-Smart Agriculture and Forestry,[30] the agency embraced the president's "focus on developing a climate-smart agriculture and forestry strategy that employs proven conservation practices," announced plans to reduce methane from livestock,[31] and significantly funded research efforts targeted at these reductions.[32] With this new momentum, policy attention and interest in manure biogas has never been greater due to the perception that it provides an easy solution to reduce atmospheric emissions without requiring significant changes to the conventional industrial livestock model. This section surveys many of the existing and overlapping funding sources and incentive programs for manure biogas.

Grants & Loans Covering Start-Up Costs

Direct financial support for anaerobic digester systems is available to livestock facilities in the form of grants and loans. At the federal level, the Rural Energy for America Program (REAP) provides guaranteed loan financing and grant funding for the construction of biogas systems.[33] Federal funds for biogas systems can also be obtained through USDA's conservation programs—the Environmental Quality Incentives Program (EQIP), the Conservation Stewardship Program (CSP), and the newer Conservation Loan Program (CLP).[34] While these conservation and energy programs are the most important sources of federal funds for manure biogas, many other programs support the development of the industry. The 2018 Farm Bill's Energy Title alone includes the Biorefinery, Renewable Chemical, and Biobased Product Manufacturing Assistance Program;[35] the Bioenergy Program for Advanced Biofuels;[36] Biomass Research and Development Program;[37] the Biodiesel Fuel Education Program;[38] and the Carbon Utilization and Biogas Education Program.[39]

USDA encourages livestock operations to "stack" multiple programs. In 2015, USDA stated:



> To coordinate and maximize the potential assistance programs, Rural Development (RD) and Natural Resources Conservation Service (NRCS) met and developed a working partnership to deliver USDA services to producers interested in getting an anaerobic digester for their farming operation…. When "stacking," both RD and NRCS funding mechanisms can be used to assist in funding a project but each has limitations; for instance, the $450,000 cap on EQIP encompasses financial assistance for any practice that the producer wants to implement during the life of the Farm Bill.[40]

The report encourages the 50-50 use of EQIP and REAP funds and provides a detailed breakdown of estimated costs, where the two programs cover the total $1,778,950 required to construct the digester system.

Some states provide a similar suite of programs to fund the installation of manure biogas systems. In California, for example, the Dairy Digester Research & Development Program (DDRDP) provides funding for the installation of dairy digesters.[41] There are many smaller programs that offer grants, such as the Minnesota Department of Agriculture's Methane Digester Loan Program.[42]

The federal 1603 program, "Payments for Specified Energy Property in Lieu of Tax Credits,"[43] provides grants to reimburse businesses for a portion of the cost of installing certain energy projects, including anaerobic digesters on farms.[44] The 1603 program's creation as part of the American Recovery and Reinvestment Act in 2009 was "motivated by difficult economic conditions and the perceived lack of tax-equity capacity to support renewable energy projects" eligible for the tax credits discussed below.[45] While most 1603 funding has gone to wind and solar projects,[46] the program has provided funding for at least 98 projects designated "biomass (open loop, livestock)" for a total of $119,133,949.00 or an average of $1,215,652.54 per operation.[47]

1603 PROGRAM:
Payments for Specified Energy Property in Lieu of Tax Credits

Private investment is also available to livestock operations seeking funding to install digester systems. As public programs to subsidize manure biogas production proliferate, the industry has become increasingly appealing to private investors. A March 2021 report by Stifel Equity Research laid out the prospects for manure biogas as follows:

> We are bullish on the fundamentals of renewable natural gas (RNG) as it is positive for the environment (net negative carbon form of energy post-combustion), it is economic today (10-60 percent project IRRs), and offers immense growth potential (IEA projects an 18x increase in supply by 2040).[48]

The report noted that the current optimistic forecast for investors is closely linked to the enormous policy supports for this technology:[49]

> The combination of policy ([CA] Senate Bill 1383, requiring reductions in short-lived climate pollutants) and regulatory incentives (both federal and state) have driven the recent inflection in RNG growth. In our view, producers are not in the business of producing RNG; they are in the business of monetizing RNG's environmental attributes through various federal and state programs.[50]

Subsidies & Other Programs That Enhance Revenue from Biogas Sales

In addition to funding sources intended to help livestock operators cover the fixed costs of biogas system construction, state and federal programs subsidize the revenue from biogas production on an ongoing basis.

The Federal Renewable Fuel Standard (RFS), which requires transportation fuels sold in the United States to contain a minimum amount of renewable fuel (a "Renewable Volume Obligation"), is a key source of potential revenue for manure biogas operations. The RFS is a market-based program intended to reduce overall emissions from transportation fuels in the United States. It is structured like a cap-and-trade program, but rather than cap net GHG emissions, the RFS mandates a quota for the amount of renewable fuel that must be incorporated into conventional transportation fuels.

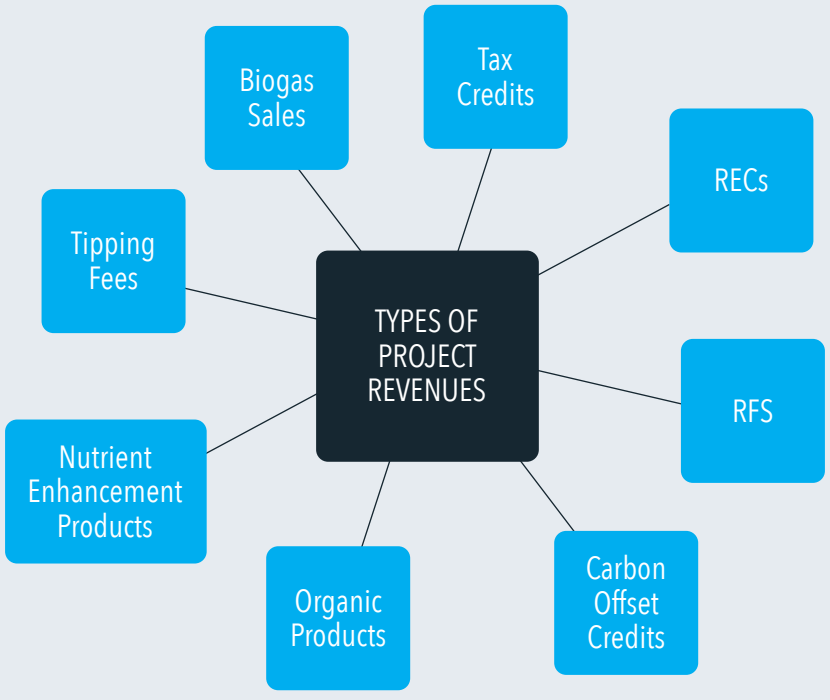
EPA measures the emissions impact of each eligible renewable fuel through the evaluation of fuel "pathways."[51] The pathway for each renewable fuel describes the inputs and processes required, as well as the life cycle GHGs.[52] Renewable fuel producers then apply to EPA for the specific pathways to which their fuel product corresponds. Once approved, these fuel producers can generate renewable identification numbers (RINs), which allow EPA to track and monitor these fuels.[53] Renewable fuels and their corresponding RINs can be sold to producers of conventional fuels so they can meet the quota required by the RFS. Biogas from manure digesters can be used to generate advanced biofuel RINs, coded D5 in the RFS regulation.[54] (77,000 British thermal units are equal to one gallon equivalent or one RIN.[55]) RINs are explicitly allowed to be layered on top of other analogous credits, such as those from California's Low Carbon Fuel Standard.[56]

Meeting the Federal Renewable Fuel Standard (RFS)

EPA measures the emissions impact of renewable fuels by evaluating their fuel "pathway," or the processes required to produce them. Biogas from manure digesters can be used to generate advanced biofuel renewable identification numbers (RINs).

Renewable fuel producers apply to EPA for their product's specific pathway.

Approved fuel producers generate RINs so EPA can track and monitor their fuels.



RINs can be sold to conventional fuel producers, allowing them to meet the Renewable Fuel Standard.

The federal Advanced Biofuel Payment Program also subsidizes biogas revenue. The program provides quarterly payments "for the actual quantity of eligible advanced biofuel produced during that quarter" to biofuel producers, including refined biogas from farms.[57] Entities that produce and sell biofuels, as defined in 7 CFR § 4288.102, can apply to participate in the program.[58] This program was granted $322,000,000 in mandatory funding between 2009 and 2023, in addition to $80,000,000 of discretionary funding authorized to be appropriated for the program between 2019 and 2023.[59]

In addition to direct payments, the federal government provides tax credits through the Electricity Production Credit and the Investment Tax Credit. Both corporate tax credits reduce energy producers' tax burdens, but while the Electricity Production Credit compensates producers on a per kilowatt-hour basis for renewable energy (including "open-loop biomass"), the Investment Tax Credit reimburses a set percentage of installation costs.[60] Importantly, taxpayers must choose either the Electricity Production Credit or the Investment Tax Credit—they cannot apply for both.

TYPES OF PROJECT REVENUES

Source: AgSTAR Project Development Handbook, Environmental Protection Agency

[61]

At the state level, the Biofuels Investment Tax Credit also allowed companies in Florida to recoup "75% of all capital, operation, maintenance, and research and development costs incurred in connection with an investment in the production, storage, and distribution of biodiesel (B10-B100), ethanol (E10-E100), or other renewable fuel" through 2016.[62] Additionally, industry groups tout California's Low Carbon Fuel Standard (LCFS) as a boon to the biogas industry's profitability.[63] The program creates a tradeable market for credits and deficits, which are allocated to transportation fuel producers based on the carbon intensity of the fuels they produce. Low carbon intensity fuels receive credits, while high carbon intensity fuels receive deficits. Like the federal RFS, California's LCFS program currently designates manure biogas as a negative emissions fuel and, consequently, awards profitable credits for its production.[64] This revenue is allocated to producers on an ongoing basis in proportion to the quantity of fuel they produce. Biogas producers that participate in the LCFS are also explicitly allowed to participate in California's cap-and-trade program, as well as the federal RFS. Like the stacking of USDA and DOE funds described above, layering multiple credits is explicitly described as a benefit.

Ultimately, however, the layering of credits from multiple market-based programs can undermine the additionality of emissions reductions claimed by those programs. Additionality is a term of art used to evaluate whether the policy intervention in question is in fact the cause of a given real-world behavior change. A behavior is not additional if it would have happened with or without the policy intervention. Compensating or crediting nonadditional behaviors, like the production of manure biogas, risks over-incentivizing them and even increasing rather than decreasing overall emissions. While California's LCFS is the most well-developed credit trading program for transportation fuels, other states are developing similarly structured programs, including Oregon's Clean Fuels Initiative program.

Finally, some states are creating reliable markets for these fuels as a source of "renewable energy" through utilities. Where renewable fuels standards like the programs described above focus on transportation fuels, renewable portfolio standards or renewable electricity standards focus on the use of renewable energy sources for electricity generation. These programs typically mandate that a certain amount of energy be derived from renewable sources and define what constitutes renewable sources for the purposes of the program. Much like the RINs in the federal renewable fuel standard, many renewable portfolio standards at the state level implement trading programs using renewable electricity certificates (RECs). State programs vary, but they usually include manure biogas as a renewable energy source.[65]

Considered collectively, these funds represent potential windfalls for operations well suited to the installation of manure biogas systems. But, smaller, less established operations, or operations that use dry manure management systems or grazing systems are unlikely to benefit from these funds, even though their models may be more climate smart overall in accord with the Biden Administration's stated goals and objectives.

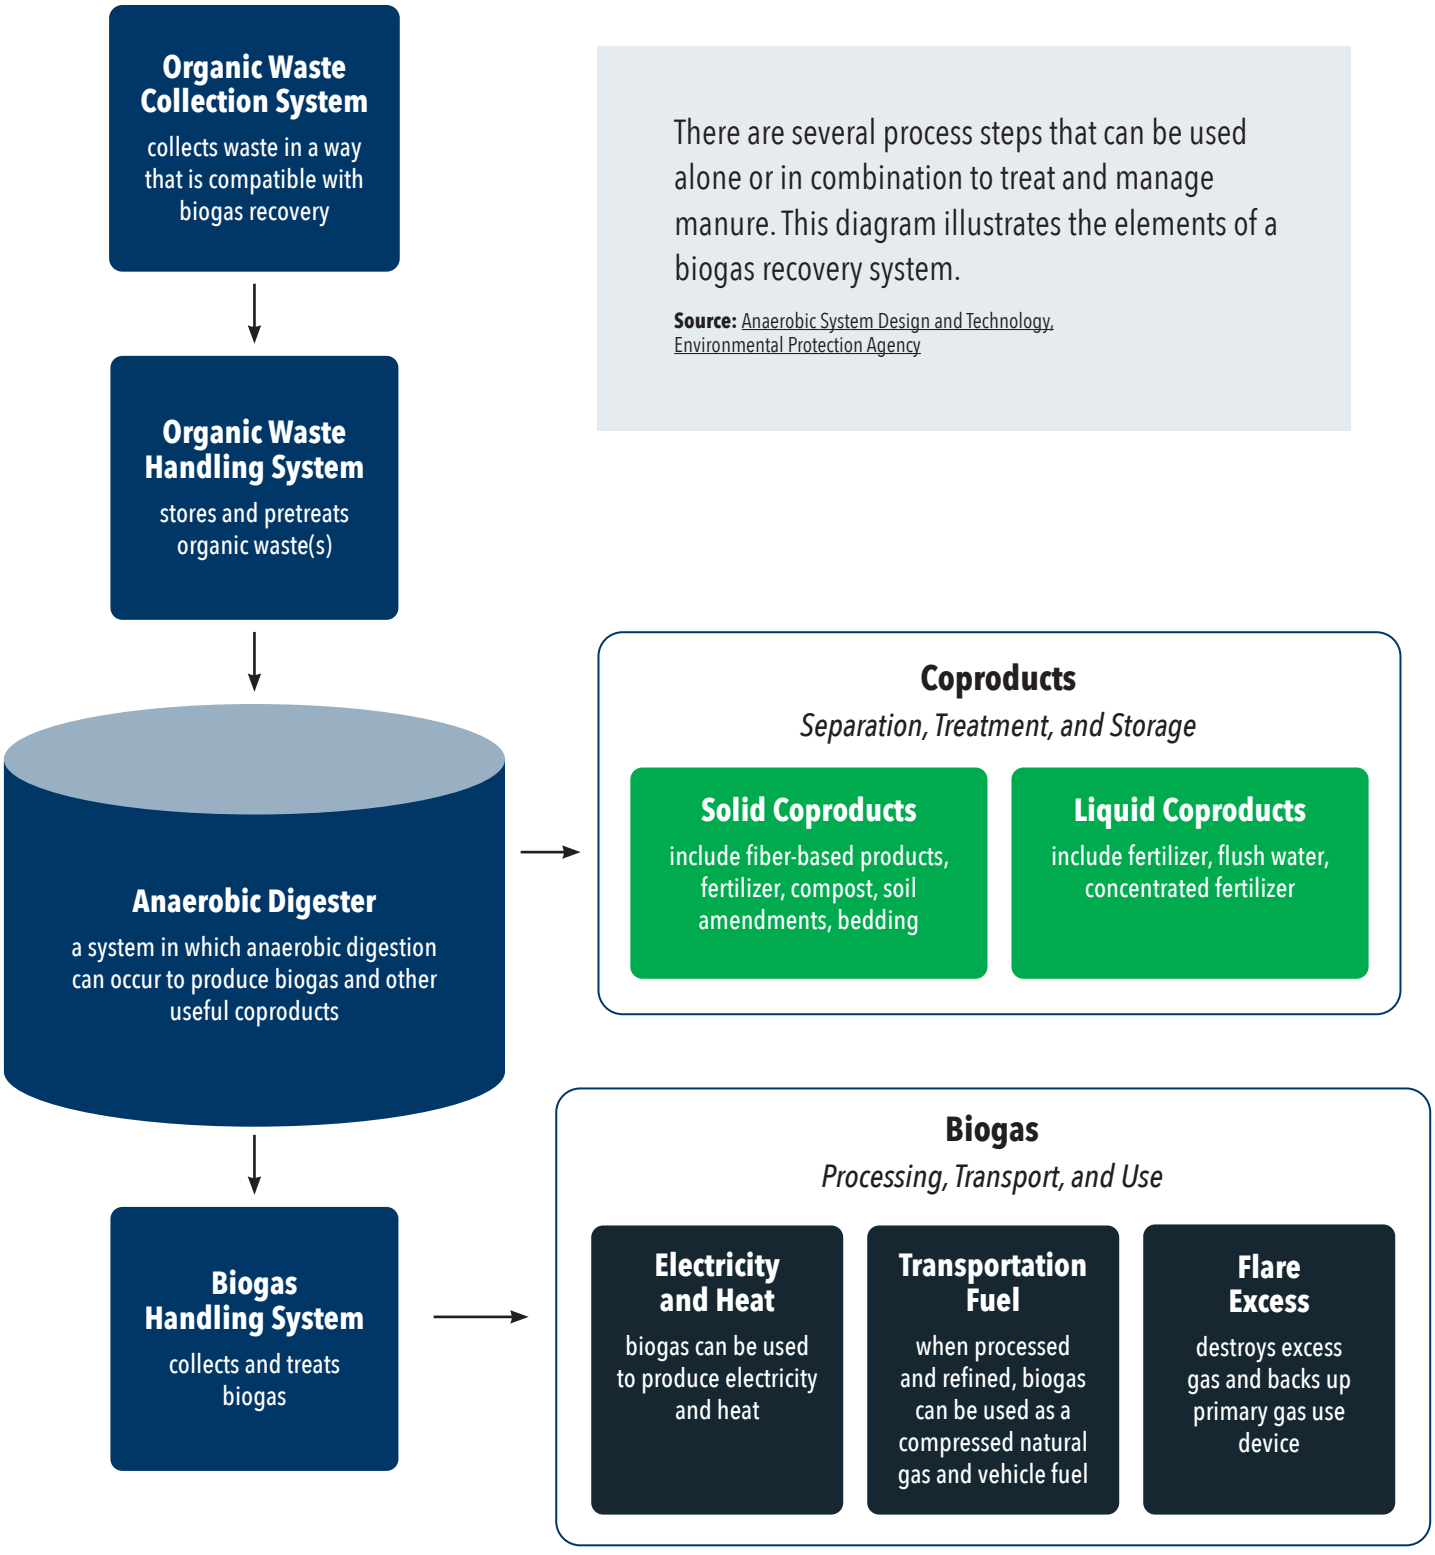
ANAEROBIC DIGESTERS CAN IMPOSE NEW ENVIRONMENTAL HARMS

TO PRODUCE BIOGAS FROM MANURE, farming operations must install an anaerobic digester, typically by capping or covering an existing manure lagoon to create an oxygen-free environment in which bacteria can break down organic matter. Biogas is a byproduct of this process. These systems offer some climate benefits (namely capturing methane and converting it to carbon dioxide during combustion) but their installation and use can also add new environmental harms. Such harms depend on a range of factors, including:



- the scale of the operations;
- the geography of the site;
- existing cumulative impacts to air and water;
- the end use of the biomethane; and
- the management of digestate (a byproduct of anaerobic digestion).

Through the process of anaerobic digestion, animal manure undergoes chemical changes that result in the production of a mix of gases, solid digestate, and liquid effluent. Biogas can be combusted to generate electricity on-site or exported as electricity and sold to the grid or at wholesale rates. The gases can be further "upgraded" to biomethane, which has a range of potential uses. Biomethane can be used on-site, injected into a pipeline, or used as a transportation fuel (when compressed to produce compressed natural gas).[66]

Through the process of anaerobic digestion, animal manure undergoes chemical changes that result in the production of a mix of gases, solid digestate, and liquid effluent.

Anaerobic System Design & Technology

There are several process steps that can be used alone or in combination to treat and manage manure. This diagram illustrates the elements of a biogas recovery system.

Source: Anaerobic System Design and Technology, Environmental Protection Agency

Biogas Systems Primarily Benefit Large Operations Using Liquid Manure Management Systems

Two of EPA's screening questions to evaluate a livestock facility's potential for anaerobic digester systems ask whether the operation is "large" and whether it uses a liquid manure management system.[67] To be financially viable, biogas recovery systems typically require manure from at least 2,000 hogs or at least 500 cows.[68] According to EPA, manure biogas projects are "most likely to succeed where manure is collected as a liquid, slurry, or semi-solid and stored in open pits, ponds, or lagoons" because liquid manure can be easily flushed into lagoons.[69] Dry manure management is more common on pasture-based operations, where there is no easy manure collection system. Industrial scale operations and liquid manure management tend to go hand-in-hand because very large facilities often cannot dispose of all of their manure safely through land application without exceeding the amount of nutrients the land can take up. Additionally, liquefaction makes manure management less costly where livestock is confined.[70] A major downside to the liquefaction of manure, however, is that it generates more GHG emissions, since the anaerobic conditions in manure lagoons produce additional methane.[71] A 2022 EPA report explains:

To be financially viable, biogas recovery systems typically require manure from at least 2,000 hogs or at least 500 cows.

> When livestock manure is stored or treated in systems that promote anaerobic conditions (e.g., as a liquid/slurry in lagoons, ponds, tanks, or pits), the decomposition of the volatile solids component in the manure tends to produce CH4 (methane). When manure is handled as a solid (e.g., in stacks or drylots) or deposited on pasture, range, or paddock lands, it tends to decompose aerobically and produce CO2 and little or no CH4.[72]

The same report tied growth in industrial animal agriculture operations that liquefy manure to the broader increase in manure-related methane and nitrous oxide emissions since 1990.[73] EPA concluded:

> In many cases, manure management systems with the most substantial methane emissions are those associated with confined animal management operations where manure is handled in liquid-based systems… The shift toward larger dairy cattle and swine facilities since 1990 has translated into an increasing use of liquid manure management systems, which have higher potential CH4 emissions than dry systems.[74]

Biogas Systems Require New Infrastructure

Depending on the desired end use of the refined biomethane produced by anaerobic digestion and subsequent refining, operations require a range of additional infrastructure. New infrastructure can introduce additional truck traffic or pipeline interconnections and result in significant wear to common infrastructure such as roads. Depending on how the biogas is to be used, on-site gas treatment systems may be necessary to process the gas accordingly. Temporary storage systems for biogas may also be required and excess biogas may need to be flared, or burned off, in some cases.

Biogas Systems Produce New Co-Pollutants & Exacerbate Existing Co-Pollutants

Anaerobic digestion creates a byproduct called digestate, which can be used as animal bedding or as fertilizer. Digestate is chemically different from the original manure. Digestate contains "more soluble plant nutrients due to mineralization and has less degradable biomass than the original substrate resulting in changes in GHG and NH3 emissions."[75] The method of storage and treatment of digestate can significantly impact the total GHG emissions from the biogas system, as well as co-pollutants like volatile organic compounds (VOCs) and hydrogen sulfide.

A 2017 study seeking to provide clarity on the emissions impact of anaerobic digestion (versus solid-liquid separation versus a combination of the two methods) found that anaerobic digestion alone resulted in an 81 percent increase in ammonia emissions during storage.[76] The authors concluded that anaerobic digestion could "significantly increase NH3 emissions from manure storage if manure covers are not implemented."[77] While ammonia is not a greenhouse gas, it

creates serious public health harms and degrades air quality.[78] The study also found that the nitrous oxide from digested separated solids "was much higher than separated solids without digestion," canceling out net GHG reductions.[79] This indicates that the simple adoption of manure biogas systems is not enough to ensure a net reduction in emissions from a given operation.

One study at a swine biogas facility in China took digestate to a research facility, stored it under controlled conditions, and then measured resulting emissions. The study identified 49 VOCs, 22 of which have been described as hazardous air pollutants by EPA. Of these 22 hazardous VOCs, "11 of these had relatively high concentrations . . . 8 were identified to be or likely to be carcinogenic, and 14 were identified to be harmful to other human organs or systems."[80] While most studies on VOCs from manure focus on the odor-causing compounds, the "proportion of hazardous air pollutants (32.77 percent) was shown to be considerably higher than that of odorous pollutants (5.15 percent)."[81]

Another study looked at manure under anaerobic conditions from two different dairy farms in Japan and found that hydrogen sulfide emissions vary considerably based on the mixing speed and frequency of disturbance of the stored manure as well as the manure's total solid content, temperature, and pH. For example, when stored at 18 degrees Celsius (64 degrees Fahrenheit), there was a sudden increase in the concentration of hydrogen sulfide (H_2S).[82] Additionally, "[the highest H_2S emissions were achieved at the fastest speed and longest duration of manure mixing."[83] Given that exposure to hydrogen sulfide is extremely dangerous and has been linked to death, the storage and treatment of manure and digestate is critical.[84]

New Impacts Must Be Evaluated in Analyses of Biogas Systems

These new impacts must be incorporated into analyses intended to evaluate the potential benefits of manure biogas systems. Unfortunately, such analyses often omit key considerations regarding co-pollutants, new infrastructure, and the environmental justice and equity implications associated with manure biogas systems. As stated above, the conventionally cited environmental benefit of manure biogas systems is a net reduction in atmospheric GHG emissions. Policy support for biogas systems rests on this reduction and as a result, life cycle analyses of manure biogas systems typically focus their impact evaluation on GHG emissions specifically and do not always address harms from co-pollutants or new infrastructure.

The metric typically used to quantify the environmental sustainability of a product or service is life cycle analysis (LCA). The goal of LCA is to provide a comprehensive view of environmental impacts to help decision-makers identify the effect of a given good or service. LCAs estimate

To properly account for the full life cycle emissions, any manure biogas LCA should include the storage and disposal of digestate, as well as the emissions generated in the production of manure, that is, the emissions resulting from raising the livestock in question.

the cumulative environmental impacts resulting from all stages of a product, process, or service through the life cycle, from raw material acquisition, manufacturing, use/reuse/maintenance, to recycling/waste management.[85] Programs like the Federal Renewable Fuel Standard and California's Low Carbon Fuel Standard, described above in part II, rely on life cycle assessments to determine the life cycle GHG emissions of participant fuels, including those derived from manure biogas systems. Both EPA and the California Air Resources Board use versions of the Greenhouse Gases, Regulated Emissions, and Energy Use in Transportation (GREET) life cycle analysis model which is designed for transportation fuels.[86]

System boundaries mark the beginning and end of the process or life cycle in question. Consequently, the boundaries and assumptions used in the LCA model are critical. For example, an LCA that excluded emissions related to digestate would not fully account for life cycle emissions of manure biogas. To properly account for the full life cycle emissions, any manure biogas LCA should include the storage and disposal of digestate, as well as the emissions generated in the production of manure, that is, the emissions resulting from raising the livestock in question.

When produced at an industrial scale, animal manure can create severe environmental harms and adverse impacts to public health. The impacts of manure include water contamination, air pollution, and foul odor (which can degrade quality of life for neighboring communities and decrease property values), in addition to GHG emissions. Manure biogas systems capture some of the emissions from livestock facilities, but fail to address the co-pollutants associated with manure production while also producing new co-pollutants from the processing and storage of the resulting digestate, as discussed above. Multiple toxic pollutants, including VOCs, ammonia, endotoxins, particulate matter, and bioaerosols are linked to large-scale industrial confined animal feeding operations.[87] To the extent that anaerobic digestion technology maintains or even expands the model of concentrated industrial animal agriculture, it can perpetuate and even increase resulting public health harms.

In many parts of the country, these impacts disproportionately harm Black, Indigenous, and low-income communities. Multiple disparity analyses (and resulting civil rights complaints submitted to regulators) have challenged states' approaches to the regulation of industrial animal agriculture. One recent complaint filed with EPA's External Civil Rights Compliance

"These harms disproportionately affect Black and Latinx people living near the Hog Operations, and it is these communities who will suffer most if pollution from the Hog Operations worsens, as is expected with the Permits. Decades of research–including research reviewed by this office–demonstrate how the lagoon and sprayfield waste management system authorized by the Permits pollute rivers, streams, and air quality throughout eastern North Carolina. Despite this, and despite evidence indicating the increased risk of pollution and adverse health impacts to nearby residents from the increases to harmful hog waste pollutants resulting from biogas production, DEQ issued the Permits without addressing these harms. This is unacceptable and a violation of federal law." – SELC complaint to EPA, 2021

Source: Southern Environmental Law Center

Office under Title VI of the Civil Rights Act alleged that North Carolina's new general permit for manure biogas exacerbated existing discriminatory impacts of the livestock industry in the state.[88] The complaint alleges that the North Carolina Department of Environmental Quality's new general permit for biogas systems on confined animal feeding operations "authorizes not only the continued use of the discriminatory lagoon and sprayfield system, but also the use of anerobic digesters and uncovered 'secondary' lagoons, which will exacerbate the underlying system's impacts on communities of color."[89] This complaint follows another civil rights complaint addressing the discriminatory harms of the hog industry in North Carolina, to which EPA responded with a letter expressing "deep concern."[90]

Typical Pollutants Found in Air Surrounding CAFOs

CAFO EMISSIONS	SOURCE	TRAITS	HEALTH RISKS
Ammonia	Formed when microbes decompose undigested organic nitrogen compounds in manure	Colorless, sharp pungent odor	Respiratory irritant, chemical burns to the respiratory tract, skin, and eyes, severe cough, chronic lung disease
Hydrogen Sulfide	Anaerobic bacterial decomposition of protein and other sulfur containing organic matter	Odor of rotten eggs	Inflammation of the moist membranes of eye and respiratory tract, olfactory neuron loss, death
Methane	Microbial degradation of organic matter under anaerobic conditions	Colorless, odorless, highly flammable	No health risks. Is a greenhouse gas and contributes to climate change
Particulate Matter	Feed, bedding materials, dry manure, unpaved soil surfaces, animal dander, poultry feathers	Comprised of fecal matter, feed materials, pollen, bacteria, fungi, skin cells, silicates	Chronic bronchitis, chronic respiratory symptoms, declines in lung function, organic dust toxic syndrome

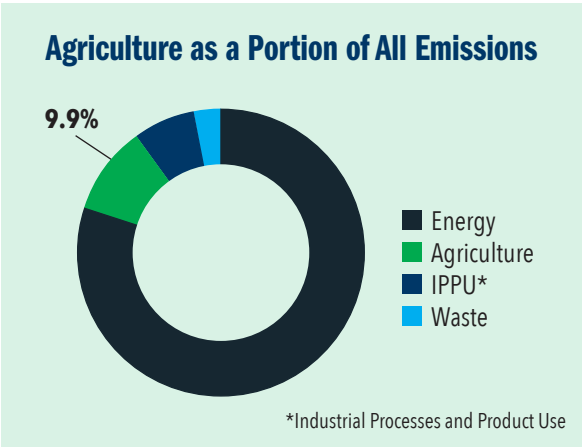
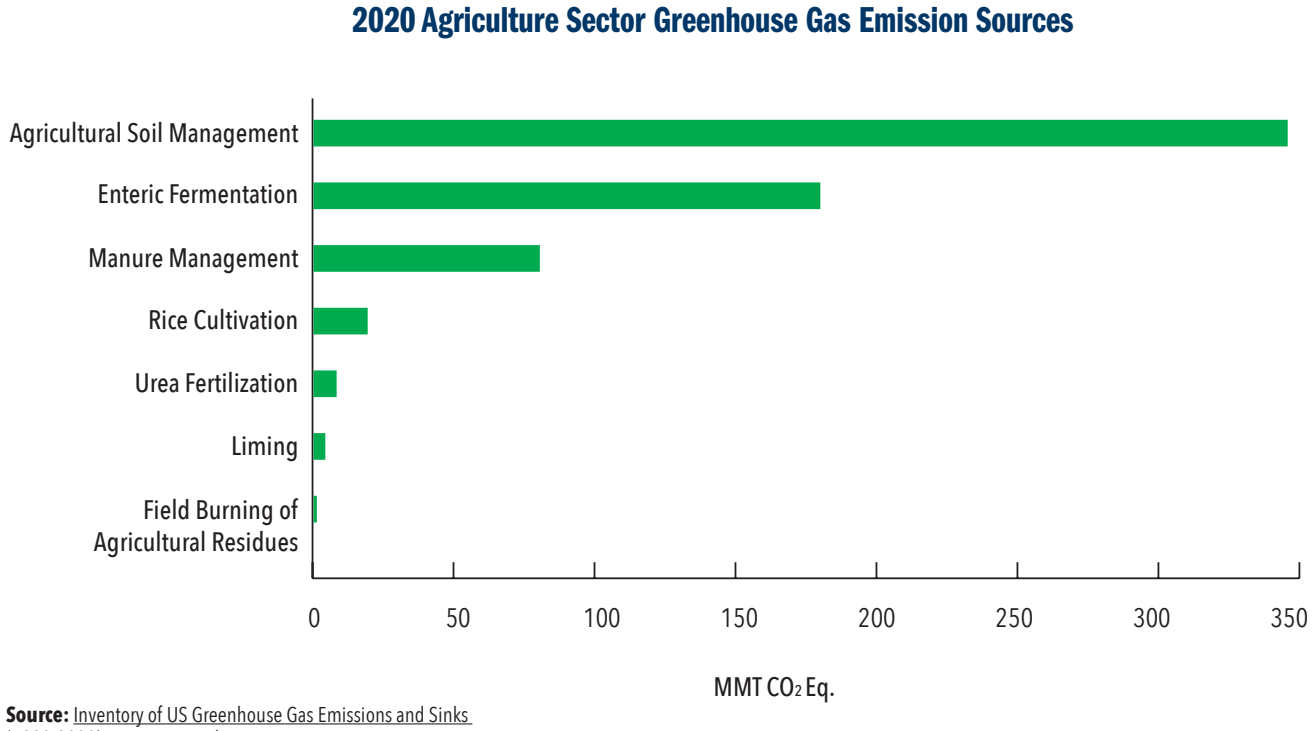
INVESTING IN MANURE BIOGAS SYSTEMS REWARDS THE LARGEST FACILITIES AND MAINTAINS THEIR UNSUSTAINABLE MODEL

THE SHEER NUMBER OF PROGRAMS designed to support the installation and operation of manure biogas systems on livestock operations presents two important questions. First, are these programs necessary to obtain the intended climate benefits of biogas systems and to what extent do they contribute to an overall emissions reduction? Second, what are the opportunity costs of the intense focus on this one method of reducing livestock emissions, given the range of alternatives? The fact that alternatives exist, coupled with the requirement that manure production continue at staggering rates to ensure the productivity of manure biogas systems calls into question whether it is prudent to focus policy efforts on a single solution.

Biogas Systems May Not Reduce Overall Emissions



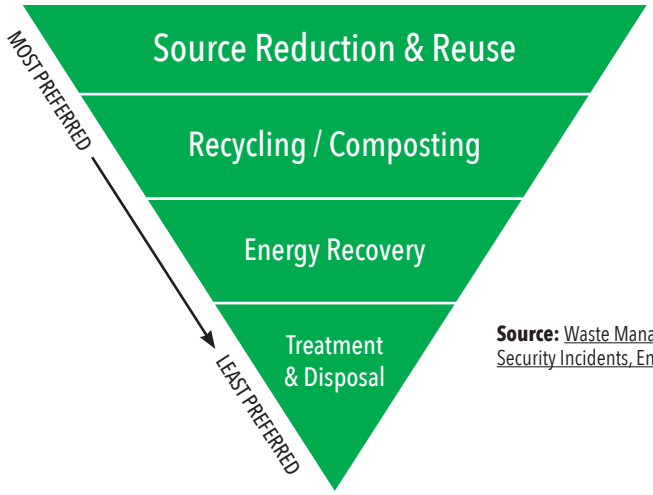
Anaerobic digesters are designed to capture (and monetize) methane and other gases that would otherwise be emitted into the air from manure lagoons. However, *capturing* emissions does not avoid or reduce emissions at the source. Reducing emissions at the source would entail significant changes in livestock production systems. Digester systems are sometimes described as stopgap measures—a means to reduce emissions quickly in the absence of developing or implementing alternative measures. However, climate science demonstrates that significant reductions at the source are required in the next decade. Investing in expensive durable infrastructure that requires ongoing manure production at current rates without emissions reductions fails to meet this imperative.



Because manure biogas systems capture rather than reduce emissions, these systems **require the ongoing generation of GHG emissions** to be financially viable. The digester's function is to capture the emissions, so the system breaks down if emissions are reduced at the source. Producers must continue to generate manure at scale for the facilities to remain financially sustainable. The large upfront investment in these systems then fixes the current numbers and concentration of livestock at facilities where they are installed, despite the range of harms

Photo source: Ag Partners, Hartley, Iowa by TumblingRun is licensed under CC BY-NC-ND 2.0.

generated by such concentrated operations. Simultaneously, the new subsidized revenue streams support the ongoing generation of manure at scale. This outcome is sharply at odds with the prescriptions of climate scientists and the Biden Administration's stated climate goals.



Additionally, while anaerobic digesters capture manure methane from lagoons, they do not capture greenhouse gas emissions before or after this point. The emissions from manure management that can be targeted by digesters make up 9.2 percent of total methane emissions from anthropogenic activities, while emissions from enteric fermentation, which remain untouched by digester systems, make up 26.9 percent.[91] In contrast, other interventions in the industrial animal agriculture system, including alternative methods of manure management and changes to animals' diet, address emissions throughout or at various points in the process of raising livestock. Importantly, a significant portion of livestock GHG emissions result from the decision to liquefy manure.[92] Some manure management emissions can be avoided by using dry manure management systems, as many farmers do. Capturing GHG emissions should be a last resort option after other alternatives have been pursued to avoid

Source: Inventory of US Greenhouse Gas Emissions and Sinks (1990-2020), Environmental Protection Agency

Waste Management Hierarchy

Source: Waste Management Hierarchy and Homeland Security Incidents, Environmental Protection Agency

or reduce emissions. This tracks with other federal policy efforts and priorities, as reduction is the management method at the top of EPA's waste management hierarchy for decision-making (organized from least to most detrimental to human and animal health and the environment).[93]

Alternative measures to reduce methane emissions from animal agriculture are available and feasible. Manure management systems generally include processes for the collection, transfer, storage, and sometimes treatment and end-use of manure.[94] Alternatives are available at each point along the way. At the initial collection stage, operations can opt for dry-scrape systems, rather than the flush systems typically used for lagoons. Dry scrape systems use mechanical scrapers to move manure into holding pits.

Livestock operations can also be designed as pasture-based, rather than confinement. On pasture-based operations, manure is typically left on pasture and produces minimal methane.[95] Pasture-based operations that rely primarily on grazing for animals' nutrition can also avoid emissions associated with the production and transportation of the feed used on confinement operations[96] and can potentially provide carbon sequestration benefits if grasslands and grazing are properly managed.[97] At the storage stage, operations can employ solid-liquid separation rather than flushing all liquefied manure directly into a lagoon. Once liquids have been separated out, manure solids can be composted.[98] A technical report prepared for the California Air Resources Board concluded that, in addition to manure biogas system installation:

> Methane emissions from lagoon storage systems can be decreased by reducing the amount or modifying anaerobic storage (i.e. solids separation and diversion from lagoon, modifying dominant flush collection to manure scraping with drying/composting or other lagoon diversion, etc.), aerating the lagoon (to reduce or eliminate anaerobic conditions).[99]

These are viable methods of manure management that would avoid, rather than simply capture, at least some emissions associated with open-air lagoons of liquid manure.[100] Many livestock operations already employ these lower-emissions practices. Unfortunately for them, however, smaller operations, pasture-based operations, or operations that have a more sustainable business model of dry manure management will not benefit from the significant public funds currently being channeled to biogas-eligible facilities. This sets a perverse precedent of neglecting historically good actors while rewarding the worst polluters in the livestock industry with new revenue and fodder for positive public relations.

Tied to the claim that biogas systems reduce emissions is the argument that the use of manure systems displaces the use of fossil fuels. An empirical analysis of this claim is beyond the scope of this report. However, regulators and policymakers should carefully consider the climate value of replacing fossil fuels with the combustion of biomethane, especially for the magnitude of public funds invested in this displacement. Renewability does not necessarily mean that a fuel is sustainable or climate friendly.[101]

Biogas Systems May Not Generate Revenue & "Design Out Waste"

Another important consideration is whether manure biogas systems really generate revenue and "design out" waste. This reflects a broader trend in policy prescriptions, sometimes referred to as the "circular economy," that seeks to "design out" waste from various industrial life cycles.[102] Proponents of the circular economy use the phrase "designing out" manure or any other waste product to mean that the waste is made profitable through other industrial processes. Unlocking new profits from waste,[103] however, does not necessarily entail any changes to the processes of waste generation or to any environmental or public health harms that arise from these processes.

In the case of manure biogas systems, manure is still produced, liquefied, and transported to manure lagoons—it must be for the biogas system to function. Anaerobic digestion does not make the manure vanish, it produces digestate. As discussed above, digestate has industrial uses, as fertilizer, for example, but also carries many of the same potential environmental harms as manure. Therefore, while it is correct to say that manure biogas systems access the potential economic value of manure as a fuel source, the waste does not disappear and can continue to cause environmental and public health harms, before, during, and after (as digestate) the process of anaerobic digestion.

While it is correct to say that manure biogas systems access the potential economic value of manure as a fuel source, the waste does not disappear and can continue to cause environmental and public health harms, before, during, and after (as digestate) the process of anaerobic digestion.

The massive quantities of manure produced at industrial scale livestock facilities can and do cause serious environmental, quality of life, and public health harms to neighboring communities. These harms do not cease to exist upon the addition of an anaerobic digester. In fact, while proponents of biogas systems sometimes argue that capping lagoons can address these issues, impacted environmental justice communities around the country have organized against the proliferation of biogas because it is viewed as maintaining and supporting a harmful system.[104]

Beyond the Baseline: Evaluating Mitigation Measures Against Policy Alternatives

The climate benefits associated with greater public resources devoted to expanding manure biogas production can only be evaluated relative to other available policy options. Such policy options cannot be limited to a business-as-usual scenario, which the scientific community has made clear is untenable. Regulators currently consider the displacement of fossil fuels when evaluating the benefits associated with these systems, but they must also consider the alternative emissions reduction strategies that are displaced now and into the future upon investment in large-scale manure biogas systems.

Unfortunately, conventional win-win claims break down when framed in the broader context of policy mechanisms available to address emissions from livestock. This is attributable to the many alternative approaches to reducing emissions from livestock facilities, some of which could reduce emissions throughout the life cycle, instead of those emitted only from

manure lagoons. The Biden Administration's plan to reduce methane names several of these alternatives, including installing "solid separators that reduce methane-producing slurries; providing conservation assistance for transitions to alternative manure management systems, such as deep pits, composting, transitions to pasture, or other practices that have a lower greenhouse gas profile."[105] Despite the administration's support of reducing methane-producing slurries on paper, funding for manure biogas systems that require methane-producing slurries to function continues to dwarf alternatives.

While it is unreasonable to expect a single policy mechanism or technology to solve all problems, there are viable alternative manure management practices and policy mechanisms to decrease emissions as well as co-pollutants in a more equitable manner. Currently, however, these programs are not being funded at nearly the same rate as manure biogas. In California, for example, the Alternative Manure Management Program (AAMP) has been funded at roughly half the rate of the Dairy Digester Research & Development Program (DDRDP) in recent years.[106]

In addition to a broad evaluation of each of these alternative mechanisms and potential policy mechanisms to promote them, it is essential to note the reason policy incentives are strictly necessary in this case—industrial livestock operations have historically been essentially exempt from any regulation of GHG emissions. It is, in fact, only this absence of regulation that makes the calculation of emissions reductions from the addition of digesters so high. The primary alternative policy mechanism should be to treat industrial livestock operations like every other industry in the country and regulate the emissions they externalize to the detriment of the public—the primary funders of manure biogas systems. Regulators should actively support farmers that engage in climate-friendly practices less likely to harm neighboring communities.

In the United States, livestock agriculture has dramatically shifted toward "large scale industrialized production systems."[107] As a result, livestock operations are producing more manure in centralized regions.[108] The storage, transportation, and land application[109] of this waste poses serious environmental risks, in addition to the GHG emissions from other parts of the livestock life cycle. Methane emissions from livestock manure are significant, but experts note that the trade-offs associated with manure management options, including the use of biodigesters, are not well studied and have not been proven to be "climate smarter."[110]

While it is unreasonable to expect a single policy mechanism or technology to solve all problems, there are viable alternative manure management practices and policy mechanisms to decrease emissions and co-pollutants in a more equitable manner.

POLICY RECOMMENDATIONS AND CONCLUSION

LIVESTOCK OPERATIONS' IMPACT ON CLIMATE CHANGE presents an opportunity for a real win-win: the US can develop policies that reduce GHG emissions from these facilities—as is required in order to mitigate the substantial impact of livestock agriculture on the climate—while simultaneously reducing the additional environmental harms many such facilities externalize into local communities. In many cases, have a discriminatory impact on the basis of race. These prerogatives are well aligned with the Biden Administration's Climate Smart Agriculture policy, Executive Order 14008, and Executive Order 13985.[111] Specifically, policymakers should consider the following:

USDA must ensure that recipients of its funding are in compliance with Title VI of the Civil Rights Act of 1964. This includes ensuring that state agencies that receive USDA funding and implement programs supporting manure biogas are developing such policies in a manner that does not disproportionately benefit white operators or disproportionately harm nearby communities on the basis of race, national origin, or color.

Evaluate USDA's programs to ensure that they do not have a disproportionate impact on the basis of race, national origin, or other protected class.

Properly account for the full climate impacts of manure biogas and ensure that emissions life cycle analyses consider the full range of upstream and downstream emissions in the manure biogas life cycle.

Move beyond business-as-usual as a point of comparison for manure biogas, which does not ensure a viable climate-smart future. The point of comparison should be the range of policy alternatives to biogas promotion, including the regulation of methane from agricultural operations.

Properly account for the full impacts of policies supporting manure biogas, including environmental, public health, and quality of life impacts from co-pollutants caused by manure.

Ensure a just transition for all, including for livestock farmers. Policy should ensure that farmers and farmworkers can make viable livelihoods while transitioning to more sustainable models.

Evaluate the efficacy of overlapping programs to ensure that public funds for manure biogas are effectively promoting new emissions reductions.

101 Renewability describes an energy source that is replenished over time. However, even renewable sources can contribute to climate change or impose environmental harms. For example, wood pellets used as biomass may technically be renewable but the . Similarly, a solar array may provide renewable energy and climate benefits but cause other environmental harms by destroying habitat. Policymakers evaluating a given energy source should be vigilant to avoid the all-too-common slippage between "renewable" and "climate-friendly" in order to properly identify the costs and benefits of a given intervention.

- **Discussion**

BCAs of water quality regulations are typically very incomplete

- BCAs of water quality regulations typically show monetized benefits < costs
- Many have pointed out important missing benefit categories
  - Health effects, existence values, non-standard pollutants, benefits to coastal and groundwaters from nutrient management policies (Keiser et al., Griffiths et al.)
- GHG emissions reductions from lakes are another benefit from nutrient management that has been ignored to date

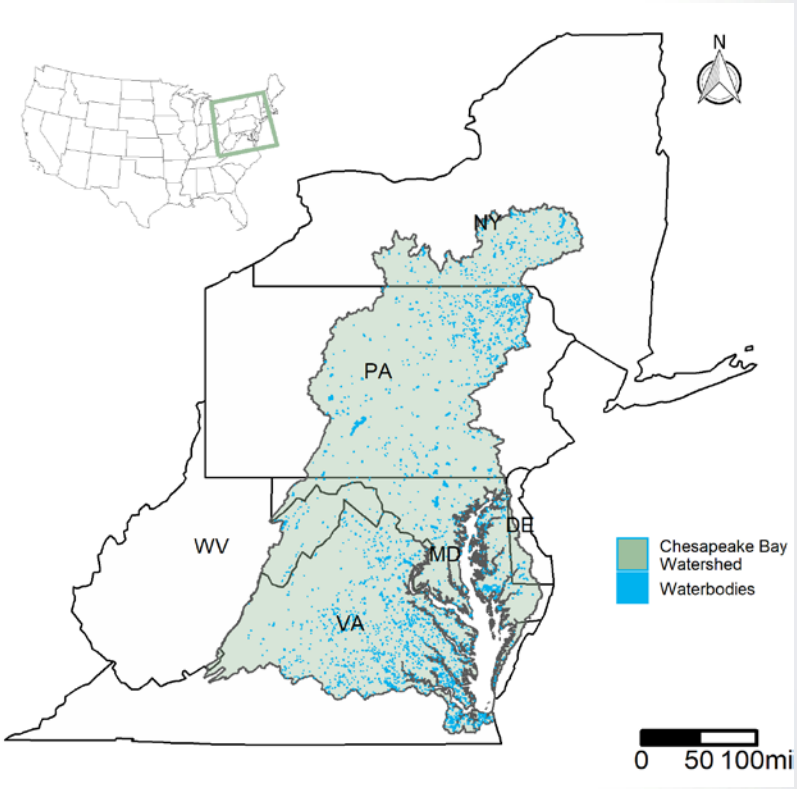
Case study: Chesapeake Bay TMDL

Objective

- **Monetize the climate benefits of a water quality regulation**

Chesapeake Bay Total Maximum Daily Load



- **Reduce nitrogen loads to Bay by 25%**
- **Reduce phosphorus loads to Bay by 24%**

Watershed Implementation Plans (WIPs)

- **Included management practices for agriculture, urban stormwater, and point sources**

Lake Benefits

- **As part of the stated preference benefits estimation, EPA modeled changes in nutrient loads and trophic status for over 4,200 lakes in the watershed**

GHG Emission Reductions in GWP

CH_4 GWP is 28x that of CO_2
N_2O GWP is 265 times that of CO_2

Climate Benefits of GHG Reductions

- We monetize the social benefits of GHG emissions reductions using estimates of the social cost of carbon (SC-CO_2), social cost of methane (SC-CH_4), and social cost of nitrous oxide (SC-N_2O)
  - Collectively referred to as "social cost of greenhouse gases" (SC-GHG)

- The SC-GHG is the monetary value of the net harm to society associated with an incremental increase in emissions of that GHG in a given year (and conversely, the benefits for an incremental decrease).
  - This is how benefits of GHG reductions are valued in benefit-cost analysis.

- We use SC-GHG estimates based on the same methodology underlying the USG's interim SC-GHGs developed under Executive Order 13990 (issued in February 2021).
  - We use SC-GHG estimates for 2030 based on 2% and 3% discount rates.

2030 Climate Benefits of the Chesapeake Bay TMDL

	CO_2	CH_4	N_2O

Industrial Swine and Poultry Production Causes Chronic Nutrient and Fecal Microbial Stream Pollution

Abstract Concentrated animal feeding operations (CAFOs) are the principal means of livestock production in the USA and Europe, and these industrial-scale facilities have a high potential to pollute nearby waterways. Chemical and biological stream water quality of a swine and poultry CAFO-rich watershed was investigated on 10 dates during 2013. Geometric mean fecal coliform counts were in the thousands at five of seven sites, especially in locations near swine waste sprayfields. Nitrate concentrations were very high and widespread throughout the watershed, with some individual samples yielding >10 mg-N/L. Ammonium concentrations were likewise high, but greatest near swine waste sprayfields, ranging up to 38 mg-N/L. Five-day biochemical oxygen demand (BOD5) concentrations exceeded 10 mg/L in 11 of 70 stream samples, reaching as high as 88 mg/L. BOD5 concentrations were significantly correlated with components of animal waste including total organic carbon, ammonium, and phosphorus, as well as the nutrient response variable chlorophyll *a*. The degree of nutrient and fecal contamination did not significantly differ between rainy and dry periods, indicating that surface and groundwater pollution occurs independently of stormwater runoff. This research shows that industrial-scale swine and poultry production leads to chronic pollution that is both a human health and ecosystem hazard. There are approximately 450,000 CAFOs currently operating in the USA, with the majority located in watersheds feeding major riverine and estuarine systems with known water quality problems. Current US waste management protocols for this widespread system of livestock production fail to protect freshwater and estuarine ecosystems along the US Mid-Atlantic, Southeast and Gulf coasts, and expansion into industrializing nations will likely bring severe pollution with it.

1 Introduction

Industrial-scale livestock production is the most common and widespread means of swine and poultry production in the USA and Europe (Thu and Durrenberger 1998; Thorne 2007) and occurs within facilities known as concentrated, or confined, animal feeding operations (CAFOs). The USEPA (2014) defines large CAFOs as containing ≥1000 head of beef cattle, 2500 swine >25 kg, 10,000 swine <25 kg, 125,000 chickens, 82,000 laying hens, or 55,000 turkeys. Large-scale production of livestock in CAFOs involves shipping in vast quantities of feed from elsewhere (often from other states) which results in the deposition of large amounts of excretory nitrogen, phosphorus, organic matter, and fecal microbes in the watershed where the CAFO is located (Cahoon et al. 1999; Mallin and Cahoon 2003). Waste generated by swine in CAFOs is hosed

through slats in the floor of confinement buildings and is drained or pumped outdoors into a cesspit which the industry calls a "lagoon." Periodically, the liquid waste supernatant of lagoons is pumped out and sprayed onto surrounding fields (i.e., sprayfields), which are planted with a cover crop such as Bermuda grass to absorb excess nutrients. Poultry waste is usually collected as dry litter, mixed with straw, and spread on neighboring fields; some CAFOs containing laying hens use the lagoon system. However, the production of vast quantities of animal manure within watersheds can overload the ecosystem's capacity to dilute and process such waste (Carpenter et al. 1998; Weldon and Hornbuckle 2006). According to the USEPA (2014), there are approximately 450,000 CAFOs in the USA, unevenly distributed with the vast majority concentrated in a few states. While inventory and sales vary year to year, the largest swine-producing states include Iowa, North Carolina, Minnesota, Illinois, and Nebraska; the largest broiler chicken producers include Arkansas, Alabama, Mississippi, North Carolina, and Texas; and the largest turkey producers include North Carolina, Arkansas, Minnesota, Missouri, and South Carolina (USDA 2014a). This investigation did not include cattle CAFOs; however, cattle production is especially large in Texas, Nebraska, Kansas, Oklahoma, Iowa, Mississippi, and Wisconsin (USDA 2014a). The CAFO system has currently expanded beyond the USA and northern Europe into Eastern Europe and South America (Thorne 2007).

Serious human health (Cole et al. 2000; Wing and Wolf 2000) and environmental impacts (Campagnolo et al. 2002; Burkholder et al. 2007) of industrial animal production have been documented by researchers, including water quality impacts. The acute polluting impacts of large-scale accidents and hurricanes involving CAFO waste on freshwater streams and estuaries have been well documented (Burkholder et al. 1997; Mallin 2000; Mallin et al. 1999). The location of many CAFOs on river and stream floodplains renders receiving water vulnerable to such accidents, especially during major storms (Wing et al. 2002). CAFOs have been cited as supplying excessive nitrate to Midwestern streams in Ohio and Iowa (Weldon and Hornbuckle 2006; Hoorman et al. 2008). Karr et al. (2001) were able to trace nitrogen that was derived from CAFOs several kilometers downstream using isotopic techniques. A broad-scale study found that streams whose watersheds contained swine and poultry CAFOs had significantly higher concentrations of ammonium, nitrate, and total N than streams whose watersheds lacked CAFOs (Harden 2015). Additionally, the deposition of manure and urine in storage lagoons and on surrounding fields has caused ammonium and/or nitrate pollution of groundwater on or near production facilities (Ritter and Chirnside 1990; Westerman et al. 1995; Liebhardt et al. 1979).

However, chronic pollution of surface waters by a suite of potential pollutants has not been comprehensively assessed for a CAFO-rich watershed. This research investigated physical, chemical, and biological pollution of stream waters in a watershed containing numerous swine and poultry CAFOs while lacking industrial or municipal point sources of pollution and containing little traditional crop agriculture. The degree of pollution was determined from two perspectives: first, since this stream consists of public waters, it was of interest to investigate whether or not these waters were impaired based on state chemical and biological standards. Second, comparative water quality conditions based on parameter concentrations were made using the published literature on coastal plain streams as well as broad-scale literature analyses of streams in general.

Stocking Head Creek (Fig. 1) is a second-order blackwater stream located in the Northeast Cape Fear River basin in eastern North Carolina. Catchment area is 1980 ha (4893 acres), and stream length to where it enters the Northeast Cape Fear River is 22.1 km (13.7 mi). The watershed soils are dominated by Noboco loamy fine sand, Johns fine sandy loam, Autryville loamy fine sand, Pactolus fine sand, Lumbee sandy loam, and Marvyn and Gritney soils (NRCS 2014a). There is some traditional row crop agriculture within this watershed, but aerial photography indicates that coverage by such is small in comparison to CAFO sprayfields and forest cover. The Northeast Cape Fear River is a fifth-order tributary of the sixth-order Cape Fear River, the watershed of which contains approximately half of the 9,000,000 plus swine in North Carolina as well as vast numbers of confined poultry. Cahoon et al. (1999) estimated that the Cape Fear River basin annually received 82,700 metric tons of nitrogen and 26,000 metric tons of phosphorus as animal waste in this watershed from CAFOs alone. Thus, CAFO-rich subwatersheds are likely to be sources of considerable nutrient pollution to larger rivers and estuaries (Mallin and Cahoon 2003; Burkholder et al. 2007). As such, our primary objective was to investigate potential environmental impacts to a stream draining a swine and poultry

CAFO-rich watershed. From July to October 2013, we sampled four main channels and three tributary stations for a broad selection of physical, chemical, and biological water quality parameters.

The location of swine CAFOs and the permitted numbers of swine for each are available from the North Carolina Department of Environment and Natural Resources, and we used these data to map and enumerate swine CAFOs. However, the N.C. Department of Agriculture and Consumer Services (NCDA & CS) does not provide such watershed-specific information on poultry CAFOs to the public or other agencies, although counts of each type of livestock are available on a county-by-county basis from NCDA & CS. Thus, a second objective was to obtain the locations of poultry CAFOs within this basin and estimate poultry numbers confined within them using alternative GIS and aerial photography-based techniques.

2 Methods

2.1 Sample Locations and Frequency

Seven stations were sampled, four on the main stream and two on first-order tributaries (Table 1, Fig. 1). The seventh station (MC-50) was collected on second-order Maxwell Creek, which joins lower Stocking Head Creek before it enters the Northeast Cape Fear River. The Maxwell Creek watershed also contains CAFOs, but they are not as concentrated near stream waters as those in the Stocking Head Creek watershed and they are not quantified in this investigation; MC-50 is used as a comparison site herein. All sites were sampled from bridges on public right-of-ways. The sampling design included five sample trips each taken during two different 30-day periods, one in mid-summer and one in fall. This was planned in accordance with the North Carolina Department of Environment and Natural Resources (NCDENR)'s protocol for fecal coliform sampling for assessment of whether a given stream supported its designated use or if it belongs on the state's 303(d) list for impaired waters. Sampling of Stocking Head Creek occurred during both dry and wet periods. Rainfall data were obtained from the NC CRONOS data set, using Station #319026 Wallace, latitude 34.72, longitude 77.97778, in Duplin County. Rainfall amount was computed for the day of sampling, the day of sampling plus the previous 24-h period, and the day of sampling plus the previous 48-h period.

2.2 Sample Parameters and Methodology

To obtain a full perspective of the stream's physical and chemical qualities, a suite of parameters was sampled. Field measurements were made on-site using YSI field meters calibrated and checked according to standard procedures for water temperature, pH, dissolved oxygen, turbidity, and specific conductance. Samples were collected from surface waters by bucket haul and distributed into pre-cleaned bottles for nutrient (ammonium, nitrate, total nitrogen, orthophosphate, total phosphorus), total suspended solids (TSS), chlorophyll *a*, and 5-day biochemical oxygen demand (BOD5) analyses. Samples were kept on ice and delivered to the laboratory for subsequent analysis within proper holding times. Chain of custody records was maintained.

Analytical methods used (see APHA 1995; USEPA 1983, 1997) were as follows: TSS, SM 2540D; ammonium, EPA 350.1; nitrate+nitrite, EPA 353.2; TKN, EPA 351.2, total nitrogen as calculation of TKN+nitrate; orthophosphate, SM 4500PE; total phosphorous, SM 4500 PE; BOD5, SM 5210B; and fecal coliform bacteria, SM 9222D MF. Total organic carbon concentrations (TOC) were obtained during the fall sampling in an effort to better understand causes of high BOD5 levels that were seen in the summer; the analytical method used for TOC was SM 5310B. Chlorophyll *a* measurements were performed using EPA method 445.0, based on the Welschmeyer (1994) fluorometry method.

2.3 Statistical Analyses

Summary statistics were derived for each parameter (means, standard deviations, medians, minimum, maximum for all data, also geometric means for fecal coliform analysis). Data were tested for normality using the Shapiro-Wilk test, with most chemical and biological parameters requiring log-transformation prior to further statistical analysis. An important consideration was whether or not the pollutant concentrations measured in Stocking Head Creek were the result of acute stormwater-driven surface runoff into the creek or a result of chronic, long-term pollution impacting groundwater as well as surface waters. As such, we analyzed whether or not rainfall produced higher pollutant

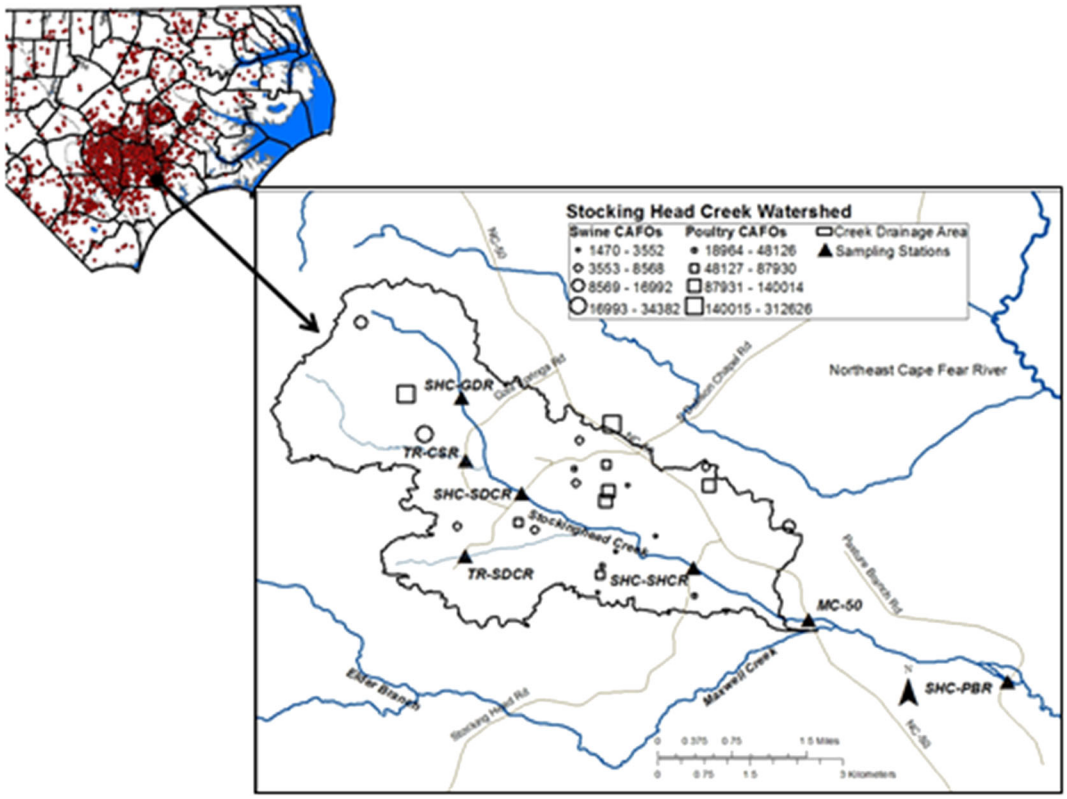

Fig. 1 Map of the Stocking Head Creek watershed, eastern North Carolina, USA, including streams, roads, sampling sites, and swine and poultry CAFOs sorted by size groups. *Inset* is the North Carolina Coastal Plain with *red dots* indicating location of swine CAFOs

parameter concentrations than occurred on non-rain periods. Measurable rainfall occurred either on the day of sampling or within the 48 h preceding the sample day on five of 10 sampling occasions. They were August 1 and 13, September 24, and October 8 and 10. *T* tests were used to test selected parameter concentrations between wet and dry periods (α=0.05). Parameters tested for wet-dry differences included ammonium, nitrate, and fecal coliform bacterial concentrations. To assess potential chemical and biological parameters influencing BOD, correlation and regression analyses were performed using SAS (Schlotzhauer and Littell 1987).

2.4 CAFO Map Construction

A digital elevation model was downloaded from the USGS geospatial portal and used as the data input to delineate the watershed boundaries of Stocking Head Creek. The ArcMap 10.1 Hydrology toolset was utilized, and the catchment area of Stocking Head Creek system was identified. A shapefile including all of the documented animal operations from the NC OneMap geospatial portal was clipped to only display those CAFOs within the newly defined watershed area. After establishing these boundaries and existing CAFOs (primarily swine operations), 2012 orthophotography from the North Carolina OneMap service was analyzed for undocumented CAFOs. The signature shape of the farm buildings (long rectangles side by side) was used to identify these locations, which were presumed to be poultry CAFOs. These were manually digitized as polygons superimposed on the aerial photos, and added to the existing CAFO location data to provide a more accurate assessment of the total number of animal operations within the Stocking Head Creek watershed. Besides the lack of inclusion on the NCDENR database, other characteristics that distinguish North Carolina poultry from swine CAFOs from the air include a lack of waste lagoons for poultry (all swine CAFOs contain waste lagoons but few poultry CAFOs do—egg-laying facilities only). Also, based on aerial photography, poultry CAFO structures are generally longer than swine

Table 1 Description and location of sampled sites, roughly in descending order from headwaters downstream in Stocking Head Creek. See Fig. 1 for locations, nearby roads, and CAFOs

SHC-GDR (Stocking Head Creek at Graham Dobson Road): N 34.91197, W 77.94507. This location collects the uppermost branch of Stocking Head Creek; a swine CAFO and sprayfields are present several hundred of meters upstream from the sampling site. Aerial photos indicate that this stream initiates in what is now a swine CAFO sprayfield.

TR-CSR (unnamed first-order tributary at Cool Springs Road): N 34.90279, W 77.94440. This site had no immediately adjoining CAFOs or sprayfields, but the GIS map (Fig. 1) indicates a large swine CAFO and a large poultry CAFO upstream.

TR-SDCR (unnamed first-order tributary entering Stocking Head Creek at South Dobson Chapel Road): N 34.88878, W 77.94453. Grazing cattle were occasionally present upstream within 75 m of this site, and waste spraying equipment was stationed within 50 m upstream on several sampling dates.

SHC-SDCR (Stocking Head Creek at South Dobson Chapel Rd.): N 34.89796, W 77.93628. Numerous CAFOs, sprayfields, and grazing cattle were located within 200 m of the stream at this site.

SHC-SHCR (Stocking Head Creek at Stocking Head Road): N 34.88710, W 77.91124. A large CAFO sprayfield was located within 50 m of the stream, with a ditch carrying sprayfield runoff that emptied directly into the stream at this location.

MC-50 (Maxwell Creek at SR 50): N 34.87950, W 77.89438. This sampling site adjoined a wetland area which was hydrologically connected to Stocking Head Creek. The Maxwell Creek watershed also contains CAFOs, although fewer than those in Stocking Head Creek watershed (Fig. 1).

SHC-PBR (Stocking Head Creek at Pasture Branch Road): N 34.87043, W 77.86539. This location was the farthest downstream site sampled. This downstream area also likely receives inputs from CAFOs in the Maxwell Creek drainage. There was also an adjoining forested wetland that supplied flow to the stream here.

CAFOs and have the feeding silo located at the building midpoint, while swine CAFOs have feeding silos located at the building's end.

The dimensions of each poultry building were computed from the digitized aerial photographs. Maximum bird (considered as broiler chickens) populations per building were estimated by assuming 743 cm^2 (0.80 ft^2) of space allotted per bird as is standard for a major poultry producer (Sanderson Farms 2007). The United Egg Producers (2010) recommend 436–557 cm^2 (0.47 to 0.60 ft^2) of space per egg-laying chicken; thus, we feel our counts are conservative. As there is no way to distinguish chicken from turkey operations from the air, for the purposes of this study, we assumed all broiler chickens. As a comparative reference regarding livestock manure production, the National Resources Conservation Service within the US Department of Agriculture uses animal units, i.e., 1 cow=9 hogs=455 broiler chickens=67 turkeys (NRCS 2014b).

3 Results

The Stocking Head Creek watershed (excluding Maxwell Creek) contains 13 swine CAFOs that are permitted by NCDENR for collectively 108,068 heads of swine. This watershed also contains 11 poultry CAFOs, consisting of a total of 42 individual buildings. Average poultry house size was approximately 2323 m^2 (25,000 ft^2), with an average capacity of 31,250 birds. Thus, the watershed can house a maximum of 1,312,500 broiler chickens or equivalent turkeys using the animal unit conversions above. Grazing cattle were visibly present in this watershed (with some photographed grazing directly under swine waste sprays), but an accurate count is beyond the capability of this study. Confined swine, poultry, and cattle produce large quantities of manure; conversion factors of excreted waste into total nitrogen, phosphorus, and fecal bacteria for these three livestock types can be found in Mallin and Cahoon (2003). While the local human population relies on septic systems for sewage treatment, aerial photography revealed only 67 human dwellings in the watershed, yielding a scant 0.03 septic systems/ha.

Summer water temperatures ranged between 22.0 and 28.0 °C, and fall water temperatures ranged from 16.1 to 22.6 °C. Most sampling events reflected neutral stream pH conditions ranging from 6.5 to 7.3. Dissolved oxygen concentrations ranged from mildly hypoxic (3.5 mg/L) to supersaturation (17.0 mg/L) during an algal bloom. Average turbidity by station ranged from 1.1 to 21.0 NTU (nephelometric turbidity units). Total suspended solids (TSS) in most cases were less than 25 mg/L (Table 2). Elevated TSS concentrations occurred a few times primarily at the tributary station TR-SDCR.

Ammonium in Stocking Head Creek during the 10 sample trips ranged from the detection limit (0.05 mg/L) to 37.8 mg/L (Table 2). Highest ammonium concentrations were found at station TR-SDCR, followed by station SHC-SHCR. These stations are both within 50 m of swine CAFO sprayfields (Table 1, Fig. 1). Nitrate concentrations in Stocking Head Creek were very high (Table 2). Whereas the highest ammonium

Table 2 Water quality parameter concentrations in Stocking Head Creek, 2013, given as mean±standard deviation/median/range; fecal coliforms as geometric mean/range. $n=70$, except for TOC where $n=35$

concentrations were found at the two sites located closest to waste sprayfields, several sites showed high nitrate, including sites distant from sprayfields (Table 2; Fig. 1). Concentrations ranged from 0.08 to 13.60 mg-N/L, with station means ranging from 0.30 to 7.94 mg-N/L. Particularly high nitrate concentrations were documented at these four sites: SHC-GDR, TR-CSR, SHC-SDCR, and SHC-SHCR. On 12 of 70 sampling occasions, stream nitrate concentrations exceeded 8 mg-N/L. Total nitrogen (TN) concentrations ranged

from 0.11 to 46.70 mg-N/L, while highest individual station average TN concentrations occurred at TR-SDCR, TR-CSR, and SHC-SHCR. The TN values in this stream were dominated by inorganic nitrogen (i.e., nitrate and ammonium) rather than organic nitrogen, with average percent inorganic N ranging from 80 to 100 % of TN, depending upon station.

Orthophosphate concentrations in Stocking Head Creek ranged from 0.04 to 5.45 mg-P/L, with station means ranging from 0.11 to 1.78 mg-P/L (Table 2). Highest concentrations were found at station TR-SDCR, followed by SHC-SHCR. Total phosphorus ranged from 0.040 to 10.70 mg-P/L, and station means ranged from 0.15 at SHC-GDR to 2.83 mg-P/L at TR-SDCR, with SHC-SHCR second highest at 0.50 mg-P/L (Table 2). Most TOC concentrations were in the 10–20 mg/L range; however, higher TOC concentrations occurred at TR-SDCR and SHC-SHCR, the stations nearest to sprayfields (Table 2).

Chlorophyll *a* represents the amount of suspended live microalgal biomass found in a sample of water (Wetzel 2001). Elevated chlorophyll *a* concentrations (algal blooms) occurred at TR-SDCR on July 29 (40 μg/L) and at this same site on September 18 (44 μg/L), with smaller blooms occurring several times at other sites. Thus, algal blooms occurred within Stocking Head Creek, but were inconsistent in time and among sampling sites (Table 2).

Biochemical oxygen demand (BOD) is a measure of the organic matter available for consumption by the bacteria in a body of water during respiration; excessive BOD can lead to hypoxia. Five-day BOD (BOD5) varied widely (Table 2), from background concentrations of 1.0 mg/L up to high values of 21 mg/L at MC-50, 25 mg/L at SHC-SHCR, and the maximum of 88 mg/L at station TR-SDCR. That station maintained the highest overall BOD5 concentrations (Table 2), reaching 10 mg/L or more on six of 10 dates, while station SHC-SHCR exceeded 10 mg/L on three dates. The stream stations with highest average BOD concentrations were those in closest proximity to swine waste sprayfields (Table 1; Fig. 1).

North Carolina uses fecal coliform bacteria counts as a proxy for potentially pathogenic bacteria in fresh water bodies; this standard is commonly used throughout the southeast of the USA (EPA Region 4) for freshwater contact. The NC protocol (NCDENR 1999) for sampling and the means for determining fecal impairment of a water body state that fecal coliform counts shall not exceed a geometric mean of 200 CFU/100 mL based on at least five consecutive samples during any 30-day period nor exceed 400 CFU/100 mL in more than 20 % of the samples examined during such period. Fecal coliform counts for Stocking Head Creek were generally very high (Fig. 2). During summer 2013, the upper five stations exceeded 400 CFU/100 ml on 100 % of the time sampled, and the geometric means for all seven stations exceeded 200 CFU/10 mL for five samples in 30 days. Fecal coliform counts for Stocking Head Creek in fall 2013 were even higher than those in summer; the upper five stations exceeded 400 CFU/100 ml on 96 % of the time sampled, and the geometric means for six of the seven stations exceeded 200 CFU/10 mL for five samples in 30 days. During both the summer and the fall sampling periods, fecal coliform criteria for impaired waters were well exceeded. Elevated fecal coliform counts occurred during both wet and dry periods. Highest fecal coliform counts occurred at TR-SDCR and SHC-SHCR, the stations nearest to sprayfields. Most other stations also had high counts, with geometric means exceeding 1000 CFU/100 mL (Table 2, Fig. 2). While lower Maxwell Creek (MC-50) maintained the lowest counts, it still exceeded state criteria for impaired waters.

An important consideration is whether or not the high pollutant values measured in Stocking Head Creek were the result of acute stormwater-driven surface runoff into the creek or a result of chronic, long-term pollution impacting groundwater as well as surface waters. As such, we analyzed whether or not rainfall produced higher pollutant parameter concentrations than occurred

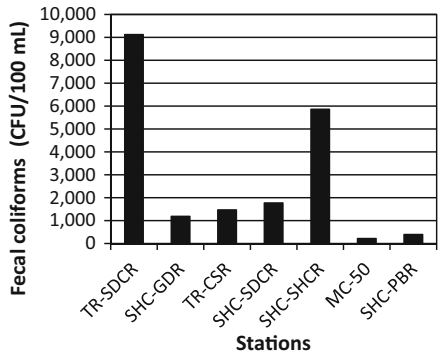

Fig. 2 Fecal coliform bacteria counts (as colony-forming units/100 mL) for Stocking Head Creek watershed sampling sites, presented as geometric mean of 10 samples per site. Note that the NC freshwater recreational standard is 200 CFU/100 mL

on non-rain periods. For all non-rain sample dates and stations, the fecal coliform geometric mean was 1455 CFU/100 mL, and counts exceeded 200 CFU/100 mL on 31 of 35 samples with 89 % exceedence of the state standard. For all rain periods and stations combined, the fecal coliform geometric mean was 1467 CFU/100 mL, and counts exceeded 200 CFU/10 mL on 30 of 35 samples with 86 % exceedence of the state standard. *T* test results showed no significant difference in means between wet and dry periods (p=0.49; df=68). Thus, fecal coliform pollution of Stocking Head Creek was not rain dependent; rather, fecal coliform pollution was a *chronic* condition.

Ammonium concentrations during non-rain periods were 2.67±7.59 mg-N/L (mean±standard deviation) vs. rain period concentrations of 1.56±4.65 mg-N/L. *T* test results on log-transformed data showed no significant difference in means (p=0.64; df=68). Nitrate concentrations during non-rain periods were 4.45±3.68 mg-N/L vs. rain concentrations of 3.82±3.56 mg-N/L. *T* test on log-transformed nitrate data showed no significant difference in means (p=0.38, df=68). Thus, inorganic nitrogen concentrations were not increased by rainfall-driven surface runoff, but instead they were a chronic condition in Stocking Head Creek, indicating groundwater pollution.

4 Discussion

Ammonium is a reduced form of inorganic nitrogen that is a major component of fresh human sewage or animal excreta (Clark et al. 1977). It is readily used by algae and bacteria, and an overabundance of ammonium can stimulate eutrophication (Wetzel 2001). Research in coastal plain blackwater streams and rivers has indicated that ammonium concentrations of 0.5 mg/L (ppm) or higher can stimulate algal blooms (Mallin et al. 2004). Additionally, ammonium exerts a significant chemical oxygen demand in sewage treatment plant discharges (Clark et al. 1977), as it is oxidized to nitrate. Thus, excess ammonium can lead to aquatic ecosystem deterioration through more than one pathway. The ammonium concentrations found in Stocking Head Creek, particularly at the sites nearest to sprayfields, greatly exceeded ammonium concentrations typically found in other coastal plain streams and rivers (Smock and Gilinsky 1992; Mallin et al. 2004, 2006). Previously, only during swine or poultry lagoon breaches have such concentrations been found in receiving streams in this region (Burkholder et al. 1997; Mallin 2000).

Ammonium pollution from CAFOs is not limited to runoff or seepage entering waterways. Volatilization of ammonia from CAFOs releases vast amounts of inorganic nitrogen to the atmosphere. On the North Carolina Coastal Plain alone, annual ammonia emissions from swine and poultry have been estimated as 73,500 and 22,900 metric tons (Costanza et al. 2008). Regionally, ammonia volatilization from waste lagoons, sprayfields, and litterfields carries ammonia well outside of the watershed of origination (Walker et al. 2000; Costanza et al. 2008) and is reflected in elevated ammonium concentrations in rainfall measurements downwind (Willey et al. 2006). In a study of the two most CAFO-rich North Carolina watersheds, ammonium concentrations were found to have increased approximately 500 % in the Neuse River and 315 % in the Northeast Cape Fear River between 1995 and 2005 (Burkholder et al. 2006).

Ammonium at the concentrations found in Stocking Head Creek can have other impacts besides increasing algal blooms and chemical oxygen demand. Recent studies (see review by Glibert et al. 2015) have indicated that ammonium at these concentrations can stimulate cyanobacterial production as well as increase the production of toxic microcystin, while suppressing growth of diatoms which are generally benign organisms that support the higher trophic levels. Ammonium has been found to preferentially enhance cyanobacterial growth in locales as diverse as San Francisco Bay (Glibert et al. 2014) to the South Carolina Coastal Plain (Siegel et al. 2011). Interestingly, in July 2011, an unprecedented (during 23 years of monitoring) bloom of cyanobacteria (mostly *Anabaena planctonica*) occurred in the blackwater Northeast Cape Fear River downstream from its confluence with Stocking Head Creek (and several other CAFO-impacted watersheds). The bloom lasted for several weeks and, upon decomposition, resulted in a BOD that decreased river DO from 5.3 to 0.7 mg/L (S. Petter Garrett, NCDENR, personal communication August 4, 2011).

Nitrate is likewise readily used by visible plants and algae for growth. It is mobile in soils and readily moves through the water table to enter streams (Keeney 1986). Average nitrate concentrations at six of seven stations well exceeded levels known to stimulate algal production and lead to elevated BOD in blackwater streams (Mallin et al. 2004). Nitrate concentrations in this stream

were well in excess of those reported from other streams in the southeast USA (Edwards and Meyer 1987; Smock and Gilinsky 1992; Mallin et al. 2004, 2006; Carey et al. 2007), but in line with nitrate concentrations reported from Ohio watersheds impacted by runoff from combined row crop and dense CAFO presence (Hoorman et al. 2008). Regarding human health, there is a US EPA drinking well nitrate standard of 10 mg-N/L to prevent blue baby syndrome (also called methemoglobinemia). It is notable that on three occasions, even the 10-mg/L standard for drinking well water was exceeded, and in seven of 70 samples collected, stream nitrate concentrations exceeded 9 mg/L, close to the methemoglobinemia standard.

There are no point-source discharges entering this creek. The local human population uses septic systems, but the 67 human dwellings in the watershed are spaced well away from the creek, with sprayfields located between human dwellings and riparian areas. Thus, the principal sources of nitrate are swine CAFO waste (either runoff from sprayfields, or subsurface movement into the stream), poultry litter spread on fields, and cattle manure deposited on land. Nitrate concentrations of similar magnitude have been documented from subsurface waters draining sprayfields and surface streams passing through or near swine sprayfields (Evans et al. 1984; Stone et al. 1995). Total nitrogen concentrations in Stocking Head Creek were very high compared to available data from other blackwater coastal plain streams (Smock and Gilinsky 1992; Mallin et al. 2004, 2006). To provide a wider perspective, using a large data set of 1070 streams, Dodds et al. (1998) determined that average TN concentrations >1.5 mg/L were characteristic of eutrophic conditions; this level was well exceeded according to average station TN at six of the seven sites (Table 2).

Orthophosphate is the most common form of inorganic phosphorus directly used by algae. It is not very mobile in soils and adsorbs readily to soil particles (Wetzel 2001). Orthophosphate station means were generally 2–10 times the average levels found in a selection of less-impacted blackwater coastal plain streams (Edwards and Meyer 1987; Mallin et al. 2004, 2006; Carey et al. 2007). Average orthophosphate concentrations in Stocking Head Creek were similar to those in streams draining mixed row crop and CAFO watersheds in Ohio (Hoorman et al. 2008).

Concentrations of TP≥0.50 mg-P/L or greater can increase BOD in blackwater streams by serving as a substrate assimilated by ambient bacteria (Mallin et al. 2004). In the present study, TP was higher than 0.50 mg-P/L in 11 of 70 samples. Using data from 1366 streams, Dodds et al. (1998) concluded that TP concentrations >0.075 mg/L were characteristic of eutrophic streams; average TP at all sites exceeded this threshold (Table 2). Additionally, a study of soils in eastern North Carolina using a soil phosphorus index developed by the N.C. Division of Agronomy found that the soils in counties where CAFOs were abundant (including Duplin County) contained excessively high index values (Cahoon and Ensign 2004). We note that besides direct eutrophication impacts, highly variable nutrient ratios (such as seen with this impacted stream) can lead to changes in taxonomic structure for resident phytoplankton and higher trophic levels (Glibert et al. 2015).

Bacteria require phosphorus both structurally and energetically (Kirchman 1994), and fecal bacteria growth in stream sediments can be stimulated by inputs of phosphate (Toothman et al. 2009). Also, fecal coliform bacteria within the water column can be significantly stimulated by additions of organic or inorganic P inputs >0.100 mg/L, increasing survival and reproduction (Chudoba et al. 2013). Mean and median concentrations of TP in all Stocking Head Creek stations exceeded 0.100 mg-P/L. The data suggest that high phosphorus inputs to stream waters polluted by fecal bacteria can magnify human health risks, as well as ecosystem impacts.

BOD5 concentrations at times were very high in Stocking Head Creek (Table 2). Comparison of BOD5 from many streams and rivers in coastal North Carolina indicates that concentrations of 1 to 2 mg/L are background for minimally impacted streams (Mallin et al. 2006). Elevated BOD can be stimulated by several causes. One common cause of elevated BOD is the introduction of organic materials such as human sewage or animal waste into the water; thus, dissolved organic carbon, if labile, can stimulate BOD (Clark et al. 1977). Another cause is algal blooms, which upon death and decay create a source of labile organic matter available for bacterial consumption. In a variety of coastal plain freshwater streams, tidal creeks, and lakes, Mallin et al. (2006) found strong statistical correlations between BOD and chlorophyll *a*. Ammonium pollution can exert a significant chemical oxygen demand in waterways, and elevated phosphorus concentrations can lead to elevated BOD by directly stimulating bacteria growth. In Stocking Head Creek, BOD5 was positively

correlated with TOC (r=0.833. p<0.0001), ammonium (r=0.666, p<0.0001), TP (r=0.626, p<0.0001), orthophosphate (r=0.569, p<0.0001), chlorophyll *a* (r=0.316, p=0.008), and TN (r=0.284, p=0.017). Multiple regression analyses indicated that the best predictive linear model for BOD5 in this stream was (as log-transformed data)

$$\mathrm{BOD5} = 0.952(\mathrm{TOC}) + 0.367(\mathrm{AMM}) - 3.961,\ r^2 = 0.85,\ p < 0.0001$$

Thus, the high BOD in Stocking Head Creek is directly related to common components of animal waste (TOC, ammonium, phosphorus) as well as to chlorophyll *a*, a response variable to nutrient inputs. As mentioned, the lower Cape Fear River and its estuary are on the 303(d) list due to DO violations. Stocking Head Creek enters the Northeast Cape Fear River, which enters the lower Cape Fear River at Wilmington. The high levels of BOD observed in Stocking Head Creek as well as the high nitrate, ammonium, and fecal bacteria loads contribute to the low DO concentrations frequently occurring in summer in the Northeast Cape Fear River.

Most troublesome from a human health perspective is the data indicating that Stocking Head Creek is highly polluted by fecal bacteria, by both measures of the NC criteria for impaired waters. The upper five stations exceeded 400 CFU/100 ml on 96–100 % of the time sampled, and six of seven stations exceeded a geometric mean of 200 CFU/10 mL for five samples in both 30-day periods. Importantly, elevated fecal coliform counts occurred during both wet and dry periods; this creek is chronically polluted by fecal bacteria. The stimulatory effect of phosphorus loading on fecal bacteria (Chudoba et al. 2013) further exacerbates the potential human health issues. Fecal bacteria generated by livestock within the watershed are not confined to the immediate watershed but are likely to be carried downstream into higher order streams. A bacterial source-tracking study using molecular techniques demonstrated swine waste contamination at Cape Fear River system sites well downstream from swine CAFOs (Arfken et al. 2013).

In addition to surface waters, groundwater under and near swine and poultry CAFOs can contain very high inorganic nitrogen concentrations. Ritter and Chirnside (1990) found ammonium concentrations up to 960 mg-N/L and nitrate up to 50 mg-N/L in test wells in close proximity to swine waste lagoons on the Delmarva Peninsula. In North Carolina, Westerman et al. (1995) analyzed seepage from two swine waste lagoons and found ammonium concentrations in nearby wells averaged more than 50 mg-N/L, with nitrate of 6–15 mg-N/L. In other areas, it has also been observed that both spreading and spraying of livestock waste on the landscape will lead to excessive nitrate in groundwater (Liebhardt et al. 1979).

The water table in this area varies seasonally but is relatively near the land surface on average. No groundwater level monitoring wells are immediately on-site, but the US Geological Survey operates a well 10 km southwest at Rose Hill (Well DU-157). At that well, annual average depth to the surficial water table from 2004 to 2014 ranged from 1.3 to 2.7 m, with an average of 2.2 m. The North Carolina Division of Water Resources operates a monitoring well 10 km southeast at Chinquapin (Well W29D9), and 2013 data showed depth to surficial water table ranging from 1.4 to 1.8 m below the land surface. The local predominating sandy loam soils (NRCS 2014a) have moderate to rapid permeability with permeability rates of 0.5–1.5 m/day and 1.5–3.0 m/day, respectively (USDA 2014b). Thus, following a swine waste spray event, nitrate (and likely some portion of the fecal bacteria load) could migrate into the water table in as little as a day or two and from there move laterally to the nearest stream. Thus, groundwater in a CAFO-rich watershed such as that of Stocking Head Creek is a source of nitrogen and fecal bacterial pollution to the stream waters, and continual (including non-storm event) groundwater inputs into the stream at selected locations results in chronic pollution. Simply considering overland runoff will underestimate the N flux to aquatic systems as this ignores infiltration and leaching (Carpenter et al. 1998). The lack of concentration differences in fecal coliform, ammonium, and nitrate concentrations between rainy and dry periods shows that the stream pollution is chronic and a result of normal CAFO operations and presently accepted waste disposal techniques.

This research has demonstrated that drainage basins rich in CAFOs cause chronic pollution that has both human health and ecosystem impacts. However, the scope of US confined animal operations is nationwide. Many CAFO-rich watersheds pollute freshwater streams and rivers, which eventually enter estuaries located on the Atlantic and Gulf coasts. For instance, poultry CAFO-rich Delaware, Maryland, and Virginia, and poultry and swine CAFO-rich North Carolina drain

into middle-Atlantic estuaries. Major swine, poultry, and cattle-producing states such as Arkansas, Alabama, Iowa, Illinois, Minnesota, Missouri, and Texas in the Mississippi River drainage feed the Gulf of Mexico. As such, Weldon and Hornbuckle (2006) determined that for four major agricultural watersheds in Iowa, nitrate was strongly correlated with CAFO densities, and these watersheds made an outsized contribution to nitrate loading to the Mississippi River.

An extensive study covering 90 % of estuarine surface area in the USA (Bricker et al. 1999) concluded that severe eutrophication conditions (toxic algal blooms, bottom-water hypoxia, losses of submersed aquatic vegetation) were most prevalent along the middle Atlantic and Gulf Coast estuaries. Howarth et al. (2012) have demonstrated that estuarine nitrogen discharge from a wide selection of rivers in Europe and North America is positively correlated with net watershed nitrogen inputs. That study showed that for watersheds that have positive increases in animal feed from outside the system, there is a strong correlation with riverine N flux. Many of those rivers drain watersheds rich in poultry CAFOs, swine CAFOs, or both. The magnitude of industrial livestock production indicates that not only are immediate watersheds severely polluted but the collective impacts of the numerous subwatersheds draining CAFO-rich areas contribute to major ecosystem impacts far downstream as well. As the magnitude of the CAFO style of industrial livestock production grows beyond the USA and Europe into developing nations (Thorne 2007), highly concentrated nutrient and fecal microbial pollution from these sources will similarly expand.

Acknowledgments For funding, we thank the Waterkeeper Alliance. We thank Mary Grace Lemon and Rena Turner for the laboratory help. For project facilitation, we thank Kelly Hunter Foster and Larry Baldwin of Waterkeeper and Kemp Burdette, Cape Fear Riverkeeper. For review comments, we thank Drs. JoAnn Burkholder and Lawrence B. Re: Izaak Walton League Comments on the West River Dairy Expansion Draft EAW

Dear Mr. Peterson,
Thank you and the Minnesota Pollution Control Agency staff for inviting comments on the draft West River Dairy Expansion Environmental Assessment Worksheet (EAW) and for holding a public meeting in Morris, Minnesota on April 28th.

Based on the history of past Riverview projects and confined animal feeding operations (CAFOs) in general, our review of the draft EAW for this exceedingly large expansion and the applicable criteria we have concluded that an environmental impact statement (EIS) is warranted. We find the draft EAW itself deficient in a lot of ways, but we do not call for its revision. Instead, the information we do find in the draft EAW is more than sufficient justification for moving forward into a full EIS.

Our comments in support of that conclusion are grouped according to the four specific criteria shown in Minnesota Rules 4410.1700, subpart 7. The MPCA, as the Responsible Governmental Unit (RGU) must consider these criteria when determining if a project has the potential for significant environmental effects and therefore warrants an Environmental Impact Statement (EIS):

1. Type, extent, and reversibility of environmental effects;
2. Cumulative potential effects;
3. Degree of mitigation by ongoing public regulatory authority, and;
4. Anticipation and control of effects from other studies.

Below is our summary outline with our comment topics listed as lettered subheadings under each of the four criteria. Following this summary is a more detailed discussion on each topic.

Comment Summary as Outline of Topics Covered

Criterion 1 - Type, extent, and reversibility of environmental effects -

A. EAW vastly under sizes the environmentally relevant area (ERA)
B. EAW fails to acknowledge that polluted groundwater may not be reversible
C. Effects on ground and surface water quantities and flows don't add up;
D. Potential ground water contamination by leachate from manure pits and basins is not quantified
E. Contamination by manure seepage to perimeter tile draining shallow groundwater from under manure pits delivered to storm water basin is unaccounted for
F. A report in EAW minimizes future low flow probability in Pomme de Terre River and is misleading and inconsistent with climate trends stated elsewhere
G. Crop land used for manure spreading may need containment to avoid runoff reaching surface waters
H. The EAW fails to identify potential increases in antibiotic resistance and/or the potential zoonotic infections effects of large CAFOs.

Criterion 2 - Cumulative potential effects

A. Deliberate under sizing the environmentally relevant area cannot be used to avoid impact overlap and claim impacts are not cumulative
B. EAW does not properly characterize past, present and future environmental conditions of the environmentally relevant area
C. EAW fails to account for impacts of feedlots in the impacted areas whether owned or operated by proposer or not.
D. EAW minimizes or ignores proposed project incremental contribution to cumulative potential effects
E. EAW describes purposeful avoidance of potential mitigation offered by "green infrastructure" as part of intentional project design
F. EAW fails to identify impaired waters as evidence of past and present projects

Criterion 3 - Degree of mitigation by ongoing public regulatory authority

A. The EPA has found MPCA's existing feedlot rules and permits to be inadequate
B. MPCA will not have strengthened feedlot rules in time to control this project
C. Local ordinances and county feedlot officers are ineffective
D. Federal Clean Water Act authority remains delegated to the state MPCA
E. MPCA may be in violation of MEPA which prohibits permitting polluting activity when less polluting alternatives exist
F. MPCA fails to extend its authority over pollution caused by manure delivered to other farmers and landowners

G. MPCA has failed to adopt nitrate standards for surface and groundwaters.

Criterion 4 - Anticipation and control of effects from other studies

A. No other EIS has been prepared on a feedlot of this size in the project area or similar setting
B. Compliance with TMDL goals for areas surface waters are not acknowledged
C. Other studies have found large feedlots degrade local economies and community health
D. Economic impacts are not included in EAWs but can be addressed in an EIS

Detailed Discussion of Each Topic

Criterion 1 - Type, extent, and reversibility of environmental effects – The RGU must examine the nature of the impacts, how widespread they are, and whether they can be undone.

A. EAW vastly under sizes the environmentally relevant area (ERA).
The EAW claims the area impacted by the project can be limited to the exact area of the feedlot site, the areas where manure will be spread and a one-mile radius around the off-site wells.

> *"The Environmentally Relevant Area (ERA) for the Project has been delineated to ensure that environmental effects from other projects do not overlap. The ERA is defined as the oversized Project Boundary, all identified manure application fields designated for the Project and Existing Facility, and a one-mile radius surrounding the off-site water-supply well (Attachment 20).*

This claim cannot be supported. Project impacted air, water and soils move freely across these property boundaries and are carried far beyond them, down rivers into aquifers that move and across neighboring properties and into other counties. Climate impacts are global in scale. Surface water impacts are regional and can exceed the bounds of the Pomme de Terre watershed into the Minnesota River. Therefore, the impacts of this exceeding large feedlot project on this larger more realistic and environmentally relevant scale are potentially significant and justify an EIS.

B. EAW fails to acknowledge that polluted groundwater may not be reversible
The potential for manure storage area leakage and field applied manure seepage below the crop root zone into groundwater is likely under the many thousands of acres proposed for this project. Despite the project's inclusion of extra thick clay liners under the manure storage pits, these liners can still be expected to leak up to 100 gallons per acre per day (one fifth of the allowable leakage rate). Manure application (along with commercial fertilizer) to farm fields has been shown to create the potential for seepage into groundwater even when applied at agronomic rates. Agronomic application rates are not designed to prevent excess nutrients or other farm chemicals from reaching groundwater, instead they are designed to maximize production with the least amount of application.

Once contaminated, groundwaters are extremely difficult if not impossible to clean. Drinking water sourced from groundwater may be treated to remove some contaminants but this is not a reversal of the original contamination.

C. Effects on ground and surface water quantities and flows don't add up

The expansion would use 287.5 million gallons per year, almost as much as the city of Morris, population 5,100. The project relies on two well water fields, one on site and one off site that are limited in available supply, either by impact on low river flows or excessive drawdown of aquifer levels. A back up storm and well water storage pond is planned to serve as a temporary water supply in when well extraction limits kick in. No calculations are supplied in the EAW to assure the backup will suffice during extended drought periods lasting several months if not years. An EIS will be required to estimate the probability and frequency at which the project operators may request emergency exemption from well pumping limits to keep their livestock alive. Depopulating such an enormous feedlot in a time of drought is impractical. Such an exemption places other well users and the river at risk for serious water shortages. This alone is a potential for significant impact warranting an EIS to evaluate available alternatives including the no-action alternative.

D. Potential ground water contamination by leachate from manure pits and basins is not quantified

At the public meeting in Morris on April 28th of this year, MPCA officials admitted that manure pit leakage, even at the reduced rates afforded by thicker clay liners, would likely reach groundwater. The MPCA dismissed these impacts as not being significant because "receptors" of this contamination (understood to be private or public wells) were far enough away. These estimates are subject to internal speculation and discussion with the project proposer but have not been made public. The basis for these estimates and the factors contributing to estimate uncertainties should be presented in an EIS and thus subjected to third party scrutiny.

E. Contamination by manure seepage to perimeter tile draining shallow groundwater from under manure pits delivered to storm water basin is unaccounted for

The draft EAW states:

> "To control potential seasonal subsurface saturation near the LMSAs, a drain-tile system will be installed around the perimeter of the LMSAs at an elevation below the LMSA liners. The clean seasonal subsurface water from the perimeter tile system will drain into a nearby stormwater basin, where it combines with Project stormwater.

MPCA acknowledges and allows (permits) manure storage ponds to leak and this leachate is most certain to find its way into the perimeter drain-tile system. The project should not be designed to dispose of manure contaminated seepage in this tile system in a stormwater system. The stormwater system is oversized but still can be predicted

to need discharge during wetter years. The EAW form fails to address the need for wastewater treatment in section 12.B.1. C as follows:

> "12.B.1.c. If the wastewater discharge is to surface water, identify the wastewater treatment methods and identify discharge points and proposed effluent limitations to mitigate impacts. Discuss any effects to surface or groundwater from wastewater discharges, taking into consideration how current Minnesota climate trends and anticipated climate change in the general location of the project may influence the effects."

The RGU's entry here is that this treatment requirement is "Not Applicable" which is interpreted to mean no wastewater discharge is planned. An EIS would need to resolve this contradiction/omission and either describe total containment of contaminated manure pit leachate which would seem impractical or the proposed treatment of this wastewater, possibly by land irrigation or other means.

F. <u>A report in EAW minimizes future low flow probability in Pomme de Terre River and is misleading and inconsistent with climate trends stated elsewhere</u>

> "Riverview LLP requested Moore Engineering Inc. (Moore) to evaluate discharge flows from Pomme de Terre River (River) in Appleton, MN. Moore assessed historic data from USGS Gage #05294000 to determine the percentage of time the flow in the River was less than three specified flow parameters. Historically, the trend of the Rivers minimum discharge has increased. This is most evident after 1991, as can be seen on Figure 1. Between 1931 and 1991, average minimum flow was approximately 8.5 cfs. After 1991, the average minimum flow increased to 50 cfs.

In the climate impacts section of the EAW, river flows are predicted to continue decreasing as average temperatures increase. These inconsistencies are confusing to the public and should be clarified in an EIS.

G. <u>Crop land used for manure spreading may need containment to avoid runoff reaching surface waters:</u>

The EAW states:

> "Increased precipitation may cause the loss of some acres of cropland due to saturation of low spots within fields or localized flooding after rain events. New drainage or water impoundment systems may need to be developed by landowners to handle increased volumes of stormwater in fields. If these structures are built on any of the manure application fields, they would take land out of crop production to convert to water management structures. With a contingency of over 3,000 additional manure application acres beyond what is needed each year, there is abundant operational flexibility if some portions of the fields are no longer available due to weather condition impacts.

This is a very important revelation that has potential for significant future effects that are a direct result of this project. If 3,000 acres of prospective manure application fields have known drainage issues that will not be identified and remedied until after some

future rain events this should be a red flag. Rainstorms that are increasing in frequency and severity due to climate change and cause localized flooding should not be relied upon as the trigger for corrective action. Surface or groundwater pollution is likely to have already happened. Simply eliminating these areas from future manure application after the drainage problem has been experienced will not prevent this pollution. Here, the EAW can serve its true function and trigger an EIS that can explore this issue more thoroughly and evaluate alternatives that would avoid predictable pollution.

H. The EAW fails to identify potential increases in antibiotic resistance and/or zoonotic infections effects of large CAFOs.

A report in 2020 by the Natural Resources Defense Council[1] (NRDC), reveals that US cattle producers use more than 40% of all medically important antibiotics—those that are also used in human medicine—sold for use in US livestock, and use them three to six times more intensively than many of their European counterparts.

NRDC says this overuse of antibiotics is a strategy used by the beef industry to offset heightened disease risks in feedlots, where cattle are routinely fed antibiotics to prevent disease whether or not they are ill, a practice that the World Health Organization discourages and that the European Union will no longer allow starting in 2022.
The reports also argues that there is little transparency or accountability in the beef industry regarding its use of medically important antibiotics, and little urgency to rectify the problem.

"Many infectious disease and antibiotic resistance experts believe such use is improper and helps contribute to reservoirs of drug-resistant bacteria on farms that can spread easily to humans through consumption of meat, exposure to soil or water contaminated with manure containing antibiotic-resistant pathogens or contact with animals. They also worry that it reduces the effectiveness of antibiotics that are needed to fight infections in people."

A 2023 report in the Journal of Dairy Science[2] states:

"Antibiotics are used in the dairy industry mainly to treat mastitis, respiratory illness, lameness, and enteric diseases (Andrews, 2000; Dodd and Booth, 2000; Alliance to Save Our Antibiotics, 2016). Some of the antibiotics used are particularly important in treating human infections; therefore, their continued use in dairy cattle is predicted to have dangerous implications for human and animal health (Alliance to Save Our Antibiotics, 2016). One of the main uses of antibiotics in dairy cattle is "dry cow" treatment, which involves a long-

[1] **Report slams beef industry for overuse of antibiotics -** *Chris Dall | News Reporter | CIDRAP News June 26, 2020* Antimicrobial Stewardship

[2] Factors influencing dairy farmers' antibiotic use: An application of the COM-B model - Journal of Dairy Science Volume 106, Issue 6, June 2023, Pages 4059-4071

*acting intramammary antibiotic infusion given to cows between lactation cycles, with the intention of treating existing infections and preventing new infections (Dodd and Booth, 2000). Blanket dry cow therapy (**BDCT**) involves the prophylactic antibiotic treatment of every cow at drying off to prevent infection; BDCT has historically has been used in mastitis control (Biggs, 2017). As this involves giving antibiotics to all cows, even those who are not infected at drying off, BDCT has been linked to the threat of AMR development (Brunton et al., 2012; Higham et al., 2018).*

With regard to zoonotic infection risks on large dairy farms, a 2017 article by Michigan State University[3] states that:

> *"People that work with dairy cattle can be at risk of becoming infected with a zoonotic disease. However, families of employees and people in close contact with dairy personnel can be at risk too. The compliance of preventive measures protects not only people in direct contact with animals, but also people in their homes. Prevention is especially important if there are children under 5 years old, elderly or people with weak immune systems in the families of the dairy personnel, since they can get sick more easily and could have more severe symptoms of the disease.*
>
> *Contracting a zoonotic disease not only has consequences on the health and wellbeing of the person affected, it also impacts the normal operation of a dairy farm. In times when the work force is very limited, producers cannot afford to have a valuable worker off the farm due to a preventable disease."*

Because these issues are highly complex, were not addressed at all in the EAW and because research has shown the overuse of antibiotics and failure to employ proper and consistent biological safeguards in feedlots can present significant threats to human health that may not be reversable, an EIS is warranted to fully inform the public and inform the permitting of an industrial scale livestock facilities like the one proposed.

Criterion 2 – Cumulative potential effects – The RGU must consider whether the project's impact is significant when added to other past, present, and reasonably foreseeable future projects, including those by other entities.

A. Deliberate under sizing the environmentally relevant area cannot be used to avoid impact overlap and then claim impacts are not cumulative

As was previously referenced above the EAW states:

> "The Environmentally Relevant Area (ERA) for the Project has been delineated to ensure that environmental effects from other projects do not overlap. The ERA is defined as the oversized Project Boundary, all identified manure application fields designated for the Project and Existing Facility, and a one-mile radius surrounding the off-site water-supply well (Attachment 20). **The**

[3] **Prevent Zoonotic Diseases on your Dairy Farm -** Paola Bacigalupo Sanguesa, Michigan State University Extension - November 29, 2017

established ERA for the Project avoids cumulative potential effects (CPE) as detailed in Item 21." (bold added for emphasis).

This is a conspicuous but unacceptable attempt to avoid having to disclose effects that are most certainly cumulative. The project is not proposed for a pristine, isolated island, it will be situated in an already degraded environment, part of which is caused by the existing feedlot that is being expanded. And degradation by the landscape having been converted to agriculture is evidence of past effects. If the air and water in the vicinity are not clean and the native ecosystems are not fully functioning, this project's impacts must be added to these "past and present" actions and then added to the impacts of reasonably foreseeable actions. The incremental degradation attributable to this project is certainly greater than most but it cannot escape its cumulative significance by simply declaring it does "overlap" with other "projects. These cumulative effects should be more honestly and accurately assessed by preparing an EIS.

B. EAW does not properly characterize past, present and future environmental conditions of the environmentally relevant area

The existing dairy and other farming operations are near the Pomme de Terre River, which flows into the Minnesota River. State testing has found E. coli in the Pomme de Terre watershed, as well as nutrients that can lead to algae blooms. Already, several sections of the river do not support aquatic life or human recreation. The river starts out clean but gets more and more polluted as it passes through farmland. TMDLs have been prepared to document the problems directly associated with animal agriculture in several streams and wetlands in the vicinity and the remedial measure needed to restore them to the fishable and swimmable condition required by law. A fair determination of the cumulative effects of this project requires the effects of all past, present and future projects be accurately characterized so this project's impacts can be added to them. An EIS is the appropriate tool for correcting this oversight in the EAW and informing the MPCA and the public as to whether a permit can be issued.

C. EAW fails to account for impacts of feedlots in the potentially affected areas whether owned or operated by proposer or not.

As stated in our comments above, Riverview owns and operates numerous other large feedlots, many of which in the same watershed as the proposed expansion. And other smaller feedlots not owned by Riverview are identified in maps included in the EAW. These feedlots are also in the same watershed and potentially are affecting the same wetlands, groundwater, habitat and air quality. Quantifying and accounting for the collective impacts of these existing livestock operations is usually beyond the scope and purpose a of an EAW. The EAW must identify and locate these feedlots but does not need to quantify their impacts. This is an appropriate function of an EIS.

D. EAW minimizes or ignores proposed project incremental contribution to cumulative potential effects

By declaring the environmentally affected area of the project so narrowly, as described above, the proposer attempts to side-step the need to acknowledge the incremental addition of the project to the effects of its own operations and those like it in the vicinity. This error should be corrected and the incremental impacts quantified in an EIS.

E. EAW describes purposeful avoidance of potential mitigation offered by "green infrastructure" as part of intentional project design

The EAW states:

> "The Project is not proposing to incorporate typical green infrastructure or planting trees at or around the Project site due to the negative effects they bring to the dairy cows. Common green infrastructure includes landscaping features such as trees, shrubs, and standing water that attract insects. In turn, this attracts birds and/or other animals. The United States Department of Agriculture (USDA) recommends incorporating enhanced biosecurity features into new dairy operations to avoid unwanted diseases. West River Dairy Expansion measures included designing the facility to minimize livestock exposure to birds and further prevent disease transmission, such as Highly Pathogenic Avian Influenza."

Landscaping with trees, shrubs, pollinator friendly plants near constructed ponds could provide aesthetic mitigation for the adverse effects of the enormous built infrastructure proposed in this project while providing a modicum of natural habitat for birds, insects and many other forms of important wildlife. As described above, this entire region has had its wildlife populations of all kinds, decimated by loss of these types of habitats. While this biosecurity practice may be recommended by the USDA, alternatives to these environmentally harmful biosecurity measures should be evaluated with an EIS.

F. EAW fails to identify impaired waters and loss of biodiversity as evidence of past and present projects

The writers of the EAW miss an opportunity to utilize comments from other agencies to document how past projects have degraded several aspects of the environment in the vicinity of this project.

The DNR letters and emails attached to the EAW identified several areas with high potential for restoration **very near the project** and recommended the project include plans to implement designs to prevent surface runoff or invasive species from damaging these areas:

> "The Minnesota Biological Survey (MBS) considered several areas very near the proposed project for Sites of Biodiversity Significance that did not meet the minimum biodiversity threshold for statewide significance. Despite being Below the statewide threshold, these areas may have conservation value at the local level as habitat for native plants and animals, corridors for animal movements, buffers surrounding higher quality natural areas, or as areas with high

potential for restoration of native habitat. **As such, indirect impacts from surface runoff or the spread of invasive species should be considered during project design and implementation**.

The project, as presently designed, does not specify any special designs or alternative measures intended to effectively avoid these impacts. This is an appropriate function of the EIS and underscores the need for that higher level of review that we support.

And the DNR identified several areas of high biological significance near the project largely due to bird populations, but mollusks and plant species were also mentioned:

> Ecologically Significant Areas • Three lakes near the proposed project area have been identified as Lakes of **High Biological Significance**. **These are Gorder Lake, Clear Lake, and an unnamed lake in T124N R43W Section 13**. Lakes of Biological Significance were ranked as Outstanding, High, or Moderate based on unique plant and animal presence. These lakes received their rank largely due to their bird populations.
>
> Elktoe (Alasmidonta marginata), a state-listed threatened mussel; Small white lady's-slipper (Cypripedium candidum) and prairie mimosa (Desmanthus illinoensis), both state-listed plant species of special concern
>
> • To benefit all of the above rare species and features, **we recommend that manure application rates and timing be carefully determined to ensure that nutrient input does not exceed the ability for crop nutrient uptake on the fields where it is applied.**
>
> The Environmental Assessment Worksheet should **address whether the proposed project has the potential to adversely affect the above rare features and, if so, it should identify specific measures that will be taken to avoid or minimize disturbance**. Sufficient information should be provided so the DNR can determine whether a takings permit will be needed for any of the above protected species."

Here the DNR recommends the EAW establish whether the proposed project has potential to affect these species but it does not. While buffers are shown around manure application fields near wetlands and water courses no analysis is provided to assure these buffers are sufficient to avoid or minimize the effects the DNR is concerned about. An EIS should be prepared to answer the question the DNR poses in order to inform the Department whether a takings permit will be needed. The EAW did not and likely could not provide this level of analysis.

The EAW reveals specific water body impairments near the project that included Lake Hattie had a nutrients TMDL plan approved in 2015 and the Pomme de Terre River identified turbidity (2002) and fecal coliform (1994) impairments. Muddy Creek has excessive E. Coli (2020) while Dry Wood Creek has listed impairments for dissolved oxygen (2012) benthic macroinvertebrates bioassessments (2012) Turbidity (2010) E. Coli (2010) with TMDL plans approved for all impairments in 2015.

The proposed project can be predicted to exacerbate these impairments given the EPA's finding that the state's feedlot rules are ineffective for protecting water quality (see item 3-A below). These impairments are, as evidenced by the TMDL plans prepared for

them, significant and in need of reduced loading primarily from improper handling of livestock wastes in their respective watersheds. An EIS is necessary to explore alternative methods for land application of livestock wastes from this facility as part of the remedial actions called for in the TMDLs.

Criterion 3 - Degree of mitigation by ongoing public regulatory authority - The RGU evaluates if existing, specific regulatory permits or processes can effectively mitigate the environmental impacts.

A. The EPA has found MPCA's existing feedlot rules and permits to be inadequate

The Minnesota Division of the Izaak Walton League of America on the advice of the Prairie Woods Chapter in Detroit Lakes joined with the MCEA, Trout Unlimited and the Minnesota Well Owners Organization (MnWOO) and others in signing a petition to the U.S. Environmental Protection Agency (EPA) that successfully convinced the EPA that the MPCA's current rules and permit requirements for feedlots were inadequate to protect water quality and the human environment as required by the Federal Clean Water Act. The EPA instructed the MPCA to revise or amend their rules and write more effective permits. While the MPCA is in the process of making these improvements, the proposed project is subject to the very same existing rules the EPA found inadequate.

The petition to EPA did focus on karst and sand plain regions of Southeaster and Central Minnesota but similar alluvial sands exist in the areas in and around Stevens County where manure application fields have been identified for this project.

While this fourth criterion is primarily intended to require identification of regulatory authority in place that could mitigate potential environmental impacts it can also function to identify shortcomings of existing regulations. That is precisely the situation we have here. There is no more compelling argument for ordering an EIS on this and any other large feedlot proposed in Minnesota than this finding by the highest environmental authority in the nation, the U.S. Environmental Protection Agency.

B. MPCA will not have strengthened feedlot rules in time to control this project

As stated in item 3-A above, the MPCA's rules and permit requirements for feedlots are in the process of being improved to satisfy the EPA and the public that they will adequately protect water quality. However, those improvements have not yet been made. Yet the MPCA has proceeded to draft an EAW and a prospective permit for this project under these decidedly inadequate rules.

In a footnote to a table showing depths to groundwater under the projects manure application fields the EAW states:

> **The Proposer has agreements with landowners for manure application covering over 16,500 acres. Depth to groundwater will vary throughout these acres.* ***There are no rules prohibiting***

manure application onto high water table soils. *The Proposer uses and exceeds BMPs for manure application and follows all state rules and local ordinances. (bolding added for emphasis)*

This declaration (in bold) by the project proposer demonstrates how feedlot operators can take advantage of the agency's overly lax feedlot rules to apply manure where shallow water tables are vulnerable.

The MPCA's moving this project forward to this point may be required by laws intended to streamline the permitting process. But by ordering an EIS on this and any other feedlot seeking a permit in the interim, the MPCA has the choice of forestalling inadequately designed feedlots from being constructed and operated until more adequate rules are in place. While not the intended purpose of the document, an EIS can serve as an effective guide in crafting rules and permit conditions that meet the EPA's requirements and fulfil the goals of the Clean Water Act.
This in effect, would declare a moratorium on large feedlot permits until such time as the rules are deemed adequate to protect the state's water quality.

We request the MPCA respond to this proposition by exploring their own and possibly the Environmental Quality Board's statutes and rules to assure the Agency has the authority and willingness to temporarily hold permits in abeyance for this purpose.

C. Local ordinances and county feedlot officers are ineffective

Here again, we apply this criterion to demonstrate the lack of regulatory authority at the local county or township level to mitigate identified environmental effects not otherwise addressed by state or federal rules. The Izaak Walton League's experience in Becker County and other rural counties has demonstrated local governments reluctance to effectively control water pollution from feedlots through local land use ordinances. In fact, these counties defer to the MPCA on these matters insisting that they control land use conflicts through ordinances, but they do not and will not control water pollution from these activities.

D. Federal Clean Water Act authority remains delegated to the state MPCA

While the EPA did find the MPCA feedlot rules inadequate the federal agency has not revoked the state's authority to continue issuing permits under the existing rules while the state's feedlot rules are undergoing amendments. Thus, citizens cannot depend on the federal government to prevent feedlot pollution.

E. MPCA may be in violation of MEPA which prohibits permitting polluting activity when less polluting alternatives exist

Minnesota Statutes 116D.04 (the Minnesota Environmental Policy Act or MEPA) in Subdivision 6 – Prohibitions states:

"No state action significantly affecting the quality of the environment shall be allowed, nor shall any permit for natural resources management and development be granted, where such action or permit has caused or is likely to cause pollution, impairment, or destruction of the air, water, land or other

natural resources located within the state, so long as there is a feasible and prudent alternative consistent with the reasonable requirements of the public health, safety, and welfare and the state's paramount concern for the protection of its air, water, land and other natural resources from pollution, impairment, or destruction. Economic considerations alone shall not justify such conduct."

Given that the EPA has officially notified the MPCA, the petitioners and the public (including Riverview Farms that the agency's feedlot rules are inadequate to protect water quality it is likely that if the agency does proceed to issue a permit for the project it will, in this federal agency's opinion, cause the pollution, impairment or destruction expressly prohibited by this section of MEPA when and if the project is constructed and operated as planned.

We agree with the EPA and also believe that this project will cause or is likely to cause pollution, impairment, or destruction of the air, water, land or other natural resources located within the state and that feasible and prudent alternatives to the issuance of this permitting action by the state exist including the no action (no permit) alternative. And, as MEPA states; any economic hardship such permit denial may inflict on permit applicants shall not be used to justify issuance of a permit for this or other similar projects.

Should the MPCA choose to issue this, or other large animal feedlot permits before it has properly amended its feedlot rules, we assert that such state agency action would be in violation of this prohibition section of MEPA.

In its response to these comments, we request the MPCA address this assertion and explain to us and the public why they should be considered in violation of MEPA in this situation.

F. <u>MPCA fails to extend its authority over pollution caused by manure delivered to other farmers and landowners</u>

MPCA feedlot permit writers and enforcement staff admit they have not attempted to extend permit conditions for land application of manure to secondary users. This means these secondary users have been knowingly allowed complete immune from compliance with the permittees manure management plan. This is an obvious failing of the MPCA's current feedlot rules and permits or the agency's enforcement policy.

The MPCA should not issue feedlot permits or approve manure management plans that allow this loophole that has significant potential for adverse effects on water quality. An EIS may be useful for exploring the jurisdictional options and authority the MPCA has or may need to close this loophole.

G. <u>MPCA has failed to adopt nitrate standards for surface and groundwaters.</u>

The Minnesota legislature granted the MPCA the authority and resources to develop nitrate standards to protect aquatic life uses for the state's surface waters and regulate

non-fertilizer sources of nitrates (primarily manure) from large feedlots decades ago but the agency has not completed the necessary rulemaking to implement this authority.

An EIS for this project that calculates nitrate loading to area surface waters (and groundwater) from the project may help underscore the urgency for the agency and the Minnesota Department of Agriculture to complete the rulemaking in effective way to control manure borne nitrates from polluting both surface and groundwaters.

Criterion 4 - Anticipation and control of effects from other studies - The RGU considers if the effects can already be managed through other available environmental studies or previous EISs conducted for the project or area

A. No other EIS has been prepared on a feedlot of this size in the project area or similar setting

This is an important fact and should be considered support for preparing an EIS for this project. The food industry in general has avoided formal environmental scrutiny by local, state or federal governments. Scientific studies of this industry's impacts are widely available in literature, and the impacts are myriad and widespread. We believe the MPCA is capable of a thorough literature search for these studies to corroborate this assertion. But, to assist the agency we've attached a report prepared by the Prairie Woods Chapter of the Izaak Walton League of America for Becker County's planned update of its comprehensive land use plan as it was dealing with a proposed CAFO in 2024. The report cites a number of environmental impacts identified by scientific studies.

The MPCA would be well justified in selecting this, the largest ever proposed CAFO in the state for the very first EIS.

B. Compliance with TMDL goals for areas surface waters are not acknowledged

C. Other studies have found large feedlots degrade local economies and community health

The following is taken from the abstract of Kelley J. Donham, et al article entitled: "*Community Health and Socioeconomic Issues Surrounding Concentrated Animal Feeding Operations"* [4]*.*

A consensus of the Workgroup on Community and Socioeconomic Issues was that improving and sustaining healthy rural communities depends on integrating socioeconomic development and environmental protection. In workshop sessions the following recommendations were developed:

"Workshop Recommendations

[4] Environmental Health Perspectives • VOLUME 115 | NUMBER 2 | February 2007

Priority research needs.
Community health studies. *Although sufficient research supports actions to protect rural residents from the negative impacts of CAFOs on community health, additional research could be conducted to further delineate mechanisms of effects and impacts on susceptible subgroups. These areas include psychophysiologic impacts of malodor; impacts of malodor on mental health and quality of life; and respiratory impacts of bioaerosol mixtures, especially among asthmatics, children, and the elderly. Wider and more effective application of community-based participatory research will be important to advance research in these areas.*

Sustainability of livestock production.
Federal funding for agricultural research should be reoriented to promote innovation in sustainable livestock production.

Translation of science to policy.
Requirements for issuing permits for CAFOs should include increased protections for health and the environment including the following:

• CAFOs should be sited and issued permits on the basis of total animal density allowed in a given watershed as determined by the carrying capacity.

• Environmental impact statements should be mandated for all new CAFOs. These should include environmental health, social justice, and socioeconomic issues.

• Decisions to issue permits for CAFOs should be considered in public meeting and decided at the local level.

• CAFOs should be regulated using standards applied to general industry based on the level of emissions and type of waste handling.

• Permits for manure storage basins should require bonding for performance and remediation.

• The current state of knowledge of community impacts of CAFOs warrants support for the American Public Health Association recommendation for a moratorium on all new CAFO construction."

D. Economic impacts are not included in EAWs but can be addressed in an EIS

Dr. John Ikerd, who holds a PhD in Agricultural Economics, now retired from University of Missouri-Columbia, in a Freshwater Futures May 15, 2024, webinar presentation entitled "Economic Fallacies of CAFOs", presented the following conclusions from multiple studies:

- 2008 Review: Reams of research dating to the 1940's show local economies

suffer economically and socially from industrial agriculture;

- 2001 Study: Many CAFO counties are forced to raise taxes to offset increased
  costs of repairs to rural roads and bridges;

- 2008 Study: Lower income, greater income inequality, more poverty, less active
  "Main Street", fewer stores, and less retail trade in CAFO counties;

- 2015 Study: Property values up to 7 miles from CAFO lowered by 3.1% to 26%;
  properties next to CAFOs down 88%;

- 2022 Study: Personal incomes dropped 8% from 1982 to 2017 in Iowa counties
  with most CAFOs. Other rural counties rose 41%.

Dr. Ikerd, in his own paper entitled: Economic Realities of CAFOs[5] draws the same conclusions and more. He includes an extensive list of reference publications that support his findings. Below are some excerpts from that paper on rural community impacts:

> *"Defenders claim that regardless of the need for CAFOs to meet the needs of consumers, CAFOs are necessary for the economic survival of many farming communities. They point specifically to community economic benefits from local investments in CAFOs, local sales of animals and animal products, and local employment in CAFOs and related local industries. However, decades of socioeconomic research and actual experience in CAFO communities reveal something very different. Whatever CAFOs contribute to local tax bases is more than offset by increased costs of maintaining rural roads and bridges that were not built to accommodate the heavy truck traffic associated with CAFOs. Also, local CAFOs operators typically source construction materials and labor from outside their local communities. Feeder animals, feed, and other supplies are shipped in from elsewhere. Even animal health care is typically provided by corporate veterinarians. Few of the economic benefits from CAFOs remain in local communities.*
>
> *The most frequent claim for community benefits is probably that CAFOs will increase local employment, which is sorely needed in many farming communities. However, the economic reality is that CAFOs employ far fewer people per dollar invested or unit of production than do the independent family farms they inevitably displace. The first research I personally did on this subject was an evaluation of CAFOs as a rural*

[5] "Economic Reality of CAFOs and Rural Communities" - Dr. John Ikerd - University of Missouri - Prepared in May 2020 for discussion at screenings of the CAFO documentary film, Right to Harm, and other uses.

economic development strategy. I evaluated the employment implications of PSF's planned operation in north Missouri. My conclusion was that if PSF came into Missouri, their CAFOs would displace up to three independent Missouri hog farmers for every job they created.[26] CAFOs came to Missouri, and Missouri lost more than 90% of its independent hog producers. I doubt that the number of workers employed in CAFOs in Missouri exceeds more than one-third of the independent hog farmers they displaced. In the case of CAFOs, once livestock and poultry production became specialized, previously diversified family farms became specialized producers of either livestock or crops.

Livestock and poultry were major sources of farm income that had made many diversified family farms economically viable. So, farmers who specialized in grain production were forced to farm more acres of land than before to maintain adequate family incomes. Larger crop and livestock operations meant fewer economic opportunities for farmers. With the industrialization of agriculture, the percentage of the U.S. labor force employed in agriculture dropped from 4.4% in 1970 to less than 1.5% in recent years. Even in the communities where they locate, CAFOs do not actually create jobs. They simply relocate and concentrate fewer lower-paying jobs in CAFO communities than had previously existed on family farms elsewhere.

In addition, this loss of farm families cannot be offset by people moving into rural communities from elsewhere. No one really wants to move to a CAFO community. A 2015 study reviewed thousands of assessed property values for residences located up to 7 miles distant from CAFOs. The review concluded: "Overall, the new studies confirm the [negative] valuation impacts reported in earlier studies, as they range from 3.1% to 26% losses depending on multiple factors, and that properties immediately abutting an AO [CAFO] can be diminished as much as 88%."

It takes people, not just production, to support rural communities. It takes people not only to buy farm supplies and equipment but also to shop on Main Street for cars, clothes, shoes, and haircuts. It takes people to send their kids to local schools, to attend local churches, and to serve on volunteer fire departments and local town councils. When independent family farmers are displaced by CAFOs, it's not just a matter of losing employment; it's a matter of losing the essence of what it takes to be a viable rural community."

After detailing our specific comments on the EAW above, it is important that we make some broader statements here about the deficiencies of Minnesota's environmental review process itself. The worksheets used to make preliminary determination on the potential significance of a project's environmental effects have evolved to be so focused on categorical details as to miss the big picture. The public who reads these lengthy EAWs gets lost in minute details and is never informed of the devastating, incrementally small but cumulatively significant destructions of nature that humans have committed.

The ecological setting for this massive, multifaceted food (milk) industry enterprise is one that has, over many decades, been incrementally degraded to such an impoverished level that the beneficial functions (services) original ecosystems once provided have been all but obliterated. These are the very services nature delivers for free that are essential for all life forms including humans. Pure clear air, clean and plentiful water, fish and wildlife once abounded here. Remnants of the tall grass prairie and wetland complex ecosystems that existed prior to its near total conversion to agriculture (dotted by small human communities) remain only in small insignificant patches here and there. This EAW hints at what the area used to be and in subtle ways justifies the projects contribution to the ecological destruction by explaining that the land is now only used for agriculture and therefore there is little measurable impact on the parts which remain in their "natural" state. That is to say that if natural attributes of our property have already been destroyed, our project's further contribution to that destruction can only be described as minimal or insignificant. Our proposed use is consistent with current land use. We find phrases like this used frequently in this and many other EAWs.

If the setting, the natural backdrop of this project was to be fairly described, it would have to disclose the plummeting populations of insects, birds, fish, reptiles, amphibians, fish and macroinvertebrates. It would have to describe soils that are no longer thriving ecosystems teeming with microscopic life forms important to healthy crops or native prairie. This is known science but this and other EAWs avoid mention of it. Thus, the public largely remains unaware of the apocalyptic declines and a projects likely role in continued declines. Only when a species for which we have some measure of its population trend (which is few) reaches a near extinction level to we call attention to in in EAWs and that is because it is required by law. There is no requirement to acknowledge mass declines on most all other wildlife and plant populations that are rapidly nearing extinction.

It was astonishing but revealing that the project proposer (who we all understand is allowed to draft the EAW) claims that natural vegetation (trees and shrubs) that might provide habitat for birds on or around the area used for confinement buildings would have to be removed in order to prevent the potential for viral infections transmitted by some birds to reach their livestock. When mere vestiges of nature are pronounced a threat to a human enterprise and sanctioned in a government document such an EAW, there is something seriously wrong with the process. It no longer serves the serves the spirit or intent of Minnesota's Environmental Policy Act that authorizes the document.

This is a substantive comment on all EAWs in general, but also on this one in particular. So, we request that the MPCA respond to it in its record of decision.

The scope and scale of the project under review is not fairly represented in the EAW. Riverview Dairy is a very large food industry spread widely across the landscape in Minnesota and other states. The huge dairy operation is but a fraction of the entire corporate food enterprise that, when viewed as a whole, has tremendous potential and

real impact. But current rules allow for segmenting incremental steps, whether large or small, into smaller parts.

We realize this may be allowed by current rules but nevertheless, nature responds (the environment is affected) according to natural rather than human law.

Karen Tolkkinen, a newspaper reporter put the subject project in its proper perspective, one not really allowed by environmental review because, as the EAW states below, the specific project is not presented as a phase or "stage" of any past, existing or future project, it's an expansion. And the proposer's existing facilities have already passed environmental muster so its impacts can no longer be counted.

The EAW states:

> "There are no past stages for the Project. The Existing Facility was permitted in August 2003 after undergoing environmental review and receiving a negative declaration on the need for an Environmental Impact Statement (EIS)."

In nature, serial impacts from a series of similar projects (especially large ones) in the same area add up. This by scientific definition is a "cumulative impact". But this is not definition allowed by Minnesota's environmental rules.

> "There are no planned future stages of the Project beyond what is described in this worksheet."

This statement above is also in the EAW and, for the moment it may be true. But do the public and the MPCA really believe that River View Dairy will not continue to expand and add more feedlots and even milk processing factories? EAWs are not allowed to speculate beyond what is not already in formal planning stages.

We refer to a more realistic assessment of the scope and scale of the no-less-than **fourteen** gigantic subcomponents of the larger project by the same owner. In Tolkkinen's recent Minnesota Star Tribune article she writes, *"the proposed expansion is the latest in a series of large dairies appearing in western Minnesota over the past two decades. Riverview's 13 dairy farms are located in Chippewa, Grant, Kandiyohi, Norman, Stevens, Swift, Traverse and Wilkin counties. A 14th in Traverse County, has been approved for 8,571 cows but not yet built."*

The article goes on to say: "*The Existing Facility in Stevens County was permitted in August 2003 after undergoing environmental review (EAW) and receiving a negative declaration on the need for an Environmental Impact Statement (EIS). The Existing Facility operates under the NPDES General Feedlot Permit and has undergone the addition of an anaerobic digester (2008), dry manure solids storage (2010), and liquid manure storage (2014). Additionally, the Existing Facility has increased its animal unit capacity three times (2008, 2011, and 2018)."*

Our state government's tolerance (it is not the MPCA alone) for siloing a segment of what is obviously a much larger industrial enterprise, that shelters it from closer

environmental scrutiny is a miscarriage of authority and a slow-moving environmental tragedy that is obvious to any student of the science.

It was one of the Izaak Walton League's early members, Aldo Leopold who aptly said:

> *"One of the penalties of an ecological education is that one lives alone in a world of wounds. Much of the damage inflicted on land is quite invisible to laymen. An ecologist must either harden his shell and make believe that the consequences of science are none of his business, or he must be the doctor who sees the marks of death in a community that believes itself well and does not want to be told otherwise."*

It is eminently and very possibly existentially regrettable that even our state agencies who accept and even produce flawed environmental assessments "do not want to be told otherwise".

These comments were prepared by Willis Mattison, professional ecologist, retired MPCA Regional Director now volunteering for the Izaak Walton League of America – Prairie Woods Chapter as chief science advisor. These comments are offered on behalf of the Prairie Woods Chapter with permission.

This concludes with our comments.

[9] Economic Reali es of CAFOs- Dr. John Ikerd, May, 2020

Addressing AFOs and CAFOs in Becker County's Comprehensive Land Use Plan and Zoning Ordinances

A Report to the Becker County Board, Zoning Administrator, the County Planning Commission the Comprehensive Planning Consultants and the Public

from

The Izaak Walton League of America's Prairie Woods Chapter

May 22, 2024

Comprehensive Land Use Planning

Most land use decisions are inherently local. In Minnesota local governments create their own "comprehensive plan" for growth and development. The plan establishes the way development occurs in that area. The primary purposes of the plan and the ordinances that implement it is to "promote and protect the health, safety and general welfare" of the public, to "preserve and enhance the quality of surface waters" and to "provide for the wise use of water and related land resources of the County"[1]

Decisions about local planning and zoning, local utilities and other infrastructure are all made pursuant to that plan. State law requires certain minimum elements in the plans but leaves it to localities to develop and implement them through ordinances. The plan is supposed to be reviewed, updated and approved every 10 years.

The Becker County Public Engagement Survey used to gauge citizen priorities for the current land use planning effort found that 70% of Becker County citizens thought more should be done to protect the water quality of lakes and streams. When the nearly 500 respondents were asked to note their top priorities in terms of issues facing the county 83% considered housing one of the three highest concerns. Further over 70% consider Jobs and economic development a key priority and slightly more than 50% see the environment as an issue to be prioritized.

A county's land-use decisions about the livestock and poultry operations (Animal Feeding Operations, AFOs and Confined Animal Feeding Operations, CAFOs) can

[1] Quotes from statement of purpose section 101 in Becker County Zoning Ordinance

have significant effects on the county's water quality, natural resources and human health, and economy, but impacts vary widely depending on sizes and locations of the operations. The impact of a single livestock or poultry project may seem small, but when we look at the bigger picture, the challenges to the environment and human health from both the small and industrial scale agriculture projects added together can be dramatic.

The livestock industry has experienced increasingly adverse conditions attributable to over-crowding; too many large facilities in close proximity increasing animal disease risks, depletion of available clean water supplies, saturation of available crop lands with manure and growing community animosity stemming from nuisance odor, traffic and insect (fly) populations.

Because industrial scale livestock agriculture is a recent arrival in Becker County the current comprehensive plan update is particularly well timed to perform its purpose of protecting the county's water quality, natural resources and human health as well as its economy.

The information provided here will serve to inform the County Board, the Planning Commission, the Zoning staff and the public that allowing industrial scale animal feeding operations to get established and to expand in Becker County will present a very high risk to the public health and welfare of its current and future residents, is highly likely to degrade the value of the county's natural resources and is a threat to the vitality of the County's rural economy.

Filling the AFO/CAFO Information Gap

Conventional wisdom expressed in recent deliberations about these divisions of government responsibility for livestock facilities led Becker County officials to wrongly defer to state and federal laws, permits and standards to protect surface and ground water as well as look after the general welfare and economic well-being of the county's citizens. And county zoning staff and planning commission members neither had the assignment nor the time or resources to fully research the laws or the literature

on large confined feeding operations. Zoning staff stated that no one had alerted them to issues relating to these operations and invited the public's assist in gathering more information.

The Izaak Walton League's Prairie Woods Chapter located in Detroit Lakes, the Becker County seat has offered to help fill these information gaps and provides the following documentation, resources and references.

CAFOs Are Migrating North Into the Lakes Region– Why?

New industrial scale feeding operations have been migrating north from Iowa and southern Minnesota in northwestern Minnesota in order to reduce disease risks and have access to ample clean water.

> *"The number of large concentrated animal feeding operations, or large CAFOs, in Iowa increased nearly fivefold in the past two decades, a new study from Environmental Working Group reveals, with almost all of the growth from big hog-feeding operations.*
>
> *EWG found that in 1990, Iowa had 789 large CAFOs – those housing 1,000 or more animal units – swelling to 3,963 in 2019. The findings are supported by the federal Census of Agriculture, which reported that Iowa, the top hog-producing state, housed more than 22.7 million hogs in 2017, an increase of 8.5 million since 1992.*
>
> *Swine and other livestock raised in Iowa's large CAFOs now produce 68 billion pounds of manure a year – conservatively, 68 times the total amount of fecal waste produced each year by the state's 3.15 million residents.*
>
> *Large hog CAFOs house a minimum of 2,500 pigs each, and the largest hog CAFO in Iowa houses 24,000 animals. In total, more than 60 percent of the animal waste produced by the largest CAFOs in Iowa comes from hogs. The*

mountains of animal waste produced by these facilities pose a serious and growing threat to human health, the environment and water resources in the state.

EWG used satellite and aerial imagery to pinpoint where and when the new large CAFOs appeared in Iowa. The interactive map (found at the link in footnote 2) below shows their locations, the type of facility, the animals housed there and the growth in facilities over the past two decades.[2]

Industry Claims That They Handle Manure Responsibly Don't Hold Up

Industrial farming representatives often claim farmers don't contribute to water nitrate or phosphorus pollution by over-apply fertilizers or manure because these materials cost too much, and it would be wasteful. However, Jeff Mitchell, Laboratory Supervisor for the Des Moines Iowa Water Works has found ever increasing concentrations of nitrates in the Des Moines and Racoon Rivers, primary sources of the city's drinking water over the past 50 years. In an August 2023 webinar entitled "*Nitrate in Drinking Water – Public and Private*" for the Izaak Walton League, Michell presented nitrate concentration trends for the Raccoon River from 1972-2023 shown in the graph below. By multiplying river concentrations by river flow volumes Michell calculated the total amount of nitrogen flowing past the city in 2018 (if applied as anhydrous ammonia would have cost $10 million and could have fertilized 400,000 acres, over 20% of the watershed. Since 1974, he calculated that 1.8 **Billion** pounds of nitrogen had flowed past the city in the river. Using similar calculations Mitchell demonstrated that in 2015, 116,000,000 pounds of nitrogen was lost to the river at a cost of $35,000,000, and as fertilizer it would have treated 800,000 acres (40% of the watershed).[3]

---

[2] EWG Study and Mapping Show Large CAFOs in Iowa Up Fivefold Since 1990 – See interactive map at: https://www.ewg.org/interactive-maps/2020-iowa-cafos/

[3] Jeff Mitchell – 2023 Izaak Walton League Clean Water Webinar Series *"Nitrate in Drinking Water: Public and Private"* at: https://www.youtube.com/watch?v=OpSnuGti2k0

These data clearly show that farmers do over-apply both commercial and manure fertilizers at a great economic loss to the farmers themselves and at great expense to municipal water suppliers such as Des Moines to remove that fertilizer again. Nitrate removal has cost the city over $317,000 in 2016 and over $750,000 in 2015.

	2013	2014	2015	2016	2017	2018	2019	2020	2021	2022

Public water supplies must meet drinking water standards, are tested often and as shown above, treatment can be effective when nitrate contamination is found, but it is very expensive. On the other hand, private well owners in rural areas lack testing, no standards are enforced and well-owners are “on their own” when contamination comes from their neighbor’s activities.

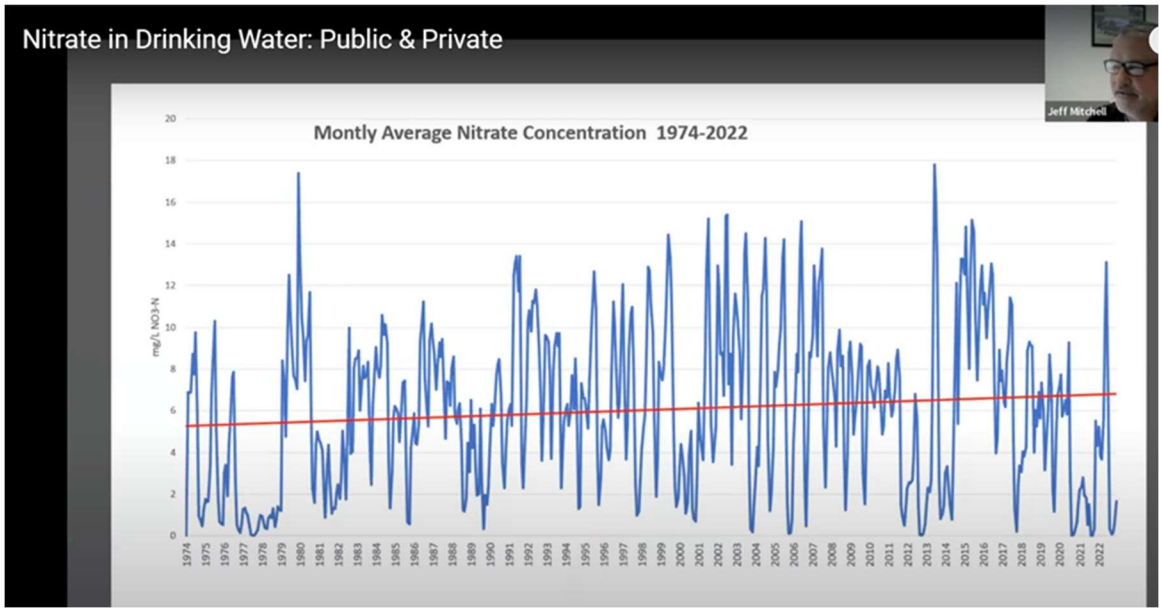
All Manure Pits and Lagoons Leak

In Wisconsin and other states including Minnesota, manure pits and lagoons are designed to limit leakage to less that 500 gallons/acre/day. This means that a three-acre lagoon is allowed to leak 1,500 gallons per day and could total over one half million gallons per year into the groundwater below. This has cause major problems for rural well owners.

A USDA study in Wisconsin examined this problem and found that not only nitrates were reaching private drinking water wells but that fecal coliform bacteria from the manure pits were traveling over three miles from the source.[4]

> *Borchardt's study found that the No. 1 risk factor for contamination was the proximity of a well to a manure storage pit. Borchardt said the closest well in the study was 150 feet from a manure pit, but even wells three miles away still have some risk of being contaminated with coliform.*
>
> *Borchardt called coliform an "indicator bacteria" for the presence of other bacteria and pathogens.*
>
> *According to state regulations, manure lagoons are allowed to leak 500 gallons per acre, per day. Borchardt said contamination of nearby wells may be due to leakage from the lagoon, as well as the tendency of farmers to spread liquid manure close to the location of their pits.*
>
> *According to a spreadsheet of permitted manure storage pits in Kewaunee County from 2017, some of the largest pits for which dimensions were listed span more than 4 acres. Borchardt said there are around 270 manure pits in the county.*
>
> *"(The findings give) policy makers and other stakeholders interested in working on solutions the information they need to think about solutions, instead of just saying 'Hey, your wells are contaminated,' " Borchardt said.*

The Minnesota Pollution Control Agency's construction standards for manure pits and lagoons are "theoretical" rather than practical. This means that if construction standards are followed the pits "should not leak more than allowed but need not demonstrate that they are indeed not leaking. Pits and lagoons are allowed to leak slightly less than 500 gal/acre/day leakage but is generally understood to be 500 non-the-less.



> "Minn. R 7020 requires that non-concrete liners for LMSAs be designed to achieve a theoretical seepage rate of no more than 1/56 of an inch per day. The required seepage standard is routinely considered to be approximately 500 gal/acre/day; however, this is slightly more than the actual 485 gal/acre/day allowed by the rule. Long-term protective

[4] **New research indicates tainted Kewaunee County wells tied to manure pits –** March 4, 2019 – Green Bay Press Gazette at: https://www.greenbaypressgazette.com/story/news/investigations/2019/03/04/tainted-kewaunee-county-drinking-water-wells-tied-manure-pits/3054018002/

and maintenance measures are required to meet this limit throughout the life of the structure."[5]

This maximum leak-rate standard applies to manure storage facilities no matter what kind of liner is provided including concrete, clay, Geotech (bentonite) or petroleum (plastic) liners.

It is important to note that while the MPCA rule requires this leak rate be maintained throughout the life of the pit or lagoon there are no requirements for demonstration that the structures are not leaking more than this rate at the time of construction or with aging over time.

As part of the same Izaak Walton League webinar Jesse Campbell, Private Well Coordinator for the Midwest Assistance Program, shared information the Iowa Environmental Council had gathered about the presence of nitrate in groundwater and the challenges faced by private well users in avoiding nitrate contamination. In a 2019 Water and Land News report Campbell revealed that "more than 6,600 private wells (12% of those tested) had nitrate averages at or above the EPA's legal limit (10 ppm) for drinking water systems and more that 12,330 wells (22%) had nitrate levels at or

[5] **Liquid Manure Storage Areas MPCA guidelines for design, construction, and operation of all types of liquid manure storage areas** – p 30 of 60, found at: https://www.pca.state.mn.us/sites/default/files/wq-f8-04.pdf

above 5 ppm. Natural background nitrate levels in Iowa ground water are generally less than 1 ppm.

Becker County, like most other rural counties, does not have private well protection strategies in policy or ordinances other than well setbacks from on-site sewer systems. And private well owners seldom, if ever have their wells tested to see if drinking water standards are being met. If a neighbor's CAFO should contaminate a private well, the well-owner has little recourse and will only have the choices of continuing to drink the contaminated water, purchase bottled water or drill a deeper well.

Economic Impact of CAFOs on Rural Communities

Dr. John Ikerd[6], who holds a PhD in Agricultural Economics, now retired from University of Missouri-Columbia, in a Freshwater Futures May 15, 2024 webinar presentation entitled *"Economic Fallacies of CAFOs*[7]*,* presented the following conclusions from multiple studies[8]:

- 2008 Review: Reams of research dating to the 1940's shows local economies suffer economically and socially from industrial agriculture;
- 2001 Study: Many CAFO counties are forced to raise taxes to offset increased costs of repairs to rural roads and bridges;
- 2008 Study: Lower income, greater income inequality, more poverty, less active "Main Street", fewer stores, and less retail trade in CAFO counties;
- 2015 Study: Property values up to 7 miles from CAFO lowered by 3.1% to 26%; properties next to CAFOs down 88%;

[7] **Freshwater Futures' Great Lakes HABs & CAFO Manure Conference Series** May 9, 2023. YouTube Recordings from the Conference can be found at: https://www.youtube.com/playlist?list=PL_JsLZuTdlRu96Q1tarJmgjsWOHEdoIYv

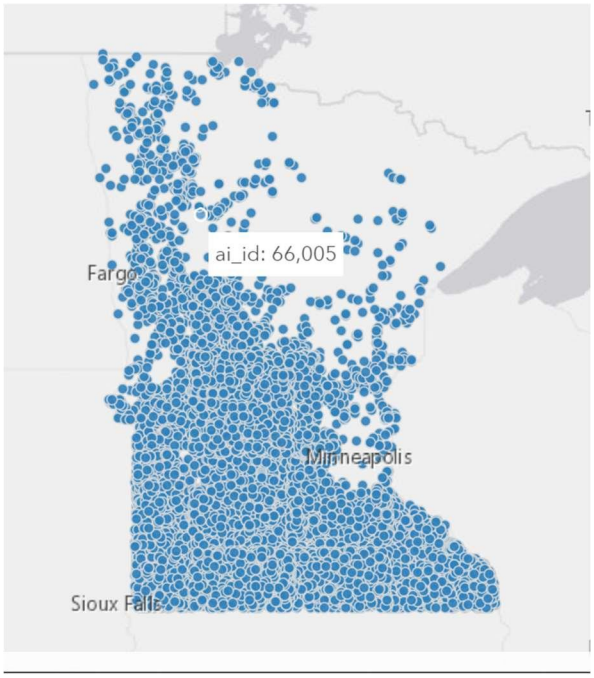
[8] Studies referenced by Dr. Ikerd are attached to the cover email transmitting this report to Becker County Planning Consultants, to the County Board and to the Zoning Administrator.

- 2022 Study: Personal incomes dropped 8% from 1982 to 2017 in Iowa counties with most CAFOs. Other rural counties rose 41%.

Dr. Ikerd, in his paper entitled: *Economic Realities of CAFOs* draws the same conclusions and more. He includes an extensive list of reference publications that support his findings.[9] Below are some excerpts from that paper on rural community impacts:

> *"Economic Reality of CAFOs and Rural Communities.*
>
> *"Defenders claim that regardless of the need for CAFOs to meet the needs of consumers, CAFOs are necessary for the economic survival of many farming communities. They point specifically to community economic benefits from local investments in CAFOs, local sales of animals and animal products, and local employment in CAFOs and related local industries. However, decades of socioeconomic research and actual experience in CAFO communities reveal something very different. Whatever CAFOs contribute to local tax bases is more than offset by increased costs of maintaining rural roads and bridges that were not built to accommodate the heavy truck traffic associated with CAFOs. Also, local CAFOs operators typically source construction materials and labor from outside their local communities. Feeder animals, feed, and other supplies are shipped in from elsewhere. Even animal health care is typically provided by corporate veterinarians. Few of the economic benefits from CAFOs remain in local communities.*
>
> *The most frequent claim for community benefits is probably that CAFOs will increase local employment, which is sorely needed in many farming communities. However, the economic reality is that CAFOs employ far fewer people per dollar invested or unit of production than do the independent family farms they inevitably displace. The first research I personally did on this subject was an evaluation of CAFOs as a rural economic development strategy. I evaluated the employment implications of PSF's planned operation in north Missouri. My conclusion was that if PSF came into Missouri,*

[9] *Economic Realities of CAFOs- Dr. John Ikerd, May, 2020 at:* https://ikerdj.mufaculty.umsystem.edu/presentation-papers/factory-farms-cafos/economic-realities-of-cafos



their CAFOs would displace up to three independent Missouri hog farmers for every job they created.[26] CAFOs came to Missouri, and Missouri lost more than 90% of its independent hog producers. I doubt that the number of workers employed in CAFOs in Missouri exceeds more than one-third of the independent hog farmers they displaced.

In the case of CAFOs, once livestock and poultry production became specialized, previously diversified family farms became specialized producers of either livestock or crops. Livestock and poultry were major sources of farm income that had made many diversified family farms economically viable. So, farmers who specialized in grain production were forced to farm more acres of land than before to maintain adequate family incomes. Larger crop and livestock operations meant fewer economic opportunities for farmers. With the industrialization of agriculture, the percentage of the U.S. labor force employed in agriculture dropped from 4.4% in 1970[27] to less than 1.5% in recent years.[28] Even in the communities where they locate, CAFOs do not actually create jobs. They simply relocate and concentrate fewer lower-paying jobs in CAFO communities than had previously existed on family farms elsewhere.

In addition, this loss of farm families cannot be offset by people moving into rural communities from elsewhere. No one really wants to move to a CAFO community. A 2015 study reviewed thousands of assessed property values for residences located up to 7 miles distant from CAFOs. The review concluded: "Overall, the new studies confirm the [negative] valuation impacts reported in earlier studies, as they range from 3.1% to 26% losses depending on multiple factors, and that properties immediately abutting an AO [CAFO] can be diminished as much as 88%."[29] It takes people, not just production, to support rural communities. It takes people not only to buy farm supplies and equipment but also to shop on Main Street for cars, clothes, shoes, and haircuts. It takes people to send their kids to local schools, to attend local churches, and to serve on volunteer fire departments and local town councils. When independent family farmers are displaced by CAFOs, it's not just a matter of losing employment; it's a matter of losing the essence of what it takes to be a viable rural community."[10]

10

The map below suggests the northerly progression of large feeding operations (CAFOs) into Minnesota stretching to the far northwestern corner of the state. [11]

These realities highlight the importance of using local land use plans and ordinances for proper siting, inspection and monitoring of large livestock facilities where the public can have greater confidence that pollutants are not and will not enter surface or groundwaters without detection. Becker County has set an important protective precedent by requiring water sampling for large feedlots needing conditional use permits. But the water sampling regime lacks sufficient sophistication to assure the monitoring would accomplish the intended purpose.

Industrialized Food System Engenders CAFOs.

Over the last 250 years, almost every sector of the American economy has become dominated by a handful of corporations. The forces that drove that trend have also come together to transform the most important sector of the American economy: the

[11] Source: MPCA on-line, data may not be current: https://hub.arcgis.com/datasets/mpca::feedlots-2/explore?layer=3&location=45.932764%2C-92.791165%2C6.00

food system. The way in which the United States produces and distributes is food has a profound effect on worker rights, animal welfare, air quality, water quality, the landscape, rural communities, public health, international trade, and the global climate. Livestock and poultry DNA are now owned, manipulated and sold to American farmers by a handful of corporations. Four companies control 66 percent of the hog genetics; three companies control 95 percent of the broiler chicken genetics; two companies control 99 percent of turkey genetics.[12]

Iowa Select Farms employes more than 7,400 people, including contractors, and brings about five million pigs to market annually. Since Iowa Select was founded in 1992, the states pig population has increased more than 50 percent while the number of hog farms has declined by over 80%. Pigs now outnumber human residents by a ratio of more than seven to one, and they produce a volume of manure equivalent to the waste of nearly eighty-four million people, more than the populations of California, Texas and Illinois combined.[13] One expert estimated that each confinement facility produces "the same amount of waste as a city of 90,000 to 150,000 people," spread over 640 acres with no sewage system.[14]

State and federal laws do regulate some environmental impacts of livestock operations but other than prohibiting siting in flood plains and wetlands, these regulations do not control the location of this particular agricultural land use. Recent findings by a federal agency show that Minnesota's regulations are inadequate to protect surface and groundwaters from nitrate pollution (more details on these findings are found later in this document). Therefore, without local government playing its role for proper siting of livestock facilities the government's protective network is not only incomplete but has been shown to be ineffective. This means that local governments must exercise their authority and responsibility for deciding if and where large

livestock facilities are located in their county in order close this loophole in the state and federal regulatory scheme.

Under the Federal Clean Water Act, direct discharge of manure to surface waters from livestock holding pits and lagoons is prohibited for large Confined Animal Feeding Operations (CAFOs are over 1000 animal units). However, the controls on land spreading of manure from both the larger CAFOs or smaller AFOs (animal feeding operations under 1000 animal units) for disposal or fertilizer use are strictly voluntary. Manure management plans, whether for CAFOs or AFOs, generally adopt what is known as best management practices (BMPs) for manure spreading based on so-called agronomic rates of application. Such agronomic rates are designed to maximize efficiency of manure application while allowing maximum application for crop production purposes alone and have no scientific basis for surface or groundwater protection. These BMPs have been demonstrated to be ineffective, not only in Minnesota but in a number of states and watersheds around the country.

Once surface and groundwaters are degraded by concentrated livestock feeding operations or other sources little can be done to reverse these impacts. Given the county's location in the heart of the lake country's tourism region, degraded surface water quality has potential significant economic consequences. Therefore, Becker County officials can benefit greatly from the experience in other states and regions by taking a "no-regrets" planning approach.

The League has researched several other states and another region of Minnesota to gather the experience of others with industrial scale agriculture beginning with Chesapeake Bay in Massachusetts.

Chesapeake Bay-

Over forty years ago, bay watchers and state officials noticed significant water quality and aquatic life deterioration. In 2004 studies investigating severely degraded water in the bay revealed the primary causes were increased nitrogen and phosphorus from intensifying livestock agriculture.

"The Chesapeake Bay is choking on nutrient pollution from a myriad of sources – from urban runoff, industry, automobiles, and human sewage, but the largest source is agriculture and, increasingly, from the manure produced by livestock, which now outnumber the watershed's human population by 11 to 1. Most of that manure is spread on the surface of nearby cropland, and studies show that within two years as much as half of its nutrient pollution washes out of the soil and into rivers and streams or seeps into groundwater. Both of these pathways lead to pollution in local waterways and, ultimately, in the Bay.

"Of the nitrogen and phosphorus that reach the Bay, agriculture is the largest source and animal manure is the largest agricultural component. Chemical fertilizers and airborne pollutants such as ammonia gas—a common manure by-product – make up the rest of the agricultural sources. This makes animal manure not only the largest source of nitrogen and phosphorus deposited on the land, but also the second largest source that reaches the Bay, behind sewage, which is deposited directly into the water. Animal manure is a major source of the Bay's pollution and must be addressed swiftly and comprehensively.[15]"

After 40 years of intensive, watershed wide efforts to restore water quality after severe degradation by non-point pollution Chesapeake Bay maybe only holding its own because crop and farm animal sources of nutrients have proven difficult to cure:

"Controlling agricultural runoff, the largest source of nutrients, has turned out to be more complex. Significant regionwide reductions have proven difficult. Data suggest, though, that efforts over the last 15 years have held the line, despite increases in crop production and growing numbers of chickens and other farm animals."

Now, as the Bay Program celebrates its 40th anniversary, its partners are contemplating what comes after 2025, the deadline for meeting most of the 31 outcomes set in its 2014 agreement. Of those, 15 are on track, 10 are off-

[15] **Manure's Impact on Rivers, Streams and the Chesapeake Bay- Keeping Manure Out of the Water, A Report by the Chesapeake Bay Foundation** July 28, 2004 at: https://www.cbf.org/document-library/cbf-reports/0723manurereport_noembargo_7567.pdf

course and the status of four others is unclear. Nutrient goals will be missed by a large margin."[16]

Maumee River in Ohio and Western Lake Erie in Michigan

Lake Erie water quality improved greatly in the 1980s-90s when point sources of nutrient pollution were remedied by the Clean Water Act but recent expansion of intensive crop and animal agriculture (factory farms) have reversed these gains and frequent toxic algae blooms have once-again become the norm.

> *"The Maumee River, overloaded with fertilizer and manure, is the single largest source of the phosphorus that triggers blooms of toxic algae in Lake Erie. Over half of the manure in the Maumee River watershed comes from an exploding number of unregulated factory farms, a new EWG and Environmental Law & Policy Center investigation reveals.*
>
> *Outbreaks of toxic algae, fueled by pollution from manure and fertilizer from farm fields, are increasing in frequency and severity across the U.S. In 2014, a toxic bloom in Lake Erie imperiled the drinking water of 500,000 residents in Toledo, Ohio. The Lake Erie outbreak, now an annual event, is getting much worse.*[17]

Tim Boring, a sixth-generation farmer and Director of Michigan's Department of Agriculture and Rural Development has bad news about Michigan's efforts to curb the farm pollution that fuels Lake Erie's toxic green algae. He finds that farm programs designed to protect water quality aren't working and that "factory-sized megafarms" are detrimental to the traditional farm economy.[18]

---

[16] **After 40 years, Chesapeake Bay Program Yields Mixed Results** – Bay Journal at: https://www.bayjournal.com/news/pollution/after-40-years-chesapeake-bay-program-yields-mixed-results/article_4af88180-92b0-11ee-9d06-ab0f3bb0d72f.html

[18] Michigan farm czar: Our fight against Lake Erie pollution isn't working: https://www.bridgemi.com/michigan-environment-watch/michigan-farm-czar-our-fight-against-lake-erie-pollution-isnt-working

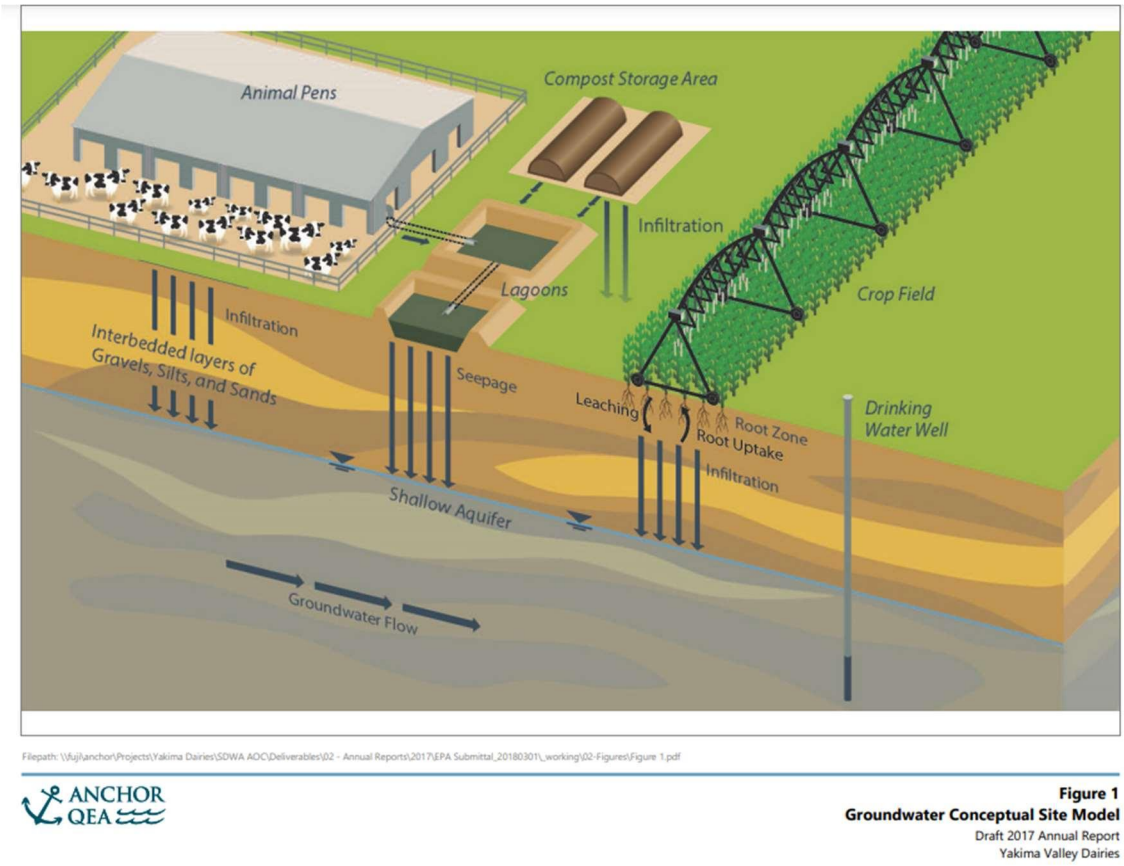
Lake Erie's phosphorus pollution problems have grown worse amid decades of consolidation in farm country. Diverse family farms have been steadily gobbled up by massive operations that primarily grow either cattle feed such as corn, or cows — and not on the same piece of land. The corn grown on one megafarm is shipped to a separate factory-sized livestock operation, which produces huge amounts of manure yet lacks the cropland on which cow poop becomes a valuable fertilizer.

The corn farm, in contrast, has plenty of acreage but no cows to fertilize it. So the farmer resorts to chemical fertilizers.

"It's not the problem that we have too much manure, it's that we have manure in all the wrong places," Boring said. Boring sees the state playing a bigger role in protecting small farms, which tend to grow more diverse crops while also raising livestock, and helping them succeed without expanding their acreage.

In doing so, he said, Michigan can bolster rural communities that rely on farming and food processing jobs.

Freshwater Futures based in Petroskey Michigan recently hosted a day-long conference on CAFO manure impacts on surface and groundwater and especially their contributions to harmful algae blooms (HABs) on Western Lake Erie. The conference was recorded and featured technical experts in all fields of concern, an attorney and a local politician. The whole recording of individual speakers and their Power Point slides can be accessed at the links below:



Great Lakes HABs & CAFO Manure Conference Series.[19]

- Great Lakes HABs & CAFO Manure Conference Recording
- Speaker Presentations - Power Point Slides

For additional questions and concerns on the conference or speakers please contact Sandy Bihn (sandylakeerie@aol.com) or Alexis Smith (alexis@freshwaterfuture.org) Jill M. Ryan, Executive Director, Freshwater Futures.

[19] This webinar, while useful to disclose the wide variety of environment, human health and economic problems with CAFOs may not be suitable for comp plan content. It may be better suited for a series of public education events for the Becker County Board, Planning Commission members and the public. Citizens, once well informed on CAFOs by these means can build fact-based support for the County's leaders taking appropriate actions.

The conference presenters used the graphic below to illustrate pathways for manure nutrients to reach groundwater. With permission, this graphic could be included in the pertinent section of Becker County's Comprehensive Plan.

EPA Intervenes to Protect Southeast Minnesota's Ground and Surface Water – Orders Permit and Guideline Improvements

In April, 2023, citizens petitioned the U.S. Environmental Protection Agency, saying nitrate in the groundwater in southeast Minnesota's karst region — largely from fertilizer and manure applied to crop land — poses an imminent danger to human health. They asked the Federal Environmental Protection Agency (EPA) to use its emergency authority under the Safe Drinking Water Act to intervene. [20]

[20] EPA says 'further actions' needed to protect human health from nitrate in southeast Minnesota Kirsti Marohn - November 8, 2023 at: https://www.mprnews.org/story/2023/11/08/epa-says-further-actions-needed-to-protect-human-health-from-nitrate-in-southeast-minn

In response to the citizen's petition, in August 2023 letter to four Minnesota State agencies the EPA stated that the MPCA's permit and manure management requirements for CAFOs were inadequate and needed to be "more protective" of sensitive groundwater resources. The federal agency says state agencies need to take additional steps to protect drinking water in southeast Minnesota from nitrate contamination.

> *"While this letter is largely focused on addressing immediate health concerns regarding nitrate contamination in drinking water in the Karst Region, Minnesota must also develop and implement a long-term solution to achieve reductions in nitrate concentrations in drinking water supplies. Developing a complete understanding of potential sources of nitrate contamination is an important immediate step for the state. A risk analysis of current and future nitrate contamination of the impacted groundwater will be critical for determining long-term solutions, and such analysis should incorporate the latest science and technologies. Minnesota has tools to effect reductions in nitrate concentrations through the National Pollutant Discharge Elimination System (NPDES) and State Disposal System permit programs, including development and implementation of more protective NPDES/SDS CAFO permits. In addition, Minnesota should consider adopting monitoring requirements in NPDES/SDS permits related to (1) subsurface discharges from manure, litter, and process wastewater storage, as well as (2) discharges from land application, similar to those proposed by EPA as modifications to* **the EPA-issued CAFO general permit for Idaho: https://www.epa.gov/npdes-***permits/npdes-general-permitconcentrated-animal-feeding-operations-cafos-idaho. We also encourage Minnesota to consider modifications to the state's Technical Standards for Nutrient Management with regard to land application of manure, litter or process wastewater, and any Minnesota guidelines for land application of commercial fertilizer, specific to Karst areas.*[21]

A similar petition to EPA has recently been filed by citizen groups in the Northeast corner of Iowa where identical topography and groundwater sensitivity exist. Private wells and public

[21] US Environmental Protection Agency August 2023 Letter to Minnesota Agencies found at: https://www.epa.gov/system/files/documents/2023-11/ao-rmod-reponse-letter_20230510-508.pdf

water treatments systems in this and other parts of Iowa as described above, have experienced rapidly increasing nitrate concentrations in both ground and surface waters.

> ***"The state's failure to regulate industrial agriculture pollution has steadily eroded Iowans' right to clean drinking water. For decades, Northeast Iowa residents have been exposed to dangerous levels of nitrate contaminated water. As the state reckons with high cancer levels and ongoing pollution regulation rollbacks, federal action is needed to safeguard the right to clean water. EPA must exercise emergency authority to hold polluters accountable and deliver safe drinking water in Iowa."***[22]

With this information and the additional reference material below, Becker County can learn from other's experience and hopefully take effective planning and zoning actions to avoid the predictable outcome of welcoming industrial agriculture into the county without the necessary safeguards and monitoring in place.

Becker County's sensitive surface and groundwater regions include its eastern Becker County sand plain areas with its high value trout streams, its highly developed central lakes area and its western agricultural areas served by extensive patterned drain tile and drainage ditch systems. Having sufficient, pre- and post-CAFO project construction ground and surface water monitoring in place can be a useful tool for holding industrial agriculture accountable for its operations and providing the assurances Becker County citizens need to keep from reliving the regretful experience of others.

These realities highlight the importance of using local land use plans and ordinances for proper siting, inspection and monitoring of large livestock facilities where the public can have greater confidence that pollutants are not and will not enter surface or groundwaters.

Importance of Water Sampling and Monitoring

[22] https://www.foodandwaterwatch.org/2024/04/16/iowa-environmental-groups-petition-epa-for-emergency-action-on-iowa-drinking-water/

The feedlot industry persistently claims that manure management plans limited to "agronomic rates" of application are sufficient to protect surface and groundwaters. One of the best strategies to test the performance of such plans is to actually monitor the water. New Mexico began requiring performance monitoring for large confined dairy operations as early and the 1990's. During the first six years of monitoring significant increases in ammonia and nitrates were found in groundwater.

> "*Feedlot milk production has increased dramatically in New Mexico in the past decade, along with the potential for groundwater contamination from animal wastes. State statutes require animal feedlots to maintain groundwater-monitoring wells and report water quality analyses quarterly to the New Mexico Water Quality Control Commission. This preliminary study analyzed six years of groundwater quality data from seven dairy feedlots and found elevated levels of nitrate, ammonia, chloride, total Kjeldahl nitrogen, and total dissolved solids. Samples were obtained from groundwater-monitoring wells located around dairy wastewater lagoons that were lined with clay, concrete, or synthetic membranes. Mean nitrate concentrations were significantly higher in groundwater samples taken in the vicinity of lagoons with clay liners. Lagoons with synthetic liners produced the lowest mean groundwater concentrations of ammonia and nitrate. Mean concentrations for all contaminants tended to increase as the size of dairy herds increased. Nitrate was the only groundwater contaminant measured that showed a consistently increasing trend from 1992 to 1997.*
>

produced the lowest mean groundwater concentrations of ammonia and nitrate. Mean concentrations for all contaminants tended to increase as the size of dairy herds increased. Nitrate was the only groundwater contaminant measured that showed a consistently increasing trend from 1992 to 1997. [23]

In 2015, the state adopted the Dairy Rule, which requires dairies to monitor groundwater impacts and to line waste lagoons. The rule came following a 2009 study by NMED's Groundwater Protection Division that found 60 percent of the state's dairies were polluting groundwater. [24]

The Public Engagement Survey used to gauge citizen priorities for the current land use planning effort found that 70% of Becker County citizens thought more should be done to protect the water quality of lakes and streams.

Becker County has already set an important protective precedent by requiring water sampling for large feedlots needing conditional use permits. But the water sampling regime lacks sufficient sophistication to assure the monitoring would accomplish the intended purpose.

The comprehensive plan could present guidelines or suggest qualified consultants for designing appropriate ground or surface water monitoring regimes to clearly gauge the effectiveness of manure lagoons or pits and manure management plans to protect waters of the county.

Ordinary Small Farmers Can Get Financially Trapped and Even Puntished by the Industry

Conventional scale (small) farmers are not at fault or in any way to be blamed for being attracted to the offers from the industry representatives. With persistently narrow profit margins it makes

[23] **Dairy Feedlot Contributions to Groundwater Contamination - A Preliminary Study in New Mexico** – Sept, 1999. At: https://go.gale.com/ps/i.do?id=GALE%7CA55884900&sid=googleScholar&v=2.1&it=r&linkaccess=abs&issn=00220892&p=HRCA&sw=w&userGroupName=anon%7Ee4bab884&aty=open-web-entry

[24] **New report looks at dairy operations in NM** -March 29, 2022 https://nmpoliticalreport.com/news/new-report-looks-at-dairy-operations-in-nm/

a lot of sense to scale up and grow overall profits even though margins remain slim. But once "in the contract system" farmers all too often discover they are on a financial treadmill that is extremely difficult to escape. Some who try unsuccessfully to escape have suffered retribution from the industry. Some farmers who once were "contract farmers" are speaking out to alert others of the risks and their efforts to transition back out. Modern Farmer's on-line ezine published one farmer's story.

> *When Paula and Dale Boles took over Dale's father's farmland in North Carolina, they thought that poultry farming would be a good way to work the land until they were ready to pass it on to their children. They obtained a contract with Case Farms, eventually switching over to Tyson, and built two poultry barns to company specifications, going $300,000 in debt to do so. It seemed like a good situation, though—as long as they could make their annual mortgage payment of $40,000, they'd be able to pay it off within 10 years.*
>
> *But soon, other expenses started getting tacked on. Tyson required a new computer system to control the temperature in the barns. This was another $70,000. Their propane bill averaged around $25,000 per year. Not making the updates wasn't really an option—no matter how much time and money you invested to be a farmer for the company, they could cut your contract at any time.*
>
> *And the income wasn't quite what they expected. Companies like Tyson pay their farmers in what's called a tournament system. There's a base pay, but whoever raises the best flock and has the best "feed conversion"—the biggest birds for the least feed— makes the most money, and payment decreases the further you go down the ladder. This essentially pits all the regional farmers against each other.*
>
> *"While contract farming, or "factory farming," has been exposed in the media for being exploitative of animals, the farmers who sign contracts with companies like Tyson, Perdue or other big players in animal agriculture also find themselves backed into a financial corner. But, over the last several years, there has been a wave of efforts to find ways to support farmers transitioning out of factory farming.*
>
> *"The way that the current structure of factory farming is designed is that the steps that carry with it the most risk and the most debt and the most liability are transitioned to the farmers," he says. "And so what you have is you have farmers building these extremely expensive facilities at the very specific direction [and] design of the company that they're working for. But they don't own the animals.*[25]

Antibiotic Resistence Linked to Feedlots

Becker County may not have the authority to address or curb the contribution of large animal feeding operations to antibiotic resistance but the Comprehensive Plan could provide or suggest tools to educate the public about the problem. This in turn could influence policy-makers at the appropriate level of authority to take remedial steps.

> *A **report** in 2020 by the Natural Resources Defense Council (NRDC), reveals that US cattle producers use more than 40% of all medically important antibiotics—those that are also used in human medicine—sold for use in US livestock, and use them three to six times more intensively than many of their European counterparts.*
>
> *NRDC says this overuse of antibiotics is a strategy used by the beef industry to offset heightened disease risks in feedlots, where cattle are routinely fed antibiotics to prevent disease whether or not they are ill, a practice that the World Health Organization discourages and that the European Union will no longer allow starting in 2022.*
>
> *The reports also argues that there is little transparency or accountability in the beef industry regarding its use of medically important antibiotics, and little urgency to rectify the problem.*
>
> *"Many infectious disease and antibiotic resistance experts believe such use is improper and helps contribute to reservoirs of drug-resistant bacteria on farms that can spread easily to humans through consumption of meat, exposure to soil or water contaminated with manure containing antibiotic-resistant pathogens, or contact with animals. They also worry that it reduces the effectiveness of antibiotics that are needed to fight infections in people."*[26]

The Izaak Walton League's Prairie Woods Chapter members have also compiled other authoritative reference materials including video interviews with groundwater experts, lawyers,

[26] https://www.cidrap.umn.edu/antimicrobial-stewardship/report-slams-beef-industry-overuse-antibiotics

and citizens from Minnesota and neighboring states that provide testimonials on their knowledge and experience with AFOs and CAFOs. Some of the content includes discussion of local economic impacts and local units of government adopting plans and ordinances to address industrial scale feedlots. Interactive MPCA maps of feedlot locations in Minnesota are also provided.

APPENDIX C

Minnesota Pollution Control Agency

West River Dairy Expansion Project
Environmental Assessment Worksheet (EAW)

ERRATA SHEET

1. Table 27 of the EAW did not display the existing GHG emissions of the feedlot. The corrected table is provided below.

Table 27: Operational emissions

Scope	Type of emission	Emission sub-type	Existing facility CO_2e emissions (tons/year)	Project related CO_2e emissions (tons/year)	Total CO_2e emissions (tons/year)
Scope 1	*Land Use*	*Conversion*	0	97	97
Scope 1	*Non-combustion*	*Area enteric fermentation CH_4*	33,941	47,531	81,472
Scope 1	*Non-Combustion*	*Area-barn/manure storage CH_4*	13,998	19,603	33,601
Scope 1	*Non-Combustion*	*Area-barn/manure storage N_2O*	2,848	3,988	6,836
Scope 1	*Land use*	*Are-barn/manure land application N_2O*	4,171	5,841	10,012
Scope 1	*Land use*	*Carbon sink-alfalfa conversion*	-1,901	-2,662	-4,563
Scope 1	*Combustion*	*Stationary-heaters*	90	126	216
Scope 1	*Combustion*	*Mobile equipment*	1,161	1,626	2,787
Scope 1	*Land use*	*Area-ammonia replacement*	-6,454	-9,038	-15,583
Scope 2	*Electricity*	*Grid-based*	3,641	5,098	8,739
TOTAL			**51,495**	**72,210**	**123,614**

The existing facility emissions is provided as supplemental context, representing the current baseline conditions — not an additional impact attributable to the proposed Project under review. All the manure generated at the pre-existing West River Dairy is processed through an anerobic digester that produces renewable natural gas.
